Overview of SAS Visual Statistics Procedures

SAS Visual Statistics procedures include predictive modeling tools that have been specially developed to take advantage of the distributed environment that SAS Viya provides. Methods include linear regression, logistic regression, quantile regression, generalized linear models, generalized additive models, reduced-rank models, nonlinear models, clustering, and decision trees. The procedures provide model selection, dimension reduction, and identification of important variables whenever this identification is appropriate for the analysis.

This book also describes utility procedures, which can be used together with any SAS Viya procedures.

NOTE: When you license SAS Visual Statistics, you also have access to SAS/STAT software. For more information about SAS/STAT procedures, see *SAS/STAT User's Guide*.

About This Book

This book assumes that you are familiar with Base SAS software and with the books *SAS Programmers Guide: Essentials* and *Base SAS Procedures Guide*. It also assumes that you are familiar with basic SAS System concepts, such as using the DATA step to create SAS data sets and using Base SAS procedures (such as the PRINT and SORT procedures) to manipulate SAS data sets.

Chapter Organization

Chapter 1, this chapter, provides an overview of SAS Visual Statistics procedures and summarizes related information, products, and services.

Chapter 2 provides information about topics that are common to multiple procedures. Topics include how to use SAS Cloud Analytic Services (CAS) sessions and how to load a SAS data set onto a CAS server. It also documents the following statements that are used across a number of procedures: CLASS, CODE, EFFECT, PARTITION, and SELECTION.

The remaining chapters for statistical and utility procedures appear in alphabetical order by procedure name and are organized as follows:

- The “Overview” section briefly describes the analysis provided by the procedure.
- The “Getting Started” section provides a quick introduction to the procedure through a simple example.
- The “Syntax” section describes the SAS statements and options that control the procedure.
- The “Details” section discusses methodology and other topics, such as ODS tables.
- The “Examples” section contains examples that use the procedure.
- The “References” section contains references for the methodology.

Typographical Conventions

This book uses several type styles for presenting information. The following list explains the meaning of the typographical conventions used in this book:

roman	is the standard type style used for most text.
UPPERCASE ROMAN	is used for SAS statements, options, and other SAS language elements when they appear in text. However, you can enter these elements in your own SAS programs in lowercase, uppercase, or a mixture of the two.
UPPERCASE BOLD	is used in the “Syntax” sections’ initial lists of SAS statements and options.
oblique	is used in the syntax definitions and in text to represent arguments for which you supply a value.

VariableName	is used for the names of variables and data sets when they appear in text.
bold	is used for matrices and vectors.
italic	is used for terms that are defined in text, for emphasis, and for references to publications.
`monospace bold`	is used for example code. In most cases, this book uses lowercase type for SAS code.

Options Used in Examples

The HTMLBLUE style is used to create the graphs and the HTML tables that appear in the online documentation. The PEARLJ style is used to create the PDF tables that appear in the documentation. A style template controls stylistic elements such as colors, fonts, and presentation attributes. You can specify a style template for an HTML ODS destination as follows:

```
ods html style=HTMLBlue;
```

You can also specify a style template for a PDF ODS destination as follows:

```
ods pdf style=PearlJ;
```

Most of the PDF tables are produced by using the following SAS System option:

```
options papersize=(6.5in 9in);
```

If you run the examples, you might get slightly different output. This is a function of the SAS System options that are used and the precision that your computer uses for floating-point calculations.

Where to Turn for More Information

Introduction to Shared Concepts

SAS Visual Statistics procedures run on SAS Viya. One component of SAS Viya is SAS Cloud Analytic Services (CAS), which is the analytic server and associated cloud services. The following subsections describe how to set up and use CAS sessions.

The section "Syntax Common to SAS Visual Statistics Procedures" on page 9 describes the common syntax elements that are supported by some of the procedures in this book. In some cases, individual procedures implement these common elements in slightly different ways. When this occurs, the differences are described in the respective procedure chapters.

The section "Details for SAS Visual Statistics Procedures" on page 62 provides details that are common to some of the procedures in this book.

Using CAS Sessions and CAS Engine Librefs

SAS Cloud Analytic Services (CAS) is the analytic server and associated cloud services in SAS Viya. This section describes how to create a CAS session and set up a CAS engine libref that you can use to connect to the CAS session. It assumes that you have a CAS server already available; contact your system administrator if you need help starting and terminating a server. This CAS server is identified by specifying the host on which it runs and the port on which it listens for communications. To simplify your interactions with this CAS server, the host information and port information for the server are stored as SAS option values that are retrieved automatically whenever this CAS server needs to be accessed. You can examine the host and port values for the server at your site by using the following statements:

```
proc options option=(CASHOST CASPORT);
run;
```

In addition to starting a CAS server, your system administrator might also have created a CAS session and a CAS engine libref for your use. You can define your own sessions and CAS engine librefs that connect to the CAS server as shown in the following statements:

```
cas mysess;
libname mylib cas sessref=mysess;
```

The CAS statement creates the CAS session named mysess, and the LIBNAME statement creates the mylib CAS engine libref that you use to connect to this session. It is not necessary to explicitly name the CASHOST and CASPORT of the CAS server in the CAS statement, because these values are retrieved from the corresponding SAS option values.

If you have created the mysess session, you can terminate it by using the TERMINATE option in the CAS statement as follows:

```
cas mysess terminate;
```

For more information about the CAS statement and the LIBNAME statement, see *SAS Cloud Analytic Services: User's Guide*. For general information about CAS and CAS sessions, see *SAS Cloud Analytic Services: Fundamentals*.

Loading a SAS Data Set onto a CAS Server

Procedures in this book require the input data to reside on a CAS server. To work with a SAS data set, you must first load the data set onto the CAS server. Data loaded on the CAS server are called *data tables*. This section lists three methods of loading a SAS data set onto a CAS server. In this section, mylib is the name of the caslib that is connected to the mysess CAS session.

- You can use a single DATA step to create a data table on the CAS server as follows:

```
data mylib.Sample;
   input y x @@;
   datalines;
.46 1 .47 2 .57 3 .61 4 .62 5 .68 6 .69 7
;
```

Note that DATA step operations might not work as intended when you perform them on the CAS server instead of the SAS client.

- You can create a SAS data set first, and when it contains exactly what you want, you can use another DATA step to load it onto the CAS server as follows:

```
data Sample;
   input y x @@;
   datalines;
.46 1 .47 2 .57 3 .61 4 .62 5 .68 6 .69 7 .78 8
;
data mylib.Sample;
   set Sample;
run;
```

- You can use the CASUTIL procedure as follows:

```
proc casutil sessref=mysess;
   load data=Sample casout="Sample";
quit;
```

The CASUTIL procedure can load data onto a CAS server more efficiently than the DATA step. For more information about the CASUTIL procedure, see *SAS Cloud Analytic Services: User's Guide*.

The mylib caslib stores the Sample data table, which can be distributed across many machine nodes. You must use a caslib reference in procedures in this book to enable the SAS client machine to communicate with the CAS session. For example, the following REGSELECT procedure statements use a data table that resides in the mylib caslib:

```
proc regselect data = mylib.Sample;
  ...statements...;
run;
```

You can delete your data table by using the DELETE procedure as follows:

```
proc delete data = mylib.Sample;
run;
```

The Sample data table is accessible only in the mysess session. When you terminate the mysess session, the Sample data table is no longer accessible from the CAS server. If you want your Sample data table to be available to other CAS sessions, then you must *promote* your data table. For more information about data tables, see *SAS Cloud Analytic Services: User's Guide*.

Syntax Common to SAS Visual Statistics Procedures

CLASS Statement

CLASS *variable* <(*options*)>. . . <*variable* <(*options*)>> </ *global-options*> **;**

This section applies to the following procedures: GAMMOD, GAMSELECT, GENSELECT, LMIXED, LOGSELECT, MODELMATRIX, PHSELECT, PLSMOD, QTRSELECT, REGSELECT, SANDWICH, and TREESPLIT.

The CLASS statement names the classification variables to be used as explanatory variables in the analysis. These variables enter the analysis not through their values, but through levels to which the unique values are mapped. For more information about these mappings, see the section "Levelization of Classification Variables" on page 62.

If the procedure permits a classification variable as a response (dependent variable or target), the response does not need to be specified in the CLASS statement.

You can specify options either as individual variable *options*, by enclosing the options in parentheses after the variable name, or as *global-options*, by placing them after a slash (/). *Global-options* are applied to all variables that are specified in the CLASS statement. If you specify more than one CLASS statement, the *global-options* that are specified in any one CLASS statement apply to all CLASS statements. However, individual CLASS variable *options* override the *global-options*.

Table 2.1 summarizes the values you can use for either an *option* or a *global-option*. The options are described in detail in the list that follows Table 2.1.

Table 2.1 CLASS Statement Options

Option	Description
DESCENDING	Reverses the sort order
MISSING	Treats missing values as valid levels
ORDER=	Specifies the sort order for the levels
PARAM=	Specifies the parameterization of the variable
REF=	Specifies the reference level of the variable
SPLIT	Splits levels of CLASS variables into independent effects

DESCENDING

DESC

reverses the sort order of the classification variable. If both the DESCENDING and ORDER= options are specified, the procedure orders the categories according to the ORDER= option and then reverse that order.

MISSING

treats missing values (“.”, “.A”, . . . , “.Z” for numeric variables and blanks for character variables) as valid values for the CLASS variable.

If you do not specify the MISSING option, observations that have missing values for CLASS variables are removed from the analysis.

ORDER=< FORMATTED | FREQ | INTERNAL > < (*var1*='*level1*' '*level2*' . . . *var2*= . . .) >

ORDER= FORMATTED | FREQ | INTERNAL | '*level1*' '*level2*' . . .

specifies the sort order for the levels of classification variables. This order determines which parameters in the model correspond to each level in the data. The following table shows how to interpret values of the ORDER= keywords:

Value of ORDER=	Levels Sorted By
FORMATTED	External formatted values, except for numeric variables that have no explicit format, which are sorted by their unformatted (internal) values. The sort order is machine-dependent. For numeric variables for which you have supplied no explicit format, the levels are ordered by their internal values.
FREQ	Descending frequency count (levels that have more observations come earlier in the order)
INTERNAL	Unformatted value. The sort order is machine-dependent.

PROC LOGSELECT also enables you to specify a particular order for variables by listing the levels in quotes in the desired order. For example, in the following statement, the global specification (after the slash) specifies that the levels of all variables except the pet variable are to be sorted by their formatted value, and the individual specification of the food variable overrides the FORMATTED order:

```
class pet food(order='wet' 'dry') / order=formatted(pet='dog' 'cat');
```

Any level of the pet and food variables that you do not specify is added to the end of the variable list in formatted order.

The ORDER= option does not apply to missing values, which are always ordered first.

For more information about sort order, see the chapter about the SORT procedure in *Base SAS Procedures Guide* and the discussion of BY-group processing in the “Grouping Data” section of *SAS Programmers Guide: Essentials*. By default, ORDER=FORMATTED.

PARAM=*keyword*

specifies the parameterization method for the classification variable or variables. You can specify any of the *keywords* shown in the following table; design matrix columns are created from CLASS variables according to the corresponding coding schemes.

Table 2.2 Value of PARAM=

Value of PARAM=	Coding
EFFECT	Effect coding. The REF= option in the CLASS statement determines the reference level.
GLM	Less-than-full-rank reference cell coding. This *keyword* can be used only as a *global-option* and is applied to all CLASS variables; all other individual variable parameterization specifications are ignored. The REF= option in the CLASS statement indirectly determines the reference level through the order of levels.
ORDINAL | THERMOMETER	Cumulative parameterization for an ordinal CLASS variable
POLYNOMIAL | POLY	Polynomial coding. If the classification variable is numeric, then the ORDER= option in the CLASS statement is ignored, and the internal unformatted values are used.
REFERENCE | REF	Reference cell coding. The REF= option in the CLASS statement determines the reference level.
ORTHEFFECT	Orthogonalizes PARAM=EFFECT coding. The REF= option in the CLASS statement determines the reference level.
ORTHORDINAL | ORTHOTHERM	Orthogonalizes PARAM=ORDINAL coding
ORTHPOLY	Orthogonalizes PARAM=POLYNOMIAL coding. If the classification variable is numeric, then the ORDER= option in the CLASS statement is ignored, and the internal unformatted values are used.
ORTHREF	Orthogonalizes PARAM=REFERENCE coding. The REF= option in the CLASS statement determines the reference level.

All parameterizations are full rank, except for the GLM parameterization. If you specify a full rank parameterization for any CLASS variable, then every CLASS variable without a specified coding is given the EFFECT coding.

By default, PARAM=GLM. For more information about how parameterization of classification variables affects the construction and interpretation of model effects, see the section "Specification and Parameterization of Model Effects" on page 64.

REF='*level***' | *keyword***

REFERENCE='*level***' | *keyword***

specifies the reference level that is used when you specify a nonsingular parameterization. You can specify the following values:

'*level*' specifies the *level* of the variable to use as the reference level. Specify the formatted value of the variable if a format is assigned. You can specify this value only for an individual variable *option*.

FIRST designates the first ordered level as reference. You can specify this value either for an individual variable *option* or for a *global-option*.

LAST designates the last ordered level as reference. You can specify this value either for an individual variable *option* or for a *global-option*.

By default, REF=LAST.

SPLIT

specifies that design matrix columns that correspond to any effect that contains a split classification variable can be selected to enter or leave a model independently of the other design columns of that effect. This option applies to procedures that perform model selection.

Suppose that the variable temp has three levels (`'hot'`, `'warm'`, and `'cold'`), that the variable gender has two levels (`'M'` and `'F'`), and that the variables are used in a PROC REGSELECT run as follows:

```
proc regselect data=mylib.data;
   class temp gender / split;
   model y = gender gender*temp;
run;
```

The two effects in the MODEL statement are split into eight independent effects. The effect "gender" is split into two effects that are labeled "gender_M" and "gender_F". The effect "gender*temp" is split into six effects that are labeled "gender_M*temp_hot", "gender_F*temp_hot", "gender_M*temp_warm", "gender_F*temp_warm", "gender_M*temp_cold", and "gender_F*temp_cold". The previous PROC REGSELECT step is equivalent to the following:

```
proc regselect data=mylib.data;
   model y = gender_M gender_F
             gender_M*temp_hot  gender_F*temp_hot
             gender_M*temp_warm gender_F*temp_warm
             gender_M*temp_cold gender_F*temp_cold;
run;
```

The SPLIT option can be used on individual classification variables. For example, consider the following PROC REGSELECT step:

```
proc regselect data=mylib.data;
   class temp(split) gender;
   model y = gender gender*temp;
run;
```

In this case, the effect "gender" is not split and the effect "gender*temp" is split into three effects, which are labeled "gender*temp_hot", "gender*temp_warm", and "gender*temp_cold". Furthermore, each of these three split effects now has two parameters that correspond to the two levels of "gender." The PROC REGSELECT step is equivalent to the following:

```
proc regselect data=mylib.data;
   class gender;
   model y = gender gender*temp_hot gender*temp_warm gender*temp_cold;
run;
```

CODE Statement

CODE < *options* > **;**

This section applies to the following procedures: GENSELECT, KCLUS, LOGSELECT, PCA, PHSELECT, QTRSELECT, REGSELECT, TREESPLIT, and VARIMPUTE.

The CODE statement writes SAS DATA step code for computing predicted values of the fitted model to a file or to a table. For survival procedures, the predicted values include survival probabilities and cumulative hazards at specific time points. To score new data, you can then include the file in a DATA step, or you can specify the table in the **runCodeTable** action in the **dataStep** action set.

Table 2.3 summarizes the *options* that you can specify in the CODE statement.

Table 2.3 CODE Statement Options

Option	Description
COMMENT	Adds comments to the generated code
CUMHAZ	Generates cumulative hazard values at specified time points
FILE=	Names the file in which to save the generated code
FORMATWIDTH=	Specifies the numeric format width for the regression coefficients
INDENTSIZE=	Specifies the number of spaces to indent the generated code
IPROB	Computes individual predicted probabilities for ordinal response models
LABELID=	Specifies a number used to construct names and labels
LINESIZE=	Specifies the line size for the generated code
NOSURVIVAL	Suppresses the generation of survival probabilities
NOTRIM	Compares formatted values, including blank padding
OUT=	Names an output table in which to save the generated code
PCATALL	Generates probabilities for all levels of categorical response variables
SHOWTIME	Creates variables that contain the time points at which predictions are made
TIMEPOINT=	Specifies the time points at which survival probabilities or cumulative hazards are predicted

If you do not specify the FILE= option or the OUT= option and if your SAS client has a default path, then the SAS scoring code is written to an external file named *_code_*. You can specify the following *options* in the CODE statement.

COMMENT
adds comments to the generated code.

CUMHAZ
generates SAS code to predict the cumulative hazard function at the time points that you specify in the TIMEPOINT= option. This option applies to the PHSELECT procedure.

FILE=*filename*
names the external file that saves the generated code. When enclosed in a quoted string (for example, FILE="c:\mydir\scorecode.sas"), this option specifies the path and filename for writing the code to an external file. If you do not specify a path but your SAS client has a default path, then the code is written to an external file named *filename* at that location. You can also specify an unquoted *filename* of no more than eight characters. If the *filename* is assigned as a fileref in a Base SAS FILENAME statement, the file that is specified in the FILENAME statement is opened; otherwise, if your SAS client has a default path, an external file named *filename* is created. This option cannot be specified together with the OUT= option.

FORMATWIDTH=*width*
specifies the width to use in formatting derived numbers such as parameter estimates. You can specify a value in the range 12 to 32; the default is 20.

INDENTSIZE=*n*
specifies the number of spaces to indent the generated code. You can specify a value in the range 0 to 10; the default is 3.

IPROB
computes the individual predicted probabilities for ordinal response models. This option applies to the following procedures: GENSELECT and LOGSELECT. For a response variable Y with three levels, 1, 2, and 3, the individual probabilities are $\Pr(Y = 1)$, $\Pr(Y = 2)$, and $\Pr(Y = 3)$.

LABELID=*value*
specifies a number used to construct array names and statement labels in the generated code. You can specify a value in the range 0 to 1024; the default is randomly chosen.

LINESIZE=*value*

LS=*value*
specifies the line size for the generated code. You can specify a value in the range 64 to 254; the default is 120.

NOSURVIVAL
suppresses SAS code for survival probabilities prediction. This option applies to the PHSELECT procedure. If you do not specify this option, survival procedures generate SAS code to predict survival probabilities at the time points that you specify in the TIMEPOINT= option.

NOTRIM
bases comparisons of formatted values on the full format width, including blank padding. By default, blanks at the beginning and end of strings are ignored.

OUT=*libref.data-table*

creates a table that contains the score code. *libref.data-table* is a two-level name, where *libref* refers to the library, and *data-table* specifies the name of the output data table. For more information about this two-level name, see the section "Using CAS Sessions and CAS Engine Librefs" on page 7. You can specify this table in the **runCodeTable** action in the **dataStep** action set to score another data table; for more information, see *SAS Viya: System Programming Guide*. This option cannot be specified with the FILE= option.

PCATALL

generates probabilities for all levels of categorical response variables. This option applies to the following procedures: GENSELECT and LOGSELECT.

SHOWTIME

creates variables that contain the time points at which predictions are made. This option applies to the PHSELECT procedure. If T is the name of the failure time variable, these time point variables are named T_1, T_2, and so on.

TIMEPOINT=*list* | **QUANTILE(***probability-list***)**

TIME=*list* | **QUANTILE(***probability-list***)**

specifies the time points at which survival probabilities or cumulative hazards are predicted. This option applies to the PHSELECT procedure. You can specify a list of numbers that represent exact time points. For example:

```
code cumhaz timepoint = 40 to 60 by 10;
```

If T is the name of the failure time variable, the preceding specification requests the predicted cumulative hazard and survival probability at the time points T=40, T=50, and T=60. If you also specify the SHOWTIME option, these time points are saved in the variables T_1, T_2, and T_3, respectively. The predicted variables are named and labeled as shown in Table 2.4.

Table 2.4 Predicted Variables

T	Name	Label
40	C_T_1	Cumulative Hazard at T_1
50	C_T_2	Cumulative Hazard at T_2
60	C_T_3	Cumulative Hazard at T_3
40	S_T_1	Survival Probability at T_1
50	S_T_2	Survival Probability at T_2
60	S_T_3	Survival Probability at T_3

Alternatively, you can use the keyword QUANTILE to specify a list of quantile probabilities. For example:

```
code timepoint = quantile(.2, .5, .8);
```

Survival procedures compute the 20th, 50th, and 80th percentiles from the Kaplan-Meier curve (or the Breslow curve if you also specify the ENTRY= option in the MODEL statement) and use them as the time points for the prediction.

By default, TIMEPOINT=QUANTILE(0.25, 0.50, 0.75).

DISPLAY Statement

DISPLAY < *table-list* > < / *options* > **;**

This section applies to the following procedures: CORRELATION, GAMMOD, GAMSELECT, GENSELECT, ICA, KCLUS, LMIXED, LOGSELECT, MBC, NLMOD, NMF, PARTITION, PCA, PHSELECT, PLSMOD, QTRSELECT, REGSELECT, SANDWICH, and VARREDUCE.

The DISPLAY statement enables you to specify a list of display tables to display or exclude. This statement is similar to the ODS SELECT, ODS EXCLUDE, and ODS TRACE statements. However, the DISPLAY statement can improve performance when a large number of tables could be generated (such as in BY-group processing). The procedure processes the DISPLAY statement on a CAS server and thus sends only a subset of ODS tables to the SAS client. Because ODS statements are processed on a SAS client, first all the generated display tables are sent to the client, and then the client creates a subset.

If you use both DISPLAY and ODS statements together, the DISPLAY statement takes precedence over the ODS statements. Note that the ODS EXCLUDE statement processes tables that are sent to the client after they have been filtered by the DISPLAY statement. In some cases, it might appear that the ODS EXCLUDE statement is taking precedence because it can further filter the tables. For more information about ODS, see *SAS Output Delivery System: Procedures Guide*.

You can specify the *table-list* as a list of table names, paths, partial pathnames, and regular expressions.

The table names that you can specify are listed in the specific procedure chapters. A path is a table name that is prefixed with dot-separated grouping information. For example, a SelectionSummary table that a procedure produces during a selection routine might have the path *Bygroup1.Summary.SelectionSummary*. A partial pathname does not include all groups; for example, *SelectionSummary* and *Summary.SelectionSummary* are partial pathnames for *Bygroup1.Summary.SelectionSummary*.

When you specify a table name or partial pathname, all display tables whose paths end in the specified name are selected for display or exclusion. For example, both *SelectionSummary* and *Summary.SelectionSummary* select *Bygroup1.Summary.SelectionSummary*.

A regular expression is enclosed in forward slashes (/). For example, specifying "/tions/" selects all pathnames that contain the substring "tions"; in particular, the *Bygroup1.Summary.SelectionSummary* table is selected. Specifying "!/tions/" selects all pathnames that do not contain the substring "tions"; in particular, the *Bygroup1.Summary.SelectionSummary* table is not selected.

You can specify the following *options* after a slash (/):

CASESENSITIVE
performs a case-sensitive comparison of table names in the *table-list* to display table names when tables are subsetted for display. To preserve case, you must enclose table names in the *table-list* in quotation marks.

EXCLUDE
displays all display tables except those that you specify in the *table-list*.

EXCLUDEALL
suppresses display of all tables. This option takes precedence over the other options.

TRACE
displays the display table names, labels, and paths.

DISPLAYOUT Statement

DISPLAYOUT *table-spec-list* < / *options* > **;**

This section applies to the following procedures: CORRELATION, GAMMOD, GAMSELECT, GENSELECT, ICA, KCLUS, LMIXED, LOGSELECT, MBC, NLMOD, NMF, PARTITION, PCA, PHSELECT, PLSMOD, QTRSELECT, REGSELECT, SANDWICH, and VARREDUCE.

The DISPLAYOUT statement enables you to create output tables from your displayed output. This statement is similar to the ODS OUTPUT statement. For more information about ODS, see *SAS Output Delivery System: Procedures Guide*.

The *table-spec-list* specifies a list of output tables to create. Each entry in the list has either a *key*=*value* format or a *key* format:

key=*value*	specifies *key* as the ODS table name, path, or partial pathname, and specifies *value* as the output table name.
key	specifies *key* as the ODS table name and also as the output table name.

The table names that you can specify are listed in the specific procedure chapters.

Table names and partial pathnames are discussed under the DISPLAY statement. The DISPLAYOUT statement does not support regular expressions.

You can specify the following *options* after a slash (/):

INCLUDEALL
creates output tables for all display tables. The name of the created output table is the same as the name of the corresponding display table. If you specify this option, the *table-spec-list* specification is ignored.

NOREPLACE
does not replace any existing output table of the same name.

REPEATED
replicates all output tables on all nodes.

EFFECT Statement

EFFECT *effect-name* = *effect-type* **(***var-list* < / *effect-options*>**) ;**

This section applies to the following procedures: GENSELECT, LMIXED, LOGSELECT, MODELMATRIX, PHSELECT, PLSMOD, QTRSELECT, and REGSELECT.

The EFFECT statement enables you to construct special collections of columns for design matrices. These collections are called *constructed effects* to distinguish them from the usual model effects that are formed from continuous or classification variables, as discussed in the section "GLM Parameterization of Classification Variables and Effects" on page 67. For example, the terms A, B, x, A*x, and A*B in the following statements define fixed effects of the usual type in a generalized linear model:

```
proc genselect;
   class A B;
   model y = A B x A*x;
run;
```

A constructed effect, on the other hand, is assigned through the EFFECT statement. For example, in the following program, the EFFECT statement defines a constructed effect named spl:

```
proc genselect;
   class A B;
   effect spl = spline(x);
   model y = A B A*spl;
run;
```

The columns of spl are formed from the data set variable x as a cubic B-spline basis with three equally spaced interior knots.

Each constructed effect corresponds to a collection of columns that are referred to by the name you supply. You can specify multiple EFFECT statements, and all EFFECT statements must precede the MODEL statement.

You must specify the following arguments:

effect-name
names the effect. This name can appear in only one EFFECT statement and cannot be the name of a variable in the input data set.

effect-type
specifies the type of effect. You can specify the following *effect-types*:

COLLECTION specifies a collection effect that defines one or more variables as a single effect that has multiple degrees of freedom. The variables in a collection are considered as a unit for purposes of estimation and inference. For more information, see the section "Collection Effects" on page 20.

MULTIMEMBER | MM specifies a multimember classification effect whose levels are determined by one or more variables that appear in a CLASS statement. For more information, see the section "Multimember Effects" on page 21.

POLYNOMIAL | POLY specifies a multivariate polynomial effect in the specified numeric variables. For more information, see the section "Polynomial Effects" on page 22.

SPLINE specifies a regression spline effect whose columns are univariate spline expansions of one or more variables. A spline expansion replaces the original variable with an expanded or larger set of new variables. For more information, see the section "Spline Effects" on page 25.

var-list
specifies a list of variables that are used in constructing the effect. You can also specify any of the *effect-options* that are shown in Table 2.5 after a slash following the *var-list*.

Table 2.5 EFFECT Statement Options

Option	Description
Collection Effects Options	
DETAILS	Displays the constituents of the collection effect
Multimember Effects Options	
DETAILS	Displays the levels of the multimember effect
NOEFFECT	Specifies that observations whose levels are all missing for the multimember variables should have 0 values in the corresponding design matrix columns
STDIZE	Standardizes the design matrix entries so that each observation has a sum of 1
WEIGHT=	Specifies the weight variable for the contributions of each classification effect

Table 2.5 *continued*

Option	Description
Polynomial Effects Options	
DEGREE=	Specifies the degree of the polynomial
DETAILS	Displays details of the specified polynomial
MDEGREE=	Specifies the maximum degree of any variable in a term of the polynomial
NOSEPARATE	Treats the polynomial as a single effect with multiple degrees of freedom
STANDARDIZE=	Specifies centering and scaling suboptions for the variables that define the polynomial
Spline Effects Options	
BASIS=	Specifies the type of basis (B-spline basis or truncated power function basis) for the spline effect
DATABOUNDARY	Uses the extremes of the data as boundary knots for a B-spline basis
DEGREE=	Specifies the degree of the spline effect
DETAILS	Displays the knots and locations for each spline basis function
KNOTMAX=	Requests equally spaced right-side boundary knots starting at the variables' maximum and ending at the KNOTMAX= value
KNOTMETHOD=	Specifies how to construct the knots for the spline effect
KNOTMIN=	Requests equally spaced left-side boundary knots starting at the KNOTMIN= value and ending at the variables' minimum value
NATURALCUBIC	Specifies a natural cubic spline basis for the spline effect
SEPARATE	Treats the spline basis for each variable as a separate effect when multiple variables are specified
SPLIT	Treats each design matrix column as a separate effect for selection methods

Collection Effects

EFFECT *effect-name*=**COLLECTION (***var-list* < / **DETAILS** >**) ;**

You use a collection effect to define a set of variables that are treated as a single effect that has multiple degrees of freedom. The variables in *var-list* can be continuous or classification variables. Columns in the design matrix that are contributed by a collection effect are the design columns of its constituent variables in the order in which they appear in the definition of the collection effect. If you specify the DETAILS option, then a table that shows the constituents of the collection effect is displayed.

Multimember Effects

EFFECT *effect-name*=**MULTIMEMBER (***var-list* < / *mm-options*>**) ;**

EFFECT *effect-name*=**MM (***var-list* < / *mm-options*>**) ;**

A multimember effect is formed from one or more classification variables in such a way that each observation can be associated with one or more levels of the union of the levels of the classification variables. In other words, a multimember effect is a classification-type effect with possibly more than one nonzero column entry for each observation. Multimember effects are useful, for example, in modeling the following:

- nurses' effects on patient recovery in hospitals
- teachers' effects on student scores
- lineage effects in genetic studies

The levels of a multimember effect consist of the union of formatted values of the variables that define this effect. Each such level contributes one column to the design matrix. For each observation, the value that corresponds to each level of the multimember effect in the design matrix is the number of times that this level occurs for the observation.

For example, the following data provide teacher information and end-of-year test scores for students after two semesters:

Student	Score	Teacher1	Teacher2
Mary	87	Tobias	Cohen
Tom	89	Rodriguez	Tobias
Fred	82	Cohen	Cohen
Jane	88	Tobias	.
Jack	99	.	.

For example, Mary had different teachers in the two semesters, Fred had the same teacher in both semesters, and Jane received instruction only in the first semester.

You can model the effect of the teachers on student performance by specifying a multimember effect as follows:

```
CLASS teacher1 teacher2;
EFFECT teacher = MM(teacher1 teacher2);
```

The levels of the teacher effect are Cohen, Rodriguez, and Tobias, and the associated design matrix columns are as follows:

Student	Cohen	Rodriguez	Tobias
Mary	1	0	1
Tom	0	1	1
Fred	2	0	0
Jane	0	0	1
Jack	.	.	.

You can specify the following *mm-options* after a slash (/):

DETAILS
displays a table that shows the levels of the multimember effect.

NOEFFECT
specifies that, for observations of the multimember variables whose levels are all missing, the values in the corresponding design matrix columns be set to 0. If, in the preceding example, the teacher effect is defined by the following statement, then the associated design matrix columns' values for Jack are all 0:

```
EFFECT teacher = MM(teacher1 teacher2 / noeffect);
```

This statement enables you to include Jack in the analysis even though there is no effect of teachers on his performance.

A situation where it is important to designate observations as having no effect that can be attributed to a classification variable is the analysis of crossover designs, where lagged treatment levels are used to model the carryover effects of treatments between periods. Because there is no carryover effect for the first period, the treatment lag effect in a crossover design can be modeled by using a multimember effect that consists of a single classification variable and the NOEFFECT option, as in the following statements:

```
CLASS Treatment lagTreatment;
EFFECT Carryover = MM(lagTreatment / noeffect);
```

The lagTreatment variable contains a missing value for the first period. Otherwise, it contains the value of the treatment variable for the preceding period.

STDIZE
specifies that for each observation, the entries in the design matrix that corresponds to the multimember effect be scaled to have a sum of 1.

WEIGHT=*weight-list*
specifies numeric variables used to weigh the contributions of each of the classification effects that define the constructed multimember effect. The number of variables in *weight-list* must match the number of classification variables that define the effect.

Polynomial Effects

EFFECT *effect-name*=**POLYNOMIAL (***var-list* < / *polynomial-options* >**) ;**

EFFECT *effect-name*=**POLY (***var-list* < / *polynomial-options* >**) ;**

The variables in *var-list* must be numeric. A design matrix column is generated for each term of the specified polynomial. By default, each of these terms is treated as a separate effect for the purpose of model building. For example, the following two PROC genselect,upper() steps yield the identical analysis:

```
proc genselect;
   effect MyPoly = polynomial(x1-x3/degree=2);
   model y = MyPoly;
run;
```

```
proc genselect;
   model y = x1 x2 x3 x1*x1 x1*x2 x1*x3 x2*x2 x2*x3 x3*x3;
run;
```

You can specify the following *polynomial-options* after a slash (/):

DEGREE=*n*
: specifies the degree of the polynomial, where *n* must be a positive integer and is typically a small integer, such as 1, 2, or 3. By default, DEGREE=1.

DETAILS
: displays a table that shows the details of the specified polynomial, including the number of terms generated. If you also specify the STANDARDIZE option, then a table that shows the standardization details is also produced.

MDEGREE=*n*
: specifies the maximum degree of any variable in a term of the polynomial, where *n* must be a positive integer. The default is the degree of the specified polynomial. For example, the following statement generates the terms x_1, x_2, x_1^2, x_1x_2, x_2^2, $x_1^2x_2$, $x_1x_2^2$ and $x_1^2x_2^2$:

```
EFFECT MyPoly=POLYNOMIAL(x1 x2/degree=4 MDEGREE=2);
```

NOSEPARATE
: treats the polynomial as a single effect that has multiple degrees of freedom. The *effect-name* that you specify is used as the constructed effect name, and the labels of the terms are used as labels of the corresponding parameters.

STANDARDIZE < (*centerscale-opts***) > < = *standardize-opt* >**
: standardizes the variables that define the polynomial. By default, the standardized variables receive prefix "s_" in the variable names.

  You can use the following *centerscale-opts* to specify how the center and scale are estimated:

  METHOD=MOMENTS
  : estimates the center by the variable mean and the scale by the standard deviation. If a weight variable is specified using a WEIGHT statement, the weights are not used in the computation of the mean and standard deviation, and observations that have invalid weights are ignored. Only observations that are used in performing the analysis are used for the standardization.

  METHOD=RANGE
  : estimates the center by the midpoint of the variable range and the scale as half the variable range. Any observation that has a missing value for any regressor used in the model is ignored when the range of variables in a polynomial effect is computed. Observations that have valid regressor values but missing or invalid values of frequency variables, weight variables, or dependent variables are used in computing variable ranges. By default, METHOD=RANGE.

METHOD=WMOMENTS
is the same as METHOD=MOMENTS except that weighted means and weighted standard deviations are used.

PREFIX=NONE | *quoted-string*
specifies the prefix that is appended to standardized variables when forming the term labels. You can specify the following values:

quoted-string	specifies the prefix
NONE	does not apply a prefix

By default, PREFIX="s_".

Let

$$
\begin{aligned}
n &= \text{number of observations used in the analysis} \\
w &= \text{weight variable} \\
f &= \text{frequency variable} \\
x &= \text{variable to be standardized} \\
x_{(n)} &= \text{Max}_{i=1}^{n}(x_i) \\
x_{(1)} &= \text{Min}_{i=1}^{n}(x_i) \\
F &= \text{sum of frequencies} \\
&= \Sigma_{i=1}^{n} f_i \\
\text{WF} &= \text{sum of weighted frequencies} \\
&= \Sigma_{i=1}^{n} w_i f_i
\end{aligned}
$$

Table 2.6 shows how the center and scale are computed for each of the supported methods.

Table 2.6 Center and Scale Estimates by Method

Method	Center	Scale
RANGE	$(x_{(n)} + x_{(1)})/2$	$(x_{(n)} - x_{(1)})/2$
MOMENTS	$\bar{x} = \Sigma_{i=1}^{n} f_i x_i / F$	$\sqrt{\Sigma_{i=1}^{n} f_i (x_i - \bar{x})^2/(F-1)}$
WMOMENTS	$\bar{x}_w = \Sigma_{i=1}^{n} w_i f_i x_i / \text{WF}$	$\sqrt{\Sigma_{i=1}^{n} w_i f_i (x_i - \bar{x}_w)^2/(F-1)}$

You can control whether the standardization is to center, scale, or both center and scale by specifying one of the following *standardize-opts*:

CENTER
centers but does not scale the variables. For a variable x,

$$\text{s\_x} = x - \text{center}$$

CENTERSCALE
centers and scales the variables. This is the default if you do not specify a *standardization-opt*. For a variable x,

$$\text{s\_x} = \frac{x - \text{center}}{\text{scale}}$$

NONE
performs no standardization.

SCALE
scales but does not center the variables. For a variable x,

$$\text{s\_x} = \frac{x}{\text{scale}}$$

Spline Effects

This section discusses the construction of spline effects through the EFFECT statement. A spline effect expands variables into spline bases whose form depends on the options that you specify. For more information about regression splines and spline bases, see the section "Splines and Spline Bases" on page 28. You request a spline effect with the syntax

EFFECT *name*=**SPLINE (***var-list* < / *spline-options* >**) ;**

The variables in *var-list* must be numeric. Design matrix columns are generated separately for each of these variables, and the set of columns is collectively referred to with the specified name. By default, the spline basis that is generated for each variable is a cubic B-spline basis that has three equally spaced knots positioned between the minimum and maximum values of that variable. This yields by default seven design matrix columns for each of the variables in the SPLINE effect.

You can specify the following *spline-options* after a slash (/):

BASIS=BSPLINE
uses a B-spline basis for the spline expansion. For splines of degree d that are defined with n knots, this basis consists of $n + d + 1$ columns. In order to completely specify the B-spline basis, d left-side boundary knots and $\max\{d, 1\}$ right-side boundary knots are also required. For information about how to specify the positions of both the internal and boundary knots, see the KNOTMETHOD=, DATABOUNDARY, KNOTMIN=, and KNOTMAX= suboptions.

BASIS=TPF(*options***)**
specifies a truncated power function basis for the spline expansion. For splines of degree d that are defined with n knots for a variable x, this basis consists of an intercept, polynomials $x, x^2, \ldots, x^d$, and one truncated power function for each of the n knots. Unlike the B-spline basis, no boundary knots are required. For information about how you can specify the position of the internal knots, see the KNOTMETHOD= suboption.

You can modify the number of columns when you request BASIS=TPF by specifying the following *options*:

NOINT excludes the intercept column.

NOPOWERS excludes the intercept and polynomial columns.

By default, BASIS=BSPLINE.

DATABOUNDARY
uses the extremes of the data as boundary knots when building a B-spline basis.

DEGREE=*n*
specifies the degree of the spline transformation, where *n* must be a nonnegative integer and is typically a small integer, such as 0, 1, 2, or 3. By default, DEGREE=3.

DETAILS
displays tables that show the knot locations and the knots associated with each spline basis function.

KNOTMAX=*value*
requests that, for each variable in the EFFECT statement, the right-side boundary knots be equally spaced starting at the maximum of the variable and ending at the specified value. This option is ignored for variables whose maximum value is greater than the specified value or if the DATABOUNDARY option is also specified.

KNOTMETHOD=*knot-method***<(***knot-options***)>**
specifies how to construct the knots for spline effects. You can choose from the following *knot-methods* and affect the knot construction further with the method-specific *knot-options*:

EQUAL<(*n***)>**
specifies that *n* equally spaced knots be positioned between the extremes of the data. By default, *n* = 3. For a B-spline basis, any needed boundary knots continue to be equally spaced unless the DATABOUNDARY option has also been specified. By default, KNOTMETHOD=EQUAL(3).

LIST(*number-list***)**
specifies the list of internal knots to be used in forming the spline basis columns. For a B-spline basis, the data extremes are used as boundary knots.

LISTWITHBOUNDARY(*number-list***)**
specifies the list of all knots that are used in forming the spline basis columns. When you use a truncated power function basis, this list is interpreted as the list of internal knots. When you use a B-spline basis of degree *d*, then the first *d* entries are used as left-side boundary knots and the last $\max(d, 1)$ entries in the list are used as right-side boundary knots.

MULTISCALE<(*multiscale-options***)>**
generates multiple B-spline bases, which correspond to sets that have an increasing number of internal knots. As the number of internal knots increases, the spline basis that is generated can approximate features of the data at finer scales. So generating bases at multiple scales facilitates the modeling of both coarse- and fine-grained features of the data. For scale *i*, the spline basis corresponds to 2^i equally spaced internal knots. By default, the bases for scales 0–7 are generated. For each scale, a separate spline effect is generated. The name of the constructed spline effect at scale *i* is formed by appending _S*i* to the effect name that you specify in the EFFECT statement. If you specify multiple variables in the EFFECT statement, then spline bases are generated separately for each variable at each scale and the name of the corresponding effect is obtained

by appending the variable name followed by _S*i* to the name in the EFFECT statement. For example, the following statement generates effects named spl_x1_S0, spl_x1_S1, spl_x1_S2, . . ., spl_x1_S7 and spl_x2_S1, spl_x2_S2, . . ., spl_x2_S7:

```
EFFECT spl = spline(x1 x2 / knotmethod=multiscale);
```

The MULTISCALE option is ignored if you specify the BASIS=TPF *spline-option*.

The following *multiscale-options* control which scales are included:

STARTSCALE=*n* specifies the start scale, where *n* is a positive integer. By default, STARTSCALE=0.

ENDSCALE=*n* specifies the end scale, where *n* is a positive integer. By default, ENDSCALE=7.

PERCENTILES(*n***)**

requests that internal knots be placed at *n* equally spaced percentiles of the variable or variables named in the EFFECT statement. For example, the following statement positions internal knots at the deciles of the variable x. For a B-spline basis, the extremes of the data are used as boundary knots:

```
EFFECT spl = spline(x / knotmethod=percentiles(9));
```

RANGEFRACTIONS(*fraction-list***)**

places internal knots at each fraction of the ranges of the variables in the EFFECT statement. For example, if variable x1 ranges between 1 and 3 and variable x2 ranges between 0 and 20, then the following EFFECT statement uses internal knots 1.2, 2, and 2.5 for variable x1 and internal knots 2, 10, and 15 for variable x2:

```
EFFECT spl = spline(x1 x2 / knotmethod=rangefractions(.1 .5 .75));
```

For a B-spline basis, the data extremes are used as boundary knots.

KNOTMIN=*value*

requests that, for each variable in the EFFECT statement, the left-side boundary knots be equally spaced starting at the specified value and ending at the minimum of the variable. This option is ignored for variables whose minimum value is less than the specified value or if the DATABOUNDARY option is also specified.

NATURALCUBIC

uses a natural cubic spline basis for the spline expansion. Natural cubic splines, also known as restricted cubic splines, are cubic splines that are constrained to be linear beyond the extreme knots. The natural cubic spline basis that is produced by the EFFECT statement is obtained by starting from the unrestricted truncated power function cubic spline basis that is defined with n distinct knots and imposes the linearity constraints beyond the extreme knots. This basis consists of an intercept, the polynomial x, and $n - 2$ functions that are all linear beyond the largest knot. The ith function, $i = 1, 2, \ldots, n - 2$, is 0 to the left of the ith knot, which is called the "break knot." For more information about this basis, see the section "Splines and Spline Bases" on page 28. You can use the NOINT and NOPOWERS suboptions of the BASIS=TPF option to suppress the intercept and

polynomial x when the columns of the natural cubic spline basis are formed. When you specify the NATURALCUBIC option, the options BASIS=BSPLINE, DATABOUNDARY, DEGREE=, and KNOTMETHOD=MULTISCALE are not applicable.

SEPARATE

requests that, when multiple variables are specified in the EFFECT statement, the spline basis for each variable be treated as a separate effect. The names of these separated effects are formed by appending an underscore followed by the name of the variable to the name that you specify in the EFFECT statement. For example, the following statement generates the effect names spl_x1 and spl_x2:

```
EFFECT spl = spline(x1 x2 / separate);
```

In procedures that support variable selection, such as the GENSELECT procedure, these two effects can enter or leave the model independently during the selection process.

SPLIT

treats each individual column in the design matrix that corresponds to the spline effect as a separate effect that can enter or leave the model independently. Names for these split effects are generated by appending the variable name and an index for each column to the name that you specify in the EFFECT statement. For example, the effects generated for the spline effect in the following statement are spl_x1:1, spl_x1:2, ..., spl_x1:7 and spl_x2:1, spl_x2:2, ..., spl_x2:7:

```
EFFECT spl = spline(x1 x2 / split);
```

Splines and Spline Bases

This section provides details about how the EFFECT statement constructs spline bases. A spline function is a piecewise polynomial function in which the individual polynomials have the same degree and connect smoothly at join points whose abscissa values, called knots, are prespecified. You can use spline functions to fit curves to a wide variety of data.

A spline of degree 0 is a step function with steps located at the knots. A spline of degree 1 is a piecewise linear function where the lines connect at the knots. A spline of degree 2 is a piecewise quadratic curve whose values and slopes coincide at the knots. A spline of degree 3 is a piecewise cubic curve whose values, slopes, and curvature coincide at the knots. Visually, a cubic spline is a smooth curve, and it is the most commonly used spline when a smooth fit is desired. Note that when no knots are used, splines of degree d are simply polynomials of degree d.

More formally, suppose you specify knots $k_1 < k_2 < k_3 < \cdots < k_n$. Then a spline of degree $d \geq 0$ is a function $S(x)$ with d–1 continuous derivatives such that

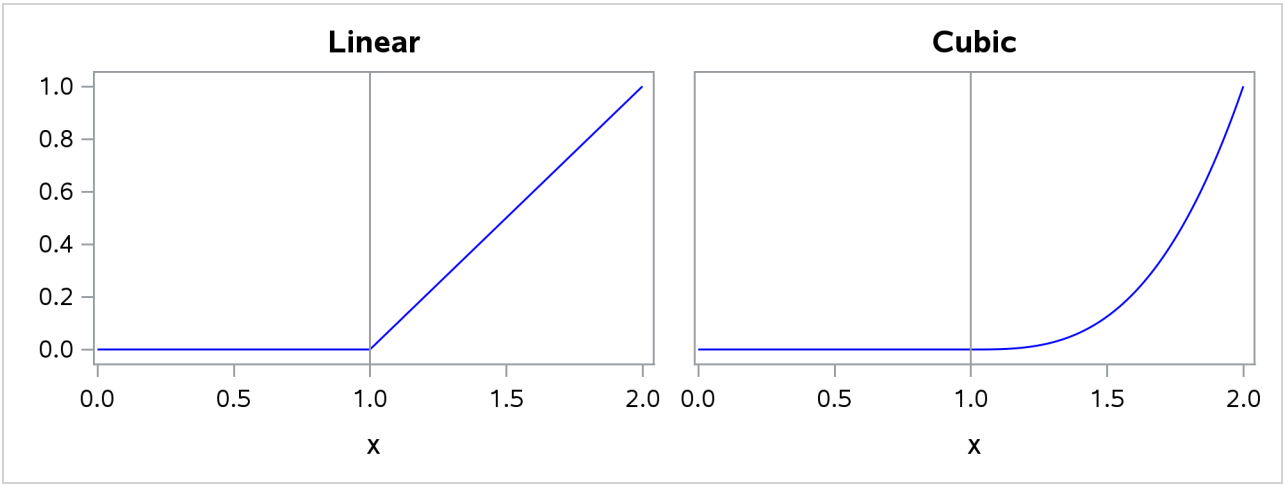
$$S(x) = \begin{cases} P_0(x) & x < k_1 \\ P_i(x) & k_i \leq x < k_{i+1};\ i = 1, 2, \ldots, n-1 \\ P_n(x) & x \geq k_n \end{cases}$$

where each $P_i(x)$ is a polynomial of degree d. The requirement that $S(x)$ has $d - 1$ continuous derivatives is satisfied by requiring that the function values and all derivatives up to order $d - 1$ of the adjacent polynomials at each knot match.

A counting argument yields the number of parameters that define a spline with n knots. There are $n + 1$ polynomials of degree d, producing $(n + 1)(d + 1)$ coefficients. However, there are d restrictions at each of the n knots, so the number of free parameters is $(n + 1)(d + 1) - nd = n + d + 1$. In mathematical terminology this says that the dimension of the vector space of splines of degree d on n distinct knots is $n + d + 1$. If you have $n + d + 1$ basis vectors, then you can fit a curve to your data by regressing your dependent variable by using this basis for the corresponding design matrix columns. In this context, such a spline is known as a regression spline. The EFFECT statement provides a simple mechanism for obtaining such a basis.

If you remove the restriction that the knots of a spline must be distinct and allow repeated knots, then you can obtain functions that have less smoothness and even discontinuities at the repeated knot location. For a spline of degree d and a repeated knot that has multiplicity $m \leq d$, the piecewise polynomials that join such a knot are required to have only $d - m$ matching derivatives. Note that this increases the number of free parameters by $m - 1$ but also decreases the number of distinct knots by $m - 1$. Hence the dimension of the vector space of splines of degree d with n knots is still $n + d + 1$, provided that any repeated knot has a multiplicity less than or equal to d.

The EFFECT statement supports the commonly used *truncated power function* basis and *B-spline* basis. With exact arithmetic and by using the complete basis, you obtain the same fit with either of these bases. The following subsections provide details about constructing spline bases for the space of splines of degree d with n knots that satisfies $k_1 \leq k_2 \leq k_3 < \cdots \leq k_n$.



Truncated Power Function Basis

A truncated power function for a knot k_i is a function defined by

$$t_i(x) = \begin{cases} 0 & x < k_i \\ (x - k_i)^d & x \geq k_i \end{cases}$$

Figure 2.1 shows such functions for $d = 1$ and $d = 3$ with a knot at $x = 1$.

Figure 2.1 Truncated Power Functions with Knot at $x = 1$

The name is derived from the fact that these functions are shifted power functions that are truncated to 0 to the left of the knot. These functions are piecewise polynomial functions that have two pieces whose function values and derivatives of all orders up to d–1 are 0 at the defining knot. Hence these functions are splines of

degree d. It is easy to see that these n functions are linearly independent. However, they do not form a basis, because such a basis requires $n+d-1$ functions. The usual way to add $d+1$ additional basis functions is to use the polynomials $1, x, x^2, \ldots, x^d$. These $d+1$ functions together with the n truncated power functions $t_i(x), i = 1, 2, \ldots, n$ form the truncated power basis.

Note that each time a knot is repeated, the associated exponent used in the corresponding basis function is reduced by 1. For example, for splines of degree d with three repeated knots $k_i = k_{i+1} = k_{i+2}$, the corresponding basis functions are $t_i(x) = (x - k_i)_+^d$, $t_{i+1}(x) = (x - k_i)_+^{d-1}$, and $t_{i+2}(x) = (x - k_i)_+^{d-2}$. Provided that the multiplicity of each repeated knot is less than or equal to the degree, this construction continues to yield a basis for the associated space of splines.

The main advantage of the truncated power function basis is the simplicity of its construction and the ease of interpreting the parameters in a model that corresponds to these basis functions. However, there are two weaknesses when you use this basis for regression. These functions grow rapidly without bound as x increases, resulting in numerical precision problems when the x data span a wide range. Furthermore, many or even all of these basis functions can be nonzero when evaluated at some x value, resulting in a design matrix that has few zeros and precludes the use of sparse matrix technology to speed up computation. This weakness can be addressed by using a B-spline basis.

B-Spline Basis

A B-spline basis can be built by starting with a set of Haar basis functions, which are functions that are 1 between adjacent knots and 0 elsewhere, and then applying a simple linear recursion relationship d times, yielding the $n + d + 1$ needed basis functions. For the purpose of building the B-spline basis, the n prespecified knots are called internal knots. This construction requires d additional knots, known as boundary knots, to be positioned to the left of the internal knots, and $\max(d, 1)$ boundary knots to be positioned to the right of the internal knots. The actual values of these boundary knots can be arbitrary. The EFFECT statement provides several methods for placing the necessary boundary knots, including the common method of using repeated values of the data extremes as the boundary knots. The boundary knot placement affects the precise form of the basis functions that are generated, but it does not affect the following two desirable properties:

- The B-spline basis functions are nonzero over an interval that spans at most $d + 2$ knots. This yields design matrix columns each of whose rows contain at most $d + 2$ adjacent nonzero entries.
- The computation of the basis functions at any x value is numerically stable and does not require evaluating powers of this value.

The following figures show the B-spline bases that are defined on $[0, 1]$ with four equally spaced internal knots at 0.2, 0.4, 0.6, and 0.8.

Figure 2.2 shows a linear B-spline basis. This basis consists of six functions, each of which is nonzero over an interval that spans at most three knots.

Figure 2.2 Linear B-Spline Basis with Four Equally Spaced Interior Knots

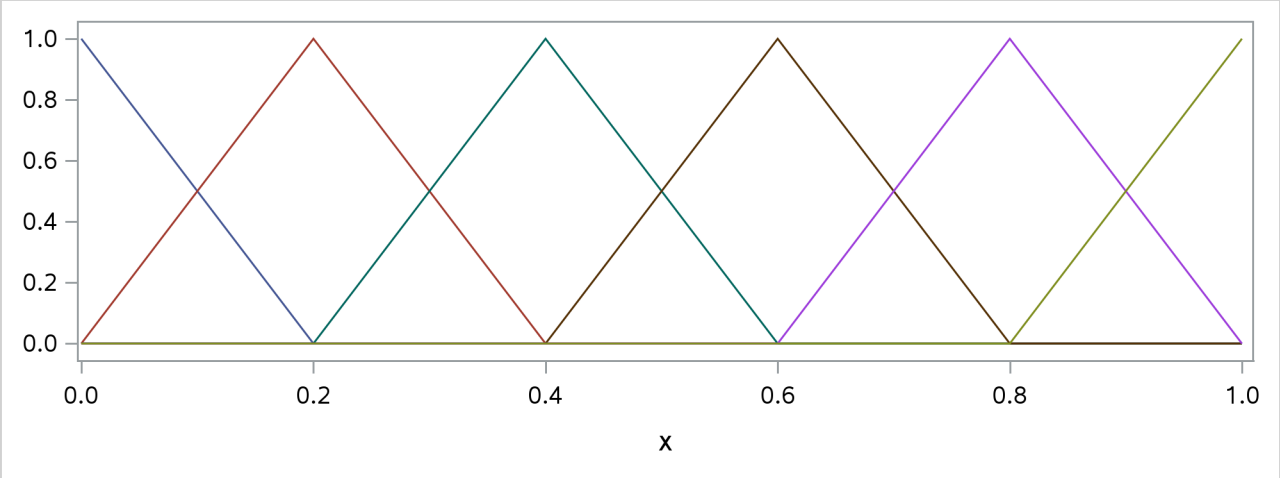


Figure 2.3 shows a cubic B-spline basis where the necessary boundary knots are positioned at $x = 0$ and $x = 1$. This basis consists of eight functions, each of which is nonzero over an interval that spans at most five knots.

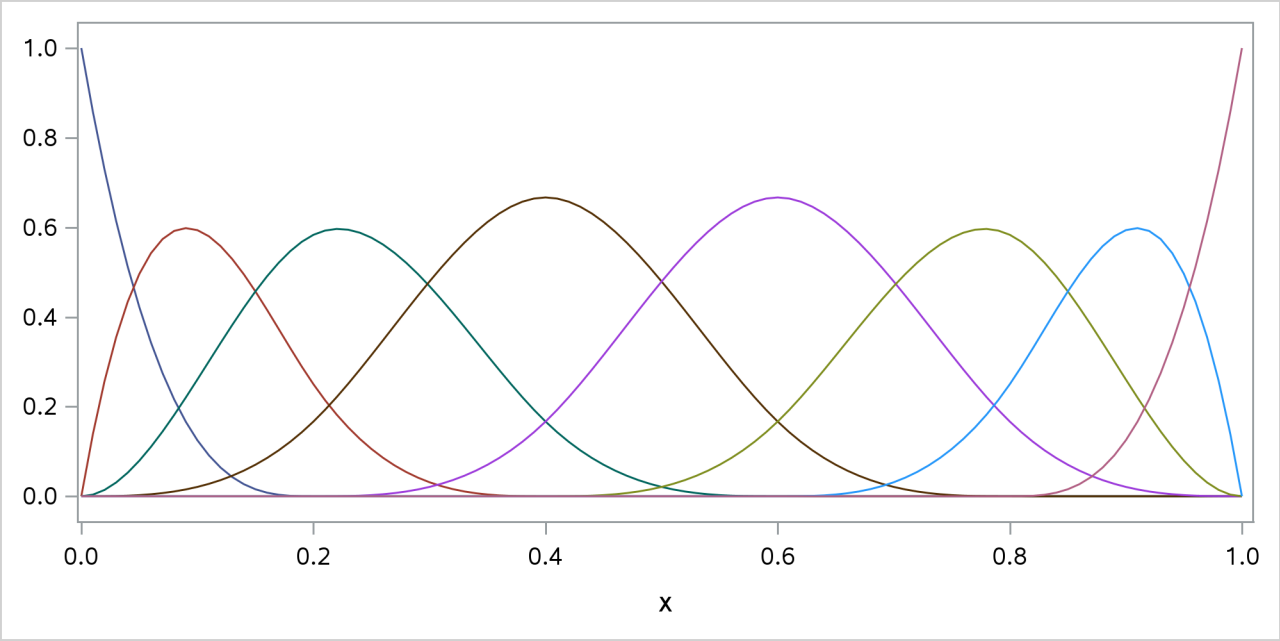
Figure 2.3 Cubic B-Spline Basis with Four Equally Spaced Interior Knots



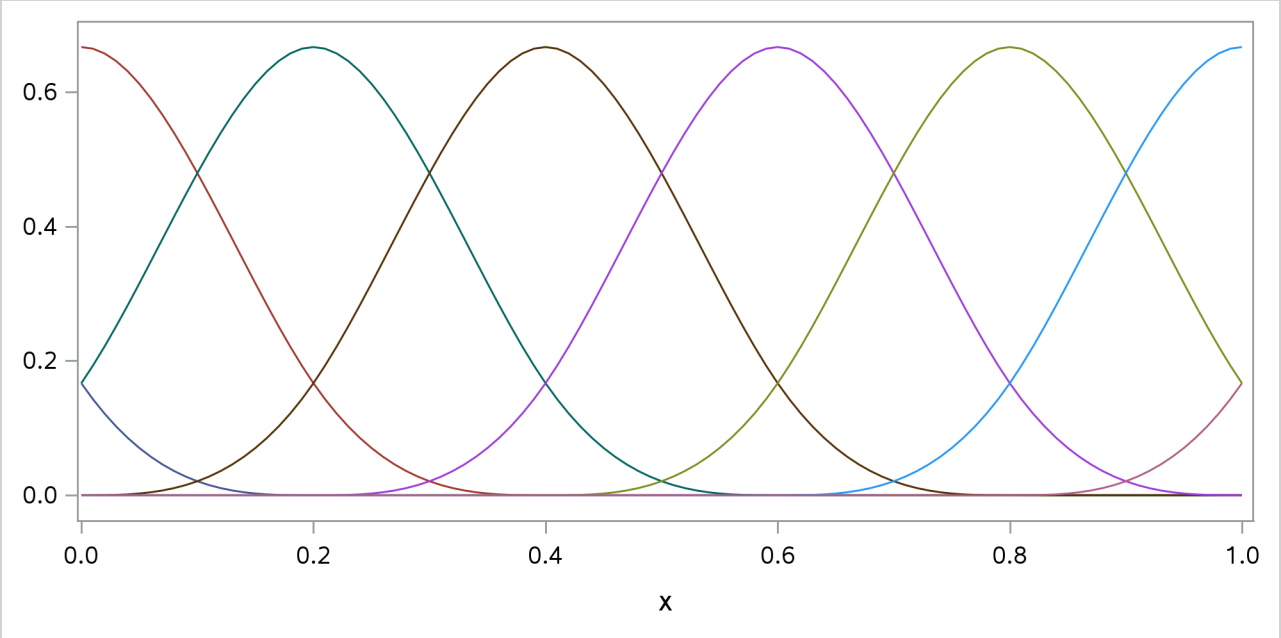


Figure 2.4 shows a different cubic B-spline basis where the necessary left-side boundary knots are positioned at –0.6, –0.4, –0.2, and 0. The right-side boundary knots are positioned at 1, 1.2, 1.4, and 1.6. As in the basis shown in Figure 2.3, this basis consists of eight functions, each of which is nonzero over an interval that spans at most five knots. The different positioning of the boundary knots has merely changed the shape of the individual basis functions.

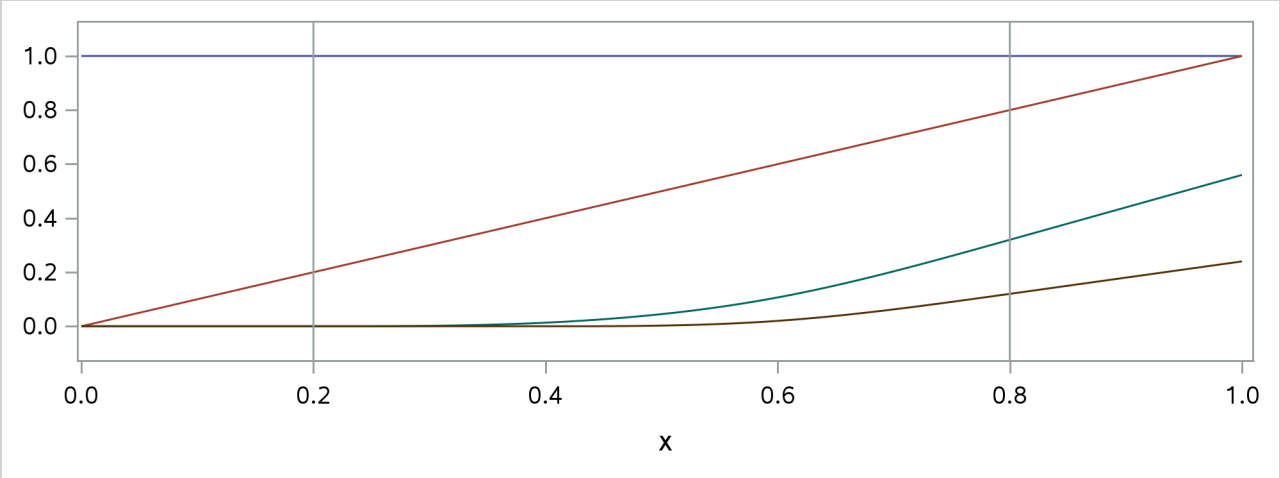
Figure 2.4 Cubic B-Spline Basis with Equally Spaced Boundary and Interior Knots



For more information about this construction, see Hastie, Tibshirani, and Friedman (2001).

Natural Cubic Spline Basis

Natural cubic splines are cubic splines with the additional restriction that the splines are required to be linear beyond the extreme knots. Some authors prefer the terminology "restricted cubic splines" to "natural cubic splines." The space of unrestricted cubic splines on n knots has the dimension $n + 4$. Imposing the restrictions that the cubic polynomials beyond the first and last knot reduce to linear polynomials reduces the number of degrees of freedom by 4, so a basis for the natural cubic splines consists of n functions. Starting from the truncated power function basis for the unrestricted cubic splines, you can obtain a reduced basis by imposing linearity constraints. For more information about this construction, see Hastie, Tibshirani, and Friedman (2001). Figure 2.5 shows this natural cubic spline basis defined on $[0, 1]$ with four equally spaced internal knots at 0.2, 0.4, 0.6, and 0.8. This basis consists of four basis functions that are all linear beyond the extreme knots at 0.2 and 0.8.

Figure 2.5 Natural Cubic Spline Basis with Four Equally Spaced Knots

ODS Table Names

Each constructed effect produces one or more informative tables when the DETAILS option is also specified. Each table has a name associated with it. This name is used to refer to the table by procedures that support a DISPLAY or DISPLAYOUT statement. You also use this name to refer to the table in ODS statements. These names are listed in Table 2.7.

Table 2.7 ODS Tables Produced by the EFFECT Statement

Table Name	Description	Option
BSplineDetails	B-spline basis details	BASIS=BSPLINE
CollectionLevelInfo	Levels of collection effects	
MMLevelInfo	Levels of multimember effects	
PolyDetails	Number of variables and columns, polynomial degree, and standardization method	
PolyScaling	Centering and scaling details	STANDARDIZE
SplineKnots	knot and boundary knot values	
TPFSplineDetails	Truncated power function spline basis details	BASIS=TPF or NATURALCUBIC

LSMEANS Statement

LSMEANS *model-effects* < / *options* > **;**

LSMEANS EFFECT=*model-effects* < / *options* > **;**

This section applies to the following procedures: GENSELECT, LMIXED, and LOGSELECT.

The LSMEANS statement computes least squares means (LS-means) of classification fixed effects. As in the GLM procedure, LS-means are *predicted population margins*—that is, they estimate the marginal means over a balanced population. In a sense, LS-means are to unbalanced designs as classification and subclassification arithmetic means are to balanced designs. You can view LS-means as linear combinations of the parameter estimates that are constructed in such a way that they correspond to average predicted values in a population where the levels of classification variables are balanced.

Each LS-mean is computed as $\mathbf{L}\widehat{\boldsymbol{\beta}}$, where $\mathbf{L}$ is the coefficient matrix that is associated with the least squares mean and $\widehat{\boldsymbol{\beta}}$ is the estimate of the fixed-effects parameter vector. This $\mathbf{L}$ matrix is the same as the $\mathbf{L}$ matrix that is constructed in PROC GLM; however, the standard errors are adjusted for the covariance parameters in the model. The approximate standard errors for the LS-mean are computed as the square root of $\mathbf{L}(\mathbf{X}'\widehat{\mathbf{V}}^{-1}\mathbf{X})^{-}\mathbf{L}'$. The approximate variance matrix of the fixed-effects estimates depends on the estimation method.

LS-means can be computed for any effect in the procedure's MODEL statement that involves only classification variables. You can specify multiple *model-effects* in one LSMEANS statement or in multiple LSMEANS statements, and all LSMEANS statements must appear after the MODEL statement. When you restore a model from an item store by using PROC GENSELECT or PROC LOGSELECT, then you must specify the desired *model-effects* in the EFFECT= option before the slash (/).

The $\mathbf{L}$ matrix is tested for estimability, and if this test fails, the procedure displays "Non-est" for the LS-means entries. Note that linear functions of LS-means, such as differences, can be estimable even when the means themselves are not estimable. Estimability checks for differences are thus applied separately from checks for the means. Assuming that the LS-mean is estimable, the procedure constructs an approximate normal test or t test (depending on the procedure) to test the null hypothesis that the associated population quantity equals zero. By default, the denominator degrees of freedom for the t test are the residual degrees of freedom.

Table 2.8 summarizes the *options* that are available in the LSMEANS statement. All *options* are subsequently discussed in alphabetical order. Note that the DF= and SLICE= options are available only with the LMIXED procedure.

Table 2.8 LSMEANS Statement Options

Option	Description
Construction and Computation of LS-Means	
AT	Modifies covariate values used to compute LS-means
ATVAR	Modifies covariate values for restored models
DIFF	Computes differences of LS-means
SINGULAR=	Tunes estimability checking
SLICE=	Partitions interaction LS-means effects

Table 2.8 *continued*

Option	Description
Degrees of Freedom and *p*-Values	
ADJUST=	Specifies the multiple comparison adjustment method for LS-means differences
ALPHA=α	Specifies the confidence level ($1-\alpha$)
DF=	Assigns a specific value to the degrees of freedom for tests and confidence limits
Statistical Output	
CL	Constructs confidence limits for means and mean differences
CORR	Displays the correlation matrix of LS-means
COV	Displays the covariance matrix of LS-means
E	Displays the **L** matrix

You can specify the following options in the LSMEANS statement after a slash (/):

ADJUST=*method*

computes a multiple comparison adjustment for the *p*-values and confidence limits for the differences of LS-means. The adjusted quantities are produced along with the unadjusted quantities. The ADJUST= option works together with the DIFF option. If you omit the DIFF option and specify a *method* other than NONE, then the ADJUST= option invokes the DIFF option.

You must specify one of the following *methods* for the ADJUST= option:

BON

performs Bonferroni *t* tests of differences between LS-means. The method involves correction factors described in Chapter 53, "The GLM Procedure" (*SAS/STAT User's Guide*), and Chapter 86, "The MULTTEST Procedure" (*SAS/STAT User's Guide*); also see Westfall and Young (1993) and Westfall et al. (1999).

DUNNETT

performs Dunnett's *t* test, which tests whether any treatments are significantly different from a single control for the effects in the LSMEANS statement. When the LS-means are correlated, the procedure uses the factor-analytic covariance approximation described in Hsu (1992) and identifies the adjustment as "Dunnett-Hsu" in the results. The approximation derives approximate "effective sample sizes" for which exact critical values are computed.

NELSON

performs Nelson's *t* test of each LS-mean against an average of the LS-means (Ott 1967; Nelson 1982, 1991, 1993). When the LS-means are correlated, the procedure uses the factor-analytic covariance approximation described in Hsu (1992) and identifies the adjustment as "Nelson-Hsu" in the results. The approximation derives approximate "effective sample sizes" for which exact critical values are computed.

NONE | T
performs no adjustment for multiple comparisons.

SCHEFFE
performs Scheffé's multiple comparison procedure.

SIDAK
performs pairwise t tests on differences between LS-means with levels adjusted according to Šidák's inequality. The method involves correction factors described in Chapter 53, "The GLM Procedure" (*SAS/STAT User's Guide*), and Chapter 86, "The MULTTEST Procedure" (*SAS/STAT User's Guide*); also see Westfall and Young (1993) and Westfall et al. (1999).

SIMULATE < (*simopts*) >
performs the simulation-based multiple comparison procedure. This method computes adjusted p-values and confidence limits from the simulated distribution of the maximum or maximum absolute value of a multivariate t random vector. All covariance parameters, except the residual scale parameter, are fixed at their estimated values throughout the simulation, potentially resulting in some underdispersion. The simulation estimates q, the true $(1-\alpha)$ quantile, where $1-\alpha$ is the confidence coefficient. The default value of α is 0.05; you can change this value by specifying the ALPHA= option in the LSMEANS statement.

The number of samples is set so that the tail area for the simulated q is within γ of $1-\alpha$ with $100(1-\epsilon)\%$ confidence. In equation form,

$$\Pr(|F(\widehat{q}) - (1-\alpha)| \leq \gamma) = 1-\epsilon$$

where $\hat{q}$ is the simulated q and F is the true distribution function of the maximum; see Edwards and Berry (1987) for details. By default, $\gamma = 0.005$ and $\epsilon = 0.01$, placing the tail area of $\hat{q}$ within 0.005 of 0.95 with 99% confidence.

You can specify the following *simopts* options in parentheses after the ADJUST=SIMULATE option:

ACC=*value*
specifies the target accuracy radius γ of a $100(1-\epsilon)\%$ confidence interval for the true probability content of the estimated $(1-\alpha)$ quantile. By default, ACC=0.005. Note that if you also specify the CVADJUST *simoption*, then the actual accuracy radius will probably be substantially less than this target.

CVADJUST
estimates the quantile by the control variate adjustment method of Hsu and Nelson (1998) instead of simply as the quantile of the simulated sample. Specifying this option usually has the effect of significantly reducing the accuracy radius γ of a $100 \times (1-\epsilon)\%$ confidence interval for the true probability content of the estimated $(1-\alpha)$ quantile. The control-variate-adjusted quantile estimate takes approximately twice as long to compute, but it is typically much more accurate than the sample quantile.

EPS=*value*
specifies the value ϵ for a $100 \times (1 - \epsilon)\%$ confidence interval for the true probability content of the estimated $(1 - \alpha)$ quantile. The default value of the accuracy confidence is 99%, corresponding to EPS=0.01.

NSAMP=*n*
specifies the sample size for the simulation. By default, *n* is set by a formula that is based on the values of the target accuracy radius γ and accuracy confidence $100 \times (1 - \epsilon)\%$ for an interval for the true probability content of the estimated $(1 - \alpha)$ quantile. When the default values are used for γ, ϵ, and α (0.005, 0.01, and 0.05, respectively), NSAMP=12605. If you omit the NSAMP= option or specify NSAMP=0, the default sample size is used.

REPORT
displays a report on the simulation, including a listing of the parameters, such as γ, ϵ, and α, as well as an analysis of various methods of estimating or approximating the quantile.

SEED=*number*
specifies an integer to be used to start the pseudorandom number generator for the simulation. If you do not specify a seed, or if you specify a *number* less than or equal to 0, the seed is generated by reading the time of day from the computer's clock.

SMM | GT2
performs pairwise comparisons based on the studentized maximum modulus and Šidák's uncorrelated-*t* inequality, yielding Hochberg's GT2 method when sample sizes are unequal.

T | NONE
performs no adjustment for multiple comparisons.

TUKEY
performs Tukey's studentized range test on LS-means. When your data are unbalanced, the procedure uses the approximation described in Kramer (1956) and identifies the adjustment as "Tukey-Kramer" in the results.

By default, ADJUST=NONE.

If you specify ADJUST=DUNNETT, the procedure analyzes all differences with the first control level unless you have specified a different control level. If you specify ADJUST=NELSON, then DIFF=ANOM is assumed.

If you specify ADJUST=TUKEY, then DIFF=ALL is assumed. If you specify other *methods*, then the procedure performs all pairwise differences unless you specify the DIFF option.

Note that computing the exact adjusted *p*-values and critical values for unbalanced designs can be computationally intensive, especially for ADJUST=NELSON.

ALPHA=*number*
specifies that a confidence interval be constructed for each of the LS-means with confidence level $1 -$ *number*. The value of *number* is between 0 and 1; the default is 0.05.

AT *at-specification*

enables you to modify the values of the covariates that are used in computing LS-means. By default, all covariates are set equal to their mean values for computing standard LS-means. The AT option enables you to assign arbitrary values to the covariates. Additional columns in the output table indicate the values of the covariates.

You can specify the following *at-specifications*:

MEANS

sets covariates equal to their mean values (as with standard LS-means) and applies this adjustment to crossproducts of covariates.

variable=*value*

sets the covariate *variable* equal to *value*.

(*variable-list*)=(*value-list*)

sets covariates in the *variable-list* equal to values in the *value-list*.

Consider the following example:

```
class A B;
model Y = A*B x1 x2 x1*x2;
LSMEANS A*B;
LSMEANS A*B / at means;
LSMEANS A*B / at x1=1.2;
LSMEANS A*B / at (x1 x2)=(1.2 0.3);
```

For the first two LSMEANS statements, the LS-means coefficient of x1 is $\overline{x}_1$ (the mean of x1) and of x2 is $\overline{x}_2$ (the mean of x2). For the first LSMEANS statement, the coefficient of x1*x2 is $\overline{x_1 x_2}$. However, for the second LSMEANS statement, the coefficient is $\overline{x}_1 \times \overline{x}_2$. The third LSMEANS statement sets the coefficient of x1 equal to 1.2 and leaves it at $\overline{x}_2$ for x2, and the final LSMEANS statement sets these values to 1.2 and 0.3, respectively.

Even if you specify a weight variable, the unweighted covariate means are used for the covariate coefficients if you omit the AT option. If you specify the AT option, then weight and frequency variables are taken into account as follows. The weighted covariate means are used for the covariate coefficients for which no explicit AT option values are given, or if you specify the AT MEANS option. Observations that do not contribute to the analysis because of a missing dependent variable are used in computing the covariate means. You should use the E option in conjunction with the AT option to verify that the modified LS-means coefficients are the ones that you want.

ATVAR *at-specification*

is the same as the AT option, except that it is required when you restore a model from an item store but do not provide a data table. This option is available with the GENSELECT and LOGSELECT procedures.

CL

constructs confidence limits for each of the LS-means. The LMIXED procedure computes *t*-type limits, whereas other procedures compute normal (z) intervals. If you specify the DDFM=NONE option in the MODEL statement in PROC LMIXED, then infinite degrees of freedom are used for this test, which essentially computes a z interval. The confidence level is 0.95 by default; you can change the level by specifying the ALPHA= option.

CORR

displays the estimated correlation matrix of the least squares means as part of the "Least Squares Means" table.

COV

displays the estimated covariance matrix of the least squares means as part of the "Least Squares Means" table.

DF=*number*

specifies the degrees of freedom for the *t* test and confidence limits. The default is the residual degrees of freedom that you define by specifying the DDFM=RESIDUAL option in the MODEL statement in the LMIXED procedure. This option is available only for PROC LMIXED.

DIFF<=*difftype***>**

displays differences of the LS-means in the "Differences of Least Squares Means" table. You can specify the following values for the optional *difftype*:

ALL

displays all pairwise differences.

ANOM

displays differences between each LS-mean and the average LS-mean, as in the analysis of means (Ott 1967). The average is computed as a weighted mean of the LS-means, with the weights being inversely proportional to the diagonal entries of the $\mathbf{L}\left(\mathbf{X}'\mathbf{X}\right)^{-}\mathbf{L}'$ matrix. When you specify a WEIGHT statement, the preceding matrix is replaced with $\mathbf{L}\left(\mathbf{X}'\mathbf{W}\mathbf{X}\right)^{-}\mathbf{L}'$, where $\mathbf{W}$ is the diagonal matrix that contains the weights. If LS-means are nonestimable, this design-based weighted mean is replaced with an equally weighted mean. Note that the ANOM procedure in SAS/QC software implements both tables and graphics for the analysis of means with a variety of response types. For one-way designs and normally distributed data, the ANOM computations are equivalent to the results of PROC ANOM.

CONTROL<('level1'<,'level2',...>)>

produces two-tailed tests and confidence limits for differences with a control; by default, the control is the first level of each specified LS-mean effect. To specify which levels of the effects are the controls, list the quoted formatted values in parentheses after the CONTROL keyword. For example, if the effects A, B, and C are classification variables, each having two levels, 1 and 2, the following LSMEANS statement specifies the (1,2) level of A*B and the (2,1) level of B*C as controls:

```
lsmeans A*B B*C / diff=control('1' '2', '2' '1');
```

For multiple effects, the results depend on the order of the list, so you should check the output to make sure that the controls are correct.

CONTROLL
produces one-tailed results and tests whether the noncontrol levels are significantly smaller than the control. The upper confidence limits for the control minus the noncontrol levels are considered to be infinity and are displayed as missing.

CONTROLU
produces one-tailed results and tests whether the noncontrol levels are significantly larger than the control. The upper confidence limits for the noncontrol levels minus the control are considered to be infinity and are displayed as missing.

E
displays the matrix coefficients for all LS-mean effects in the "Matrix Coefficients" table.

PDIFF<=*difftype*>
is the same as the DIFF option.

SINGULAR=*number*
tunes the estimability checking. If **v** is a vector, define ABS(**v**) to be the largest absolute value of the elements of **v**. If ABS($\mathbf{L} - \mathbf{LT}$) is greater than *c***number* for any row of **L** in the contrast, then $\mathbf{L}\boldsymbol{\beta}$ is declared nonestimable. Here, **T** is the Hermite form matrix $(\mathbf{X}'\mathbf{X})^{-}\mathbf{X}'\mathbf{X}$, and *c* is ABS(**L**), except when it equals 0, and then *c* is 1. The value of *number* is between 0 and 1; the default is 1E–4.

SLICE=*effect1* <,*effect2*, ... >}
specifies effects by which to partition interaction LS-mean effects. This option is available only for the LMIXED procedure. This partition can produce what are known as tests of simple effects (Winer 1971). For example, suppose that A*B is significant, and you want to test the effect of A for each level of B. The appropriate LSMEANS statement is

```
lsmeans A*B / slice=B;
```

This statement tests for the simple main effects of A for B, which are calculated by extracting the appropriate rows from the coefficient matrix for the A*B LS-means and by using them to form an *F* test.

The SLICE= option produces *F* tests that test the simultaneous equality of cell means at a fixed level of the slice effect (Schabenberger, Gregoire, and Kong 2000). It produces a table titled "Tests of Effect Slices."

ODS Table Names: LSMEANS Statement

Each table that the LSMEANS statement creates has a name associated with it. You can use this name to refer to the table when using the Output Delivery System (ODS) to select tables and create output data sets. The table names are listed in Table 2.9. For more information about ODS, see Chapter 23, "Using the Output Delivery System" (*SAS/STAT User's Guide*).

Table 2.9 ODS Tables Produced by the LSMEANS Statement

Table Name	Description	Required Option
Coef	**L** matrix coefficients	E
Diffs	Differences of least squares means	DIFF or ADJUST=
LSMeans	Least squares means	Default
SimDetails	Details for difference quantile simulation	ADJUST=SIMULATE(REPORT)
SimResults	Evaluation of difference quantile simulation	ADJUST=SIMULATE(REPORT)
Slices	Tests of LS-means effect slices	SLICE=

PARTITION Statement

PARTITION *partition-option* **;**

This section applies to the following procedures: GAMSELECT, GENSELECT, LOGSELECT, PHSELECT, QTRSELECT, REGSELECT, and TREESPLIT.

The PARTITION statement specifies how observations in the input data set are logically partitioned into disjoint subsets for model training, validation, and testing. For more information, see the section "Using Validation and Test Data" on page 101. Either you can designate a variable in the input data table and a set of formatted values of that variable to determine the role of each observation, or you can specify proportions to use for randomly assigning observations to each role.

You must specify exactly one of the following *partition-options*:

FRACTION(< TEST=*fraction* **> < VALIDATE=***fraction* **> < SEED=***number* **>)**
randomly assigns specified proportions of the observations in the input data table to the roles. You specify the proportions for testing and validation by using the TEST= and VALIDATE= suboptions. If you specify both the TEST= and VALIDATE= suboptions, then the sum of the specified fractions must be less than 1 and the remaining fraction is the proportion of the observations assigned to the training role. The SEED= option specifies an integer that is used to start the pseudorandom number generator for random partitioning of data for training, testing, and validation. If you do not specify SEED=*number* or if *number* is less than or equal to 0, the seed is generated by reading the time of day from the computer's clock.

ROLE=*variable* **(< TEST='***value***' > < TRAIN='***value***' > < VALIDATE='***value***' >)**

ROLEVAR=*variable* **(< TEST='***value***' > < TRAIN='***value***' > < VALIDATE='***value***' >)**
names the *variable* in the input data table whose values are used to assign roles to each observation. This *variable* cannot also appear as an analysis variable in other statements or options. The TEST=, TRAIN=, and VALIDATE= suboptions specify the formatted values of this variable that are used to assign observation roles. If you do not specify the TRAIN= suboption, then all observations whose role is not determined by the TEST= or VALIDATE= suboption are assigned to the training role.

SELECTION Statement

SELECTION < **METHOD=***method*< **(***method-options***)** > >< *options* > **;**

This section applies to the following procedures: GENSELECT, LOGSELECT, PHSELECT, QTRSELECT, and REGSELECT.

Procedures in this book that support model selection use the SELECTION statement to control details about the model selection process.

You can specify the following methods in the SELECTION statement:

METHOD=*method* **<(***method-options***)>**
specifies the method to be used to select the model. You can also specify *method-options* to apply to the specified method by enclosing them in parentheses after the *method*.

The following *methods* are available and are explained in detail in the section "Model Selection Methods" on page 75. By default, METHOD=STEPWISE.

BACKWARD specifies backward elimination. This method starts with all effects in the model and deletes effects.

BESTSUBSET specifies best-subset selection. This method uses the branch-and-bound technique (Furnival and Wilson 1974) to find the best subsets of model effects without examining all possible subsets. The only SAS Viya procedure that supports this method is the REGSELECT procedure.

ELASTICNET specifies the elastic net method. This is an extension of LASSO that estimates parameters by using constrained optimization, in which both the sum of the absolute regression coefficients and the sum of the squared regression coefficients are constrained. The SAS Viya procedures that support this method are the GENSELECT, LOGSELECT, and REGSELECT procedures.

FORWARD specifies forward selection. This method starts with no effects in the model and adds effects.

FORWARDSWAP specifies forward-swap selection, which is an extension of the forward selection method. Before any addition step, the procedure makes all pairwise swaps of one effect in the model and one effect out of the current model that improve the selection criterion. When the selection criterion is an R-square, this method is the same as the MAXR method in the REG procedure in SAS/STAT software. The only SAS Viya procedure that supports this method is the REGSELECT procedure.

LAR specifies least angle regression. Like forward selection, this method starts by adding effects to an empty model. The parameter estimates at any step are "shrunk" when they are compared to the corresponding least squares estimates. If the model contains classification variables, then these classification variables are split. For more information, see the SPLIT option in the CLASS statement. The only SAS Viya procedure that supports this method is the REGSELECT procedure.

LASSO specifies the LASSO method, which adds and deletes parameters by using a version of ordinary least squares in which the sum of the absolute regression coefficients is constrained. If the model contains classification variables, then these classification variables are split. For more information, see the SPLIT option in the CLASS statement.

MCP specifies the MCP method, which minimizes ordinary least squares plus the minimax concave penalty (MCP) function. As an alternative to the convex penalized methods such as LASSO and ELASTICNET, MCP is one of the nonconvex penalized methods. The only SAS Viya procedure that supports this method is the REGSELECT procedure.

NONE specifies no model selection.

SCAD specifies the SCAD method, which minimizes ordinary least squares plus the smoothly clipped absolute deviation (SCAD) function. As an alternative to the convex penalized methods such as LASSO and ELASTICNET, SCAD is one of the nonconvex penalized methods. The only SAS Viya procedure that supports this method is the REGSELECT procedure.

STEPWISE specifies stepwise regression. This method is similar to the FORWARD method except that effects already in the model do not necessarily stay there.

Note that not all selection *methods* are applicable to every procedure. Table 2.10 lists the applicable *methods* for each of the procedures.

Table 2.10 Applicable *methods* by Procedure

method	GENSELECT	LOGSELECT	PHSELECT	QTRSELECT	REGSELECT
BACKWARD	x	x	x	x	x
BESTSUBSET					x
ELASTICNET	x	x			x
FORWARD	x	x	x	x	x

The syntax of the *method-options* that you can specify in parentheses after the SELECTION= option *method* follows. As described in Table 2.11, not all selection *method-options* are applicable to every *method*.

ABSFCONV=*value*
specifies an absolute function difference convergence criterion. This *method-option* is available only when the solver is the alternating direction method of multipliers (ADMM) for elastic net selection.

ADAPTIVE < (GAMMA=*nonnegative number***) >**
applies adaptive weights to each of the coefficients when METHOD=LASSO or METHOD=ELASTICNET. Ordinary least squares estimates of the model parameters are used to form the adaptive weights. You use the GAMMA= suboption to specify the power transformation that is applied to the parameters in forming the adaptive weights. By default, GAMMA=1.

AIC
displays the AIC statistic for each model in the SubsetSelectionSummary table. This *method-option* is available only for the METHOD=BESTSUBSET option.

ALPHA=*value*
specifies the regularization parameter α to use when you specify METHOD=MCP or METHOD=SCAD. If you specify this *method-option*, then the value that you specify is used to define the MCP or SCAD method, and the MAXALPHA=, MINALPHA=, and MAXITERALPHA= *method-options* are ignored. If you do not specify the ALPHA= *method-option* together with METHOD=MCP or METHOD=SCAD, then PROC REGSELECT searches for the suitable value of the α parameter according to the values of the MAXALPHA=, MINALPHA=, and MAXITERALPHA= *method-options*.

B
displays estimated regression coefficients for each model in the SubsetSelectionSummary table. This *method-option* is available only for the METHOD=BESTSUBSET option.

BEST=*number*
is used with the best-subset selection method. If you specify the SELECT=CP or SELECT=ADJRSQ *method-option*, the BEST= *method-option* specifies the maximum number of subset models to display. For the SELECT=RSQUARE *method-option*, the BEST= *method-option* requests the maximum number of subset models for each size. A small value of this *method-option* greatly reduces the computation time required for large problems.

BIC
displays the Bayesian information criterion (BIC) statistic for each model in the SubsetSelectionSummary table. This *method-option* is available only for the METHOD=BESTSUBSET option.

BIGM=*value*
specifies the constant $\mathcal{M}$ when you specify SOLVER=MILP. For more information about the constant $\mathcal{M}$, see the section "Folded Concave Penalized Selection" on page 89. This *method-option* is available only for the METHOD=MCP or METHOD=SCAD option.

CHOOSE=*criterion*

chooses from the list of models (at each step of the selection process) the model that yields the best value of the specified criterion. If the optimal value of the specified criterion occurs for models at more than one step, then the model that has the smallest number of parameters is chosen. If you omit the CHOOSE= *method-option*, then the selected model is the model at the final step in the selection process. The criteria that are supported depend on the type of model that is being fit. For the supported values of *criterion*, see the chapters for the relevant procedures.

COEFTOL=*value*

specifies the tolerance for the truncation of the estimated coefficients of parameters. In other words, if $|\beta_j| <$ COEFTOL for some j, then β_j would be set to zero; that is, the jth effect is not selected in the final model. This *method-option* is available only for the METHOD=MCP or METHOD=SCAD option.

COMPETITIVE

is applicable as a *method-option* only when METHOD=STEPWISE and the SELECT= criterion is not SL. If you specify the COMPETITIVE *method-option*, then the SELECT= criterion is evaluated for all models in which an effect currently in the model is dropped or an effect not yet in the model is added. The effect whose removal from or addition to the model yields the maximum improvement to the SELECT= criterion is dropped or added.

CRITERION=*criterion*

is an alias for the SELECT= *method-option*.

ENSCALE

scales the results of the elastic net method to offset bias from the double shrinkage inherent in this method (Zou and Hastie 2005). This *method-option* applies only when you specify METHOD=ELASTICNET. The default is not to rescale the solution; this is the so-called naive elastic net.

FAST

implements the computational algorithm of Lawless and Singhal (1978) to compute a first-order approximation to the remaining slope estimates for each subsequent elimination of a variable from the model. When applied in backward selection, this *method-option* essentially leads to approximating the selection process as the selection process of a linear regression model in which the crossproducts matrix equals the Hessian matrix in the full model under consideration. This *method-option* is available only when METHOD=BACKWARD is specified. It is computationally efficient because the model is not fit after the removal of each effect.

FCONV=*value*

specifies a relative function difference convergence criterion. This *method-option* is available only when the solver is either the alternating direction method of multipliers (ADMM) or the limited-memory BFGS method of elastic net selection.

GCONV=*value*

specifies a relative gradient convergence criterion. This *method-option* is available only when the solver is the limited-memory BFGS method of elastic net selection.

GMSEP
displays the GMSEP statistic (estimated mean square error of prediction, assuming that both independent and dependent variables are multivariate normal (Stein 1960; Darlington 1968)) for each model in the SubsetSelectionSummary table. This *method-option* is available only for the METHOD=BESTSUBSET option.

INTTOL=*value*
specifies the amount by which an integer variable value can differ from an integer and still be considered integer-feasible, when you specify SOLVER=MILP. The value of the INTTOL= option can be any number between 1E–9 and 0.5, inclusive. By default, INTTOL=1E–7. This *method-option* is available only for the METHOD=MCP or METHOD=SCAD option.

JP
displays the J_p statistic (estimated mean square error of prediction, assuming that the values of the regressors are fixed and that the model is correct) for each model in the SubsetSelectionSummary table. This *method-option* is available only for the METHOD=BESTSUBSET option.

LAMBDA=*value(s)*
specifies the regularization parameter λ to use when you specify METHOD=ELASTICNET, METHOD=MCP, or METHOD=SCAD. Depending on the selection method, this *method-option* has the following behaviors:

ELASTICNET — If you specify a single value, elastic net selection fits a single model. If you supply a list of values, elastic net selection fits multiple models and selects the best model among the candidates. If you specify neither this *method-option* nor the NLAMBDA= *method-option*, elastic net selection fits a model by using a regularization parameter that is a fraction of $\lambda_{\max}$. In PROC REGSELECT, the value is applicable only when you specify the SOLVER= *method-option* for elastic net selection.

MCP, SCAD — If you specify a single value, then the value that you specify is used to define the MCP or SCAD method, and the MAXLAMBDA=, MINLAMBDA=, MAXITERLAMBDA=, and LAMBDAGRID= *method-options* are ignored. If you do not specify the LAMBDA= *method-option* together with METHOD=MCP or METHOD=SCAD, then the procedure searches for a suitable value of the λ parameter according to the values of the MAXLAMBDA=, MINLAMBDA=, MAXITERLAMBDA=, and LAMBDAGRID= *method-options*.

LAMBDAGRID=LINSPACE | LOGSPACE
specifies the grid pattern for searching the regularization parameter λ when you specify METHOD=MCP or METHOD=SCAD. You can specify the following values:

LINSPACE — requests an evenly spaced grid search of λ in the range $[\lambda_{\min}, \lambda_{\max}]$, where $\lambda_{\min}$ and $\lambda_{\max}$ are specified by the MINLAMBDA= and MAXLAMBDA= *method-options*, respectively.

LOGSPACE — requests a log-scale grid search of λ in the range $[\lambda_{\min}, \lambda_{\max}]$, where $\lambda_{\min}$ and $\lambda_{\max}$ are specified by the MINLAMBDA= and MAXLAMBDA= *method-options*, respectively.

This *method-option* is available only for the METHOD=MCP or METHOD=SCAD option. By default, LAMBDAGRID=LOGSPACE. For more information about this option, see the section "Folded Concave Penalized Selection" on page 89.

LSCOEFFS
requests a hybrid version of the LAR and LASSO methods, in which the sequence of models is determined by the LAR or LASSO algorithm but the coefficients of the parameters for the model at any step are determined by using ordinary least squares.

L2=*value*
specifies the ridge regularization parameter to use when you specify METHOD=ELASTICNET. If you specify this *method-option*, then the value that you specify is used to define the elastic net method, and the L2HIGH=, L2LOW=, and L2STEPS= *method-options* are ignored. If you do not specify the L2= *method-option* together with METHOD=ELASTICNET, then PROC REGSELECT searches for the suitable value of the L2 parameter according to the values of the L2HIGH=, L2LOW=, and L2STEPS= *method-options*.

L2HIGH=*value*
specifies the highest value to use in the search for the suitable value of the ridge regression parameter L2 when you specify METHOD=ELASTICNET. If you specify the L2= *method-option*, then the L2HIGH= *method-option* is ignored. By default, L2HIGH=1.

L2LOW=*value*
specifies the lowest value to use in the search for the suitable value of the ridge regression parameter L2 when you specify METHOD=ELASTICNET. If you specify the L2= *method-option*, then the L2LOW= *method-option* is ignored. By default, L2LOW=0.

L2STEPS=*n*
specifies the number of steps in the search for the suitable value of the ridge regression parameter L2 when you specify METHOD=ELASTICNET. If you specify the L2= *method-option*, then the L2STEPS= *method-option* is ignored. By default, L2STEPS=50.

MAXALPHA=*value*
specifies the highest value to use in the search for the suitable value of the regularization parameter α when you specify METHOD=MCP or METHOD=SCAD. If you specify the ALPHA= *method-option*, then the MAXALPHA= *method-option* is ignored. By default, MAXALPHA=4.7 for METHOD=MCP and MAXALPHA=5.7 for METHOD=SCAD.

MAXEFFECTS=*n*
specifies the maximum number of effects in any model that is considered during the selection process. This *method-option* is ignored when you specify METHOD=BACKWARD. If, at some step of the selection process, the model contains the specified maximum number of effects, then no candidates for addition are considered.

MAXITERALPHA=*n*
specifies the number of steps in the search for the suitable value of the regularization parameter α when you specify METHOD=MCP or METHOD=SCAD. The grid of parameter α is evenly spaced between the values of the MINALPHA= and MAXALPHA= *method-options*. If you specify the ALPHA= *method-option*, then the MAXITERALPHA= *method-option* is ignored. By default, MAXITERALPHA=4.

MAXITERLAMBDA=*n*

specifies the number of steps in the search for the suitable value of the regularization parameter λ when you specify METHOD=MCP or METHOD=SCAD. If you specify the LAMBDA= *method-option*, then the MAXITERLAMBDA= *method-option* is ignored. By default, MAXITERLAMBDA=10.

MAXLAMBDA=*value*

specifies the highest value to use in the search for the suitable value of the regularization parameter λ when you specify METHOD=MCP or METHOD=SCAD. If you specify the LAMBDA= *method-option*, then the MAXLAMBDA= *method-option* is ignored. You can find the default value of the MAXLAMBDA= *method-option* in the section "Folded Concave Penalized Selection" on page 89.

MAXSTEPS=*n*

specifies the maximum number of selection steps to perform. The default value of *n* is the number of effects in the MODEL statement when METHOD=FORWARD, METHOD=BACKWARD, or METHOD=LAR. The default is three times the number of effects when METHOD=STEPWISE or METHOD=LASSO.

MAXTIME=*value*

specifies the upper limit of time (in seconds) for performing the optimization process, in each α and λ step. By default, MAXTIME=600. This *method-option* is available only for the METHOD=MCP or METHOD=SCAD option.

MINALPHA=*value*

specifies the lowest value to use in the search for the suitable value of the regularization parameter α when you specify METHOD=MCP or METHOD=SCAD. If you specify the ALPHA= *method-option*, then the MINALPHA= *method-option* is ignored. By default, MINALPHA=1.7 for METHOD=MCP and MINALPHA=2.7 for METHOD=SCAD.

MINEFFECTS=*n*

specifies the minimum number of effects in any model that is considered during backward selection. This *method-option* is ignored unless METHOD=BACKWARD is specified. The backward selection process terminates if, at some step of the selection process, the model contains the specified minimum number of effects.

MINLAMBDA=*value*

specifies the lowest value to use in the search for the suitable value of the regularization parameter λ when you specify METHOD=MCP or METHOD=SCAD. If you specify the LAMBDA= *method-option*, then the MAXLAMBDA= *method-option* is ignored. You can find the default value of the MINLAMBDA= *method-option* in the section "Folded Concave Penalized Selection" on page 89.

MIXING=*value*

specifies the mixing parameter that controls the balance between the L_1 penalty and the L_2 penalty in elastic net selection. The specified value must be between 0 and 1, inclusive. If you specify 0, elastic net selection fits ridge regression models. If you specify 1, elastic net selection fits LASSO regression models. The default value is 0.5. In PROC REGSELECT, this *method-option* is available only when you specify the SOLVER= *method-option* for elastic net selection.

MSE
displays the mean square error for each model in the SubsetSelectionSummary table. This *method-option* is available only for the METHOD=BESTSUBSET option.

NLAMBDA=*n*
specifies the number of regularization parameters for fitting candidate models. The default value is 1. This option is ignored if you supply a list of regularization parameters by using the LAMBDA= *method-option*. In PROC REGSELECT, this *method-option* is available only when you specify the SOLVER= *method-option* for elastic net selection.

PC
displays the PC statistic (Amemiya's prediction criterion (Amemiya 1976; Judge et al. 1980)) for each model in the SubsetSelectionSummary table. This *method-option* is available only for the METHOD=BESTSUBSET option.

RELAXED < (KAPPA=*value(s)***) >**
specifies relaxed LASSO selection, in which each candidate is determined by the LASSO algorithm but the coefficients of the parameters for each candidate at any step are determined by using a linear combination of LASSO coefficients and least squares estimates. You can use the KAPPA= suboption to control the balance of LASSO coefficients and ordinary least squares in finding the relaxed LASSO solution. By default, the value of the KAPPA= suboption is 0 to 1 by increments of 0.1. The RELAXED *method-option* is available only for the REGSELECT procedure.

RHO=*value*
specifies the scaling factor ρ when the NLAMBDA= *method-option* value n_λ is greater than 1. If the LAMBDA= *method-option* sequence values are omitted, elastic net selection fits candidate models by using the following sequence of the regularization parameters: $\lambda_{\max}, \lambda_{\max}\rho, \ldots, \lambda_{\max}\rho^{n_\lambda - 1}$. If you omit the RHO= *method-option*, elastic net selection uses $\rho = 10^{-4/(n_\lambda - 1)}$ when the number of observations is greater than or equal to the number of parameters, or $\rho = 10^{-2/(n_\lambda - 1)}$ when the number of observations is less than the number of parameters. In PROC REGSELECT, this *method-option* is available only when you specify the SOLVER= *method-option* for elastic net selection.

RMSE
displays the root mean square error for each model in the SubsetSelectionSummary table. This *method-option* is available only for the METHOD=BESTSUBSET option.

SBC
displays the SBC statistic for each model in the SubsetSelectionSummary table. This *method-option* is available only for the METHOD=BESTSUBSET option.

SCALE=TRUE | FALSE
specifies whether the design matrix is scaled (TRUE) or not scaled (FALSE) during model selection. This *method-option* is available only for the METHOD=MCP or METHOD=SCAD option. By default, SCALE=TRUE; this is the same as other penalized methods, such as LASSO and ELASTICNET.

SELECT=SL | *criterion*
specifies the criterion that the procedure uses to determine the order in which effects enter or leave at each step of the selection method. For each step, the effect whose addition to or removal from the current model yields the maximum improvement in the specified criterion is selected. You can use the traditional significance-level approach by specifying the SL criterion; for other supported criteria, see the chapter for the relevant procedure. This *method-option* is not valid when METHOD=LAR, METHOD=LASSO, METHOD=ELASTICNET, or METHOD=GROUPLASSO.

SIGMA=*value*
specifies the true standard deviation of the error term to use in computing the CP and BIC statistics. If you omit this *method-option*, an estimate from the full model is used. This *method-option* is available only for the METHOD=BESTSUBSET option.

SLENTRY=*value*

SLE=*value*
specifies the significance level for entry when STOP=SL or SELECT=SL. By default, SLENTRY=0.05.

SLSTAY=*value*

SLS=*value*
specifies the significance level for staying in the model when STOP=SL or SELECT=SL. By default, SLSTAY=0.05.

SOLVER=*solver-value*
specifies the optimization solver when you specify METHOD=ELASTICNET, METHOD=MCP, or METHOD=SCAD. You can specify the following *solver-values*:

ADMM specifies the alternating direction methods of multipliers (ADMM) as the solver. This *solver-value* is applicable only in PROC REGSELECT when the selection method is elastic net.

BFGS specifies the Broyden-Fletcher-Goldfarb-Shanno (BFGS) method as the solver. This *solver-value* is applicable only when the selection method is elastic net.

LBFGS specifies the limited-memory BFGS method as the solver. This *solver-value* is applicable only when the selection method is elastic net.

MILP specifies the mixed integer linear programming (MILP) solver. This *solver-value* is applicable only in PROC REGSELECT when the selection method is either MCP or SCAD.

NLP specifies the nonlinear programming (NLP) solver.

For the MCP and SCAD selection methods, the default *solver-value* is MILP. For more information about this option for both MCP and SCAD selection, see the section "Folded Concave Penalized Selection" on page 89. For more information about this option for elastic net selection, see the section "Elastic Net Selection" on page 83.

SP
displays the SP statistic (Hocking 1976) for each model in the SubsetSelectionSummary table. This *method-option* is available only for the METHOD=BESTSUBSET option.

SSE
displays the error sum of squares for each model in the SubsetSelectionSummary table. This *method-option* is available only for the METHOD=BESTSUBSET option.

STOP=SL | NONE | *criterion*
specifies a criterion that is used to stop the selection process. The criteria that are supported depend on the type of model that is being fit. For information about the supported criteria, see the chapter for the relevant procedure.

If you omit this *method-option* but specify the SELECT= *method-option*, then the criterion specified in the SELECT= *method-option* is also used as the criterion for the STOP= *method-option*.

You can specify the following values:

NONE stops the selection process if no suitable add or drop candidates can be found or if a size-based limit is reached. For example, if you specify STOP=NONE MAXEFFECTS=5, then the selection process stops at the first step that produces a model that has five effects.

SL stops the selection process at the step where the significance level of the candidate for entry is greater than the SLENTRY= *method-option* value for addition steps when METHOD=FORWARD or METHOD=STEPWISE and where the significance level of the candidate for removal is greater than the SLSTAY= *method-option* value when METHOD=BACKWARD or METHOD=STEPWISE.

criterion stops the selection process if the selection process produces a local extremum of this *criterion* or if a size-based limit is reached. For example, if you specify STOP=AIC MAXSTEPS=5, then the selection process stops before step 5 if the sequence of models has a local minimum of the AIC criterion before step 5. The determination of whether a local minimum is reached is made on the basis of a stop horizon. The default stop horizon is 3, but you can change it by using the STOPHORIZON= option. If the stop horizon is *n* and the STOP= *criterion* at any step is better than the stop criterion at the next *n* steps, then the selection process terminates.

In addition, you can also specify the following *options*:

DETAILS=NONE | SUMMARY | ALL

DETAILS=STEPS< (CANDIDATES(ALL | *n*)) >
specifies the level of detail to be produced about the selection process. The default is DETAILS=SUMMARY.

The DETAILS=ALL and DETAILS=STEPS options produce the following output:

- tables that provide information about the model that is selected at each step of the selection process.

- entry and removal statistics for inclusion or exclusion candidates at each step. By default, only the top 10 candidates at each step are shown. If you specify STEPS(CANDIDATES(*n*)), then the best *n* candidates are shown. If you specify STEPS(CANDIDATES(ALL)), then all candidates are shown.
- a selection summary table that shows by step the effect that is added to or removed from the model in addition to the values of the SELECT, STOP, and CHOOSE criteria for the resulting model.
- a stop reason table that describes why the selection process stopped.
- a selection reason table that describes why the selected model was chosen.
- a selected effects table that lists the effects that are in the selected model.

The DETAILS=SUMMARY option produces only the selection summary, stop reason, selection reason, and selected effects tables. In addition, for METHOD=ELASTICNET with neither a specified L2 value nor a solver specification, the DETAILS=SUMMARY option also displays an elastic net summary table, which shows the ridge regularization parameter L2 (in the ratio scaling) and CHOOSE criterion values in each L2 search step.

HIERARCHY=NONE | SINGLE | SINGLECLASS

specifies whether and how to apply the model hierarchy requirement. You can specify that only classification effects, or both classification and continuous effects, be subject to the hierarchy requirement. This option is ignored unless you also specify one of the following options: METHOD=FORWARD, METHOD=BACKWARD, or METHOD=STEPWISE.

Model hierarchy refers to the requirement that, for any term to be in the model, all model effects that are contained in the term must be present in the model. For example, in order for the interaction A*B to enter the model, the main effects A and B must be in the model. Likewise, neither effect A nor effect B can leave the model while the interaction A*B is in the model.

You can specify the following values:

NONE specifies that model hierarchy not be maintained. Any single effect can enter or leave the model at any step of the selection process.

SINGLE specifies that only one effect enter or leave the model at one time, subject to the model hierarchy requirement. For example, suppose that the model contains the main effects A and B and the interaction A*B. In the first step of the selection process, either A or B can enter the model. In the second step, the other main effect can enter the model. The interaction effect can enter the model only when both main effects have already entered. Also, before A or B can be removed from the model, the A*B interaction must first be removed. All effects (CLASS and interval) are subject to the hierarchy requirement.

SINGLECLASS is the same as HIERARCHY=SINGLE except that only CLASS effects are subject to the hierarchy requirement.

By default, HIERARCHY=NONE.

ORDERSELECT
specifies that effects in the selected model are displayed in the order in which they first entered the model. If you do not specify the ORDERSELECT option, then effects in the selected model are displayed in the order in which they appear in the MODEL statement.

PLOT < (*global-plot-options*) > < = *plot-request* < (*options*) > >

PLOTS < (*global-plot-options*) > < = (*plot-request* < (*options*) > < . . . *plot-request* < (*options*) > >) >
controls the selection process plots that are produced through ODS Graphics.

When you specify only one plot request, you can omit the parentheses around it. Here are some examples:

```
plots=all
plots=coefficients(unpack)
plots(unpack)=(coefficients criteria)
```

ODS Graphics must be enabled before you can request plots. For example:

```
ods graphics on;

proc regselect;
   model y = x1-x100;
   selection method=forward plots=all;
run;

ods graphics off;
```

Global Plot Options

Each *global-plot-option* applies to all plots that the SELECTION statement generates, unless you alter the option by using a specific plot option that follows a *plot-request*. You can specify the following *global-plot-options*:

ENDSTEP=*n*
terminates the step ranges shown on the horizontal axes of plots at the specified step. By default, the step range that is shown terminates at the final step of the selection process.

LOGP | LOGPVALUE
uses a logarithmic axis to display entry and removal significance levels.

MAXPARMLABEL=*n*
specifies the maximum number of characters beyond which all parameter labels on the coefficient progression panel and the coefficient progression plot are suppressed. By default, MAXPARMLABEL=20.

MAXSTEPLABEL=*n*
specifies the maximum number of characters of effect labels to display on the horizontal axes of the plots. By default, MAXSTEPLABEL=20. If the length of any effect label exceeds *n*, then step numbers are used on the horizontal axes of the plots.

STARTSTEP=*n*
specifies that the step ranges shown on the horizontal axes of plots start at the specified step. By default, the step range that is shown starts at the initial step of the selection process.

STEPAXIS=EFFECT | NORMB | NUMBER
specifies the horizontal axis to be used on the plots, where this axis represents the sequence of entering or departing effects. You can specify the following values:

EFFECT requests that each step be labeled by a prefix followed by the name of the effect that enters or leaves at that step. The prefix consists of the step number, followed by a "+" or a "-" sign, depending on whether the effect enters (+) or leaves (-) at that step.

NORMB requests that the horizontal axis value at step *i* be the L1 norm of the parameters at step *i*, normalized by the L1 norm of the parameters at the final step. STEPAXIS=NORMB is valid only with the LAR, LASSO, and elastic net selection methods.

NUMBER requests that each step be labeled by the step number.

UNPACK | UNPACKPANEL
suppresses paneling. By default, multiple plots can appear in the coefficient progression panel and the criteria panel. Specify UNPACK to see each plot individually. You can also specify UNPACK as a suboption of the CRITERIA and COEFFICIENTS options.

Specific Plot Options

You can specify the following *plot-requests* and their *options*:

ALL
produces all relevant plots.

COEFFICIENTS | COEFFICIENTPANEL < (UNPACK | UNPACKPANEL) >
creates a panel of two plots. The upper plot shows the progression of the parameter values as the selection process proceeds. The lower plot shows the progression of the CHOOSE= criterion. If no CHOOSE= criterion is in effect, then only the coefficient progression is shown. If you specify the UNPACK option, then the coefficient progression and the CHOOSE= criterion progression are shown in separate plots.

CRITERIA | CRITERIONPANEL < (UNPACK | UNPACKPANEL) >
creates a panel of model fit criteria. If you specify the UNPACK option, then each criterion progression is shown in a separate plot.

FITBYROLE
plots the progression of a fit statistic on the training, test, and validation data. The fit statistic that is displayed depends on the type of model that is being fit. The fit by role plot is not produced if you do not specify a PARTITION statement.

NONE
suppress all selection process plots, even if you specify other plot options.

SELECTION=*method* **<(***method-options***)>**
is an alias for the METHOD= option.

STOPHORIZON=*n*
specifies the number of consecutive steps at which the STOP= criterion must worsen in order for a local extremum to be detected. For example, suppose that STOP=AIC and the sequence of AIC values at steps 1 to 6 of a selection are 10, 7, 4, 6, 5, 2. If STOPHORIZON=2, then the AIC criterion is deemed to have a local minimum at step 3 because the AIC value at the next two steps are greater than the value 4 that occurs at step 3. However, if STOPHORIZON=3, then the value at step 3 is not deemed to be a local minimum because the AIC value at step 6 is lower than the AIC value at step 3. If you specify STOP=NONE then the stop horizon value is ignored. If you specify STOP=SL, then *n* is ignored and STOPHORIZON=1 is used. By default, STOPHORIZON=3 unless otherwise stated in individual procedure chapters.

STORE Statement

STORE <OUT=>*libref.data-table* **;**

SAVESTATE <OUT=>*libref.data-table* **;**

This section applies to the following procedures: BART, GAMMOD, GAMSELECT, GENSELECT, KCLUS, LMIXED, LOGSELECT, QTRSELECT, REGSELECT, and TREESPLIT.

The STORE or SAVESTATE statement saves the context and results of the analysis. The resulting analytic store has a binary file format that cannot be modified. An example of using analytic store technology is to perform a time-consuming analysis and to store its results by using the STORE statement. Later you can perform specific analysis tasks based on the saved results of the previous analysis, without having to fit the model again. The contents of the analytic store can be processed by the ASTORE procedure (see Chapter 4, "ASTORE Procedure" (*SAS Viya: Machine Learning Procedures*)) and the **`astore`** action (see Chapter 4, "Analytic Store Scoring Action Set" (*SAS Viya: Machine Learning Programming Guide*)). There might also be other actions in your action set that use the **`restore`** parameter to perform other tasks on your analytic store.

Optimization Options

This section applies to the following procedures: GENSELECT, LOGSELECT, NLMOD, and PHSELECT.

This section describes options that are typically available in the PROC statement of the procedures in this book that perform optimizations. The following notation is used to describe the options. $\boldsymbol{\beta}$ denotes the $p \times 1$ vector of parameters for the optimization and β_i is its ith element. The objective function being minimized, its $p \times 1$ gradient vector, and its $p \times p$ Hessian matrix are denoted as $f(\boldsymbol{\beta})$, $\mathrm{g}(\boldsymbol{\beta})$, and $\mathbf{H}(\boldsymbol{\beta})$, respectively. The gradient with respect to the ith parameter is denoted as $g_i(\boldsymbol{\beta})$. Superscripts in parentheses denote the iteration count; for example, $f(\boldsymbol{\beta})^{(k)}$ is the value of the objective function at iteration k.

ABSCONV=*r*

ABSTOL=*r*

specifies an absolute function convergence criterion. For minimization, termination requires $f(\boldsymbol{\beta}^{(k)}) \leq r$, where $\boldsymbol{\beta}$ is the vector of parameters in the optimization and $f(\cdot)$ is the objective function. The default value of *r* is the negative square root of the largest double-precision value, which serves only as a protection against overflows.

ABSFCONV=*r* **<** *n* **>**

ABSFTOL=*r* **<** *n* **>**

specifies an absolute function difference convergence criterion. For all techniques except NMSIMP, termination requires a small change of the function value in successive iterations:

$$|f(\boldsymbol{\beta}^{(k-1)}) - f(\boldsymbol{\beta}^{(k)})| \leq r$$

Here, $\boldsymbol{\beta}$ is the vector of parameters in the optimization and $f(\cdot)$ is the objective function. The same formula is used for the NMSIMP technique, but $\boldsymbol{\beta}^{(k)}$ is defined as the vertex that has the lowest function value and $\boldsymbol{\beta}^{(k-1)}$ is defined as the vertex that has the highest function value in the simplex. PROC NLMOD provides an optional integer value *n*, which specifies the number of successive iterations for which the criterion must be satisfied before the process can be terminated. By default, ABSFCONV=0.

ABSGCONV=*r* **<** *n* **>**

ABSGTOL=*r* **<** *n* **>**

specifies an absolute gradient convergence criterion. Termination requires the maximum absolute gradient element to be small:

$$\max_j |g_j(\boldsymbol{\beta}^{(k)})| \leq r$$

Here, $\boldsymbol{\beta}$ is the vector of parameters in the optimization and $g_j(\cdot)$ is the gradient of the objective function with respect to the jth parameter. This criterion is not used by the NMSIMP technique. PROC NLMOD provides an optional integer value *n*, which specifies the number of successive iterations for which the criterion must be satisfied before the process can be terminated. By default, ABSGCONV=1E–5.

ABSXCONV=*r* < *n* >

ABSXTOL=*r* < *n* >

specifies an absolute parameter convergence criterion: For all techniques except NMSIMP, termination requires a small Euclidean distance between successive parameter vectors,

$$\| \boldsymbol{\beta}^{(k)} - \boldsymbol{\beta}^{(k-1)} \|_2 \leq r$$

For the NMSIMP technique, termination requires either a small length $\alpha^{(k)}$ of the vertices of a restart simplex,

$$\alpha^{(k)} \leq r$$

or a small simplex size,

$$\delta^{(k)} \leq r$$

where the simplex size $\delta^{(k)}$ is defined as the L1 distance from the simplex vertex $\boldsymbol{\xi}^{(k)}$ that has the smallest function value to the other p simplex points $\boldsymbol{\beta}_l^{(k)} \neq \boldsymbol{\xi}^{(k)}$:

$$\delta^{(k)} = \sum_{\boldsymbol{\beta}_l \neq y} \| \boldsymbol{\beta}_l^{(k)} - \boldsymbol{\xi}^{(k)} \|_1$$

PROC NLMOD provides an optional integer value *n*, which specifies the number of successive iterations for which the criterion must be satisfied before the process can terminate. The default is r = 1E–8 for the NMSIMP technique and $r = 0$ otherwise.

CORRECTIONS=*m*

specifies the number of the stored quasi-Newton update histories, which is referred to as the number of corrections, for the LBFGS technique. The m value is usually set as small as 3. In general, larger values improve convergence speed and solution quality for the LBFGS technique. However, for many problems, after reaching a certain threshold, the improvement can stall and the memory usage and solver's per-iteration computation cost can increase. In practice, you can set high values for small or medium problems and small values for large problems. By default, CORRECTIONS=20.

FCONV=*r* < *n* >

FTOL=*r* < *n* >

specifies a relative function difference convergence criterion. For all techniques except NMSIMP, termination requires a small relative change of the function value in successive iterations,

$$\frac{|f(\boldsymbol{\beta}^{(k)}) - f(\boldsymbol{\beta}^{(k-1)})|}{|f(\boldsymbol{\beta}^{(k-1)})|} \leq r$$

Here, $\boldsymbol{\beta}$ denotes the vector of parameters that participate in the optimization, and $f(\cdot)$ is the objective function. The same formula is used for the NMSIMP technique, but $\boldsymbol{\beta}^{(k)}$ is defined as the vertex that has the lowest function value and $\boldsymbol{\beta}^{(k-1)}$ is defined as the vertex that has the highest function value in the simplex.

PROC NLMOD provides an optional integer value *n*, which specifies the number of successive iterations for which the criterion must be satisfied before the process can terminate. The default value is r=$2 \times \epsilon$ where ϵ is the machine precision, which is the smallest double-precision floating-point number such that $1 + \epsilon > 1$.

FCONV2=*r* **<** *n* **>**

FTOL2=*r* **<** *n* **>**

specifies a second function convergence criterion. For all techniques except NMSIMP, termination requires a small predicted reduction of the objective function:

$$df^{(k)} \approx f(\boldsymbol{\beta}^{(k)}) - f(\boldsymbol{\beta}^{(k)} + \mathrm{s}^{(k)})$$

The predicted reduction

$$\begin{aligned} df^{(k)} &= -\mathbf{g}^{(k)'}\mathrm{s}^{(k)} - \frac{1}{2}\mathrm{s}^{(k)'}\mathbf{H}^{(k)}\mathrm{s}^{(k)} \\ &= -\frac{1}{2}\mathrm{s}^{(k)'}\mathbf{g}^{(k)} \leq r \end{aligned}$$

is computed by approximating the objective function f by the first two terms of the Taylor series and substituting the Newton step,

$$\mathrm{s}^{(k)} = -[\mathbf{H}^{(k)}]^{-1}\mathbf{g}^{(k)}$$

For the NMSIMP technique, termination requires a small standard deviation of the function values of the $p+1$ simplex vertices $\boldsymbol{\beta}_l^{(k)}$, $l = 0, \ldots, p$,

$$\sqrt{\frac{1}{n+1}\sum_l \left[f(\boldsymbol{\beta}_l^{(k)}) - \overline{f}(\boldsymbol{\beta}^{(k)})\right]^2} \leq r$$

where $\overline{f}(\boldsymbol{\beta}^{(k)}) = \frac{1}{p+1}\sum_l f(\boldsymbol{\beta}_l^{(k)})$. If there are p_{act} boundary constraints active at $\boldsymbol{\beta}^{(k)}$, the mean and standard deviation are computed only for the $n + 1 - p_{act}$ unconstrained vertices.

PROC NLMOD provides an optional integer value *n*, which specifies the number of successive iterations for which the criterion must be satisfied before the process can terminate. The default value is *r* = 1E–6 for the NMSIMP technique and *r*= 0 otherwise.

GCONV=*r* **<** *n* **>**

GTOL=*r* **<** *n* **>**

specifies a relative gradient convergence criterion. For all techniques except CONGRA and NMSIMP, termination requires that the normalized predicted function reduction be small:

$$\frac{\mathrm{g}(\boldsymbol{\beta}^{(k)})'[\mathbf{H}^{(k)}]^{-1}\mathrm{g}(\boldsymbol{\beta}^{(k)})}{|f(\boldsymbol{\beta}^{(k)})|} \leq r$$

Here, $\boldsymbol{\beta}$ denotes the vector of parameters that participate in the optimization, $f(\cdot)$ is the objective function, and $\mathrm{g}(\cdot)$ is the gradient. For the CONGRA technique (where a reliable Hessian estimate $\mathbf{H}$ is not available), the following criterion is used:

$$\frac{\| \mathrm{g}(\boldsymbol{\beta}^{(k)}) \|_2^2 \quad \| \mathrm{s}(\boldsymbol{\beta}^{(k)}) \|_2}{\| \mathrm{g}(\boldsymbol{\beta}^{(k)}) - \mathrm{g}(\boldsymbol{\beta}^{(k-1)}) \|_2 \, |f(\boldsymbol{\beta}^{(k)})|} \leq r$$

This criterion is not used by the NMSIMP technique. PROC NLMOD provides an optional integer value *n*, which specifies the number of successive iterations for which the criterion must be satisfied before the process can terminate. By default, GCONV=1E–8.

GCONV2=*r* **<** *n* **>**

GTOL2=*r* **<** *n* **>**

specifies another relative gradient convergence criterion. For the TRUREG, LEVMAR, NRRIDG, and NEWRAP techniques, the following criterion of Browne (1982) is used:

$$\max_j \frac{|\mathbf{g}_j(\boldsymbol{\beta}^{(k)})|}{\sqrt{f(\boldsymbol{\beta}^{(k)})\mathbf{H}^{(k)}_{j,j}}} \leq r$$

This criterion is not used by the other techniques.

PROC NLMOD provides an optional integer value *n*, which specifies the number of successive iterations for which the criterion must be satisfied before the process can terminate. By default, GCONV2=0.

MAXFUNC=*n*

MAXFU=*n*

specifies the maximum number *n* of function calls in the optimization process. The default values are as follows, depending on the optimization technique:

- TRUREG, NRRIDG, and NEWRAP: 125
- QUANEW and DBLDOG: 500
- CONGRA: 1,000
- LBFGS: 2,000
- NMSIMP: 3,000

The optimization can terminate only after completing a full iteration. Therefore, the number of function calls that are actually performed can exceed the number that is specified by this option. You can specify the optimization technique in the TECHNIQUE= option.

MAXITER=*n*

MAXIT=*n*

specifies the maximum number *n* of iterations in the optimization process. The default values are as follows, depending on the optimization technique:

- TRUREG, NRRIDG, and NEWRAP: 50
- QUANEW and DBLDOG: 200
- CONGRA: 400
- LBFGS and NMSIMP: 1,000

These default values also apply when *n* is specified as a missing value. You can specify the optimization technique in the TECHNIQUE= option.

MAXTIME=*r*

specifies an upper limit of *r* seconds of CPU time for the optimization process. The time specified by *r* is checked only once at the end of each iteration. Therefore, the actual running time can be longer than *r*. The default value is the largest floating-point double representation of your computer.

MINITER=*n*

MINIT=*n*

specifies the minimum number of iterations. If you request more iterations than are actually needed for convergence to a stationary point, the optimization algorithms can behave strangely. For example, the effect of rounding errors can prevent the algorithm from continuing for the required number of iterations. By default, MINITER=0.

NORMALIZE=YES | NO

specifies whether the objective function should be normalized during the optimization by the reciprocal of the used frequency count. This option affects the values reported in the "Iteration History" table. The results reported in the "Fit Statistics" are always displayed for the nonnormalized log-likelihood function. The default is to normalize the objective function.

TECHNIQUE=*technique*

TECH=*technique*

specifies the optimization technique for obtaining maximum likelihood estimates. You can specify one of the following *techniques*:

CONGRA	performs a conjugate-gradient optimization.
DBLDOG	performs a version of double-dogleg optimization.
LBFGS	performs a limited-memory BFGS optimization.
LEVMAR	performs a Levenberg-Marquardt nonlinear least-squares minimization. This technique is available only with PROC NLMOD.
NEWRAP	performs a Newton-Raphson optimization with line search.
NMSIMP	performs a Nelder-Mead simplex optimization.
NONE	performs no optimization.
NRRIDG	performs a Newton-Raphson optimization with ridging.
QUANEW	performs a dual quasi-Newton optimization.
TRUREG	performs a trust-region optimization

By default, TECHNIQUE=NRRIDG.

For more information, see the section "Choosing an Optimization Algorithm" on page 103.

XCONV=*r*

XTOL=*r*

specifies the relative parameter convergence criterion. Convergence requires a small relative parameter change in subsequent iterations,

$$\max_j |\delta_j^{(i)}| < r$$

where

$$\delta_j^{(i)} = \begin{cases} \beta_j^{(i)} - \beta_j^{(i-1)} & |\beta_j^{(i-1)}| < 0.01 \\ \frac{\beta_j^{(i)} - \beta_j^{(i-1)}}{\beta_j^{(i-1)}} & \text{otherwise} \end{cases}$$

and $\beta_j^{(i)}$ is the estimate of the jth parameter at iteration i. For the NMSIMP technique, the same formula is used, but $\beta_j^{(k)}$ is defined as the vertex that has the lowest function value and $\beta_j^{(k-1)}$ is defined as the vertex that has the highest function value in the simplex. The default value is r = 1E–8 for the NMSIMP technique and $r = 0$ otherwise.

Details for SAS Visual Statistics Procedures

Levelization of Classification Variables

This section applies to the following procedures: GAMMOD, GAMSELECT, GENSELECT, LMIXED, LOGSELECT, MODELMATRIX, NLMOD, PHSELECT, PLSMOD, QTRSELECT, REGSELECT, SANDWICH, and TREESPLIT.

A classification variable enters the statistical analysis or model not through its values but through its levels. The process of associating values of a variable with levels is called *levelization*.

During the process of levelization, observations that share the same value are assigned to the same level. The manner in which values are grouped can be affected by the inclusion of formats. The sort order of the levels can be determined by specifying the ORDER= option in the procedure statement. In procedures in this book, you can also control the sorting order separately for each variable in the CLASS statement.

Consider the data on nine observations in Table 2.12. The variable A is integer-valued, and the variable X is a continuous variable that has a missing value for the fourth observation. The fourth and fifth columns of Table 2.12 apply two different formats to the variable X.

Table 2.12 Example Data for Levelization

Obs	A	x	FORMAT x 3.0	FORMAT x 3.1
1	2	1.09	1	1.1
2	2	1.13	1	1.1
3	2	1.27	1	1.3
4	3	.	.	.
5	3	2.26	2	2.3
6	3	2.48	2	2.5
7	4	3.34	3	3.3
8	4	3.34	3	3.3
9	4	3.14	3	3.1

By default, levelization of the variables groups the observations by the formatted value of the variable, except for numerical variables for which no explicit format is provided. Numerical variables for which no explicit format is provided are sorted by their internal value. The levelization of the four columns in Table 2.12 leads to the level assignment in Table 2.13.

Table 2.13 Values and Levels

	A		X		FORMAT x 3.0		FORMAT x 3.1	
Obs	**Value**	**Level**	**Value**	**Level**	**Value**	**Level**	**Value**	**Level**
1	2	1	1.09	1	1	1	1.1	1
2	2	1	1.13	2	1	1	1.1	1
3	2	1	1.27	3	1	1	1.3	2
4	3	2	.	.	.	.	.	.
5	3	2	2.26	4	2	2	2.3	3
6	3	2	2.48	5	2	2	2.5	4
7	4	3	3.34	7	3	3	3.3	6
8	4	3	3.34	7	3	3	3.3	6
9	4	3	3.14	6	3	3	3.1	5

The sort order for the levels of CLASS variables can be specified in the ORDER= option in the CLASS statement.

When ORDER=FORMATTED (which is the default) is in effect for numeric variables for which you have supplied no explicit format, the levels are ordered by their internal values. To order numeric classification levels that have no explicit format by their BEST12. formatted values, you can specify the BEST12. format explicitly for the CLASS variables.

Table 2.14 shows how values of the ORDER= option are interpreted.

Table 2.14 Interpretation of Values of ORDER= Option

Value of ORDER=	Levels Sorted By
FORMATTED	External formatted value, except for numeric variables that have no explicit format, which are sorted by their unformatted (internal) value. The sort order is machine-dependent.
FREQ	Descending frequency count (levels that have the most observations come first in the order)
INTERNAL	Unformatted value. The sort order is machine-dependent.

For more information about sort order, see the chapter about the SORT procedure in the *Base SAS Procedures Guide* and the discussion of BY-group processing in the "Grouping Data" section of *SAS Programmers Guide: Essentials*.

When the MISSING option is specified in the CLASS statement, the missing values ('.' for a numeric variable and blanks for a character variable) are included in the levelization and are assigned a level. Table 2.15

displays the results of levelizing the values in Table 2.12 when the MISSING option is in effect.

Table 2.15 Values and Levels When the MISSING Option Is Specified

	A		X		FORMAT x 3.0		FORMAT x 3.1	
Obs	Value	Level	Value	Level	Value	Level	Value	Level
1	2	1	1.09	2	1	2	1.1	2
2	2	1	1.13	3	1	2	1.1	2
3	2	1	1.27	4	1	2	1.3	3
4	3	2	.	1	.	1	.	1
5	3	2	2.26	5	2	3	2.3	4
6	3	2	2.48	6	2	3	2.5	5
7	4	3	3.34	8	3	4	3.3	7
8	4	3	3.34	8	3	4	3.3	7
9	4	3	3.14	7	3	4	3.1	6

When the MISSING option is not specified, it is important to understand the implications of missing values for your statistical analysis. When a procedure in this book levelizes the CLASS variables, an observation for which any CLASS variable has a missing value is excluded from the analysis.

Procedures in this book print a "Number of Observations" table that shows the number of observations that are read from the data set and the number of observations that are used in the analysis. Pay careful attention to this table—especially when your data table contains missing values—to ensure that no observations are unintentionally excluded from the analysis.

Specification and Parameterization of Model Effects

This section applies to the following procedures: GAMMOD, GAMSELECT, GENSELECT, LMIXED, LOGSELECT, MODELMATRIX, NLMOD, PHSELECT, PLSMOD, QTRSELECT, REGSELECT, and SANDWICH.

Procedures in this book that have a MODEL statement support the formation of effects. An *effect* is an element in a linear model structure that is formed from one or more variables. At some point the statistical representations of these models involve linear structures such as

$$\mathbf{X}\boldsymbol{\beta}$$

or

$$\mathbf{X}\boldsymbol{\beta} + \mathbf{Z}\boldsymbol{\gamma}$$

The model matrices $\mathbf{X}$ and $\mathbf{Z}$ are formed according to effect-construction rules.

Procedures that also have a CLASS statement support the rich set of effects that is discussed in this section.

Procedures that also have an EFFECT statement enable you to construct special *constructed* effects that are discussed in "EFFECT Statement" on page 18.

In order to correctly interpret the results from a statistical analysis, you need to understand how construction (*parameterization*) rules apply to regression-type models, whether these are linear models as in the REGSELECT procedure or generalized linear models as in the LOGSELECT and GENSELECT procedures.

Effects are specified by a special notation that uses variable names and operators. There are two types of variables: classification (or CLASS) variables and continuous variables. *Classification variables* can be either numeric or character and are specified in a CLASS statement. For more information, see the section "Levelization of Classification Variables" on page 62. An independent variable that is not declared in the CLASS statement is assumed to be *continuous*. For example, the heights and weights of subjects are continuous variables.

Two primary operators (crossing and nesting) are used for combining the variables, and several additional operators are used to simplify effect specification. Operators are discussed in the section "Effect Operators" on page 65.

Procedures in this book that have a CLASS statement support a general linear model (GLM) parameterization and might also support nonsingular parameterizations for the classification variables. The GLM parameterization, commonly called *dummy* parameterization, is the default for all procedures in this book. For more information, see the sections "GLM Parameterization of Classification Variables and Effects" on page 67 and "Nonsingular Parameterization" on page 71.

Effect Operators

Table 2.16 summarizes the operators that are available for selecting and constructing effects. These operators are discussed in the following sections.

Table 2.16 Available Effect Operators

Operator	Example	Description
Interaction	A*B	Crosses the levels of the effects
Nesting	A(B)	Nests A levels within B levels
Bar operator	A | B | C	Specifies all interactions
At sign operator	A | B | C@2	Reduces interactions in bar effects
Dash operator	A1-A10	Specifies sequentially numbered variables
Colon operator	A:	Specifies variables with common prefix
Double dash operator	A- -C	Specifies sequential variables in data set order

Bar and At Sign Operators

You can shorten the specification of a large factorial model by using the bar operator. For example, two ways of writing the model for a full three-way factorial model follow:

```
model Y = A B C   A*B A*C B*C   A*B*C;

model Y = A|B|C;
```

When the bar (|) is used, the right and left sides become effects, and the cross of them becomes an effect. Multiple bars are permitted. The expressions are expanded from left to right, using rules 2–4 in Searle (1971, p. 390).

- Multiple bars are evaluated from left to right. For example, A | B | C is evaluated as follows:

$$\begin{aligned} \text{A | B | C} &\rightarrow \{\text{ A | B }\}\text{ | C} \\ &\rightarrow \{\text{ A B A*B }\}\text{ | C} \\ &\rightarrow \text{A B A*B C A*C B*C A*B*C} \end{aligned}$$

- Crossed and nested groups of variables are combined. For example, A(B) | C(D) generates A*C(B D), among other terms.
- Duplicate variables are removed. For example, A(C) | B(C) generates A*B(C C), among other terms, and the extra C is removed.
- Effects are discarded if a variable occurs on both the crossed and nested parts of an effect. For example, A(B) | B(D E) generates A*B(B D E), but this effect is eliminated immediately.

You can also specify the maximum number of variables involved in any effect that results from bar evaluation by specifying that maximum number, preceded by an at sign (@), at the end of the bar effect. For example, the following specification selects only those effects that contain two or fewer variables:

```
model Y = A|B|C@2;
```

The preceding example is equivalent to specifying the following MODEL statement:

```
model Y = A B C   A*B A*C B*C;
```

More examples of using the bar and at operators follow:

A | C(B)	is equivalent to	A C(B) A*C(B)
A(B) | C(B)	is equivalent to	A(B) C(B) A*C(B)
A(B) | B(D E)	is equivalent to	A(B) B(D E)
A | B(A) | C	is equivalent to	A B(A) C A*C B*C(A)
A | B(A) | C@2	is equivalent to	A B(A) C A*C
A | B | C | D@2	is equivalent to	A B A*B C A*C B*C D A*D B*D C*D
A*B(C*D)	is equivalent to	A*B(C D)

Colon, Dash, and Double Dash Operators

You can simplify the specification of a large model when some of your variables have a common prefix by using the colon (:) operator and the dash (-) operator. The dash operator enables you to list variables that are numbered sequentially, and the colon operator selects all variables with a given prefix. For example, if your data set contains the variables X1 through X9, the following MODEL statements are equivalent:

```
model Y = X1 X2 X3 X4 X5 X6 X7 X8 X9;

model Y = X1-X9;

model Y = X:;
```

If your data set contains only the three covariates X1, X2, and X9, then the colon operator selects all three variables:

```
model Y = X:;
```

However, the following specification returns an error because X3 through X8 are not in the data set:

```
model Y = X1-X9;
```

The double dash (--) operator enables you to select variables that are stored sequentially in the SAS data set, whether or not they have a common prefix. You can use the CONTENTS procedure (see *Base SAS Procedures Guide*) to determine your variable ordering. For example, if you replace the dash in the preceding MODEL statement with a double dash, as follows, then all three variables are selected:

```
model Y = X1--X9;
```

If your data set contains the variables A, B, and C, then you can use the double dash operator to select these variables by specifying the following:

```
model Y = A--C;
```

GLM Parameterization of Classification Variables and Effects

Table 2.17 shows the types of effects that are available in procedures in this book; they are discussed in more detail in the following subsections. Let A, B, and C represent classification variables, and let X and Z represent continuous variables.

Table 2.17 Available Types of Effects

Effect	Example	Description
Intercept	Default	Intercept (unless the NOINT option is specified)
Regression	X Z	Continuous variables
Polynomial	X*Z	Interaction of continuous variables
Main	A B	CLASS variables
Interaction	A*B	Crossing of CLASS variables
Nested	A(B)	Main effect A nested within CLASS effect B
Continuous-by-class	X*A	Crossing of continuous and CLASS variables
Continuous-nesting-class	X(A)	Continuous variable X1 nested within CLASS variable A
General	X*Z*A(B)	Combinations of different types of effects

Table 2.18 shows some examples of MODEL statements that use various types of effects.

Table 2.18 MODEL Statement Effect Examples

Specification	Type of Model
`model Y=X;`	Simple regression
`model Y=X Z;`	Multiple regression
`model Y=X X*X;`	Polynomial regression
`model Y=A;`	One-way analysis of variance (ANOVA)
`model Y=A B C;`	Main-effects ANOVA
`model Y=A B A*B;`	Factorial ANOVA with interaction
`model y=A B(A) C(B A);`	Nested ANOVA

Table 2.18 *continued*

Specification	Type of Model
`model Y=A X;`	Analysis of covariance (ANCOVA)
`model Y=A X(A);`	Separate-slopes regression
`model Y=A X X*A;`	Homogeneity-of-slopes regression

Intercept

By default, linear models that are created by procedures in this book automatically include a column of 1s in **X**. This column corresponds to an intercept parameter. In many procedures, you can use the NOINT option in the MODEL statement to suppress this intercept. For example, the NOINT option is useful when the MODEL statement contains a classification effect and you want the parameter estimates to be in terms of the mean response for each level of that effect.

Regression Effects

Numeric variables or polynomial terms that involve them can be included in the model as regression effects (covariates). The actual values of such terms are included as columns of the relevant model matrices. You can use the bar operator along with a regression effect to generate polynomial effects. For example, X | X | X expands to X X*X X*X*X, which is a cubic model.

Main Effects

If a classification variable has m levels, the GLM parameterization generates m columns for its main effect in the model matrix. Each column is an indicator variable for a particular level. The order of the columns is the sort order of the values of their levels and can be controlled by the ORDER= option in the CLASS statement.

Table 2.19 is an example where β_0 denotes the intercept and A and B are classification variables that have two and three levels, respectively.

Table 2.19 Example of Main Effects

Data		I	A		B		
A	B	β_0	A1	A2	B1	B2	B3
1	1	1	1	0	1	0	0
1	2	1	1	0	0	1	0
1	3	1	1	0	0	0	1
2	1	1	0	1	1	0	0
2	2	1	0	1	0	1	0
2	3	1	0	1	0	0	1

There are usually more columns for these effects than there are degrees of freedom to estimate them. In other words, the GLM parameterization of main effects is *singular*.

Interaction Effects

Often a model includes interaction (crossed) effects to account for how the effect of a variable changes along with the values of other variables. With an interaction, the terms are first reordered to correspond to the order of the variables in the CLASS statement. Thus, B*A becomes A*B if A precedes B in the CLASS statement. Then, the GLM parameterization generates columns for all combinations of levels that occur in the data. The order of the columns is such that the rightmost variables in the interaction change faster than the leftmost variables (Table 2.20).

Table 2.20 Example of Interaction Effects

Data		I	A		B			A*B					
A	B	β_0	A1	A2	B1	B2	B3	A1B1	A1B2	A1B3	A2B1	A2B2	A2B3
1	1	1	1	0	1	0	0	1	0	0	0	0	0
1	2	1	1	0	0	1	0	0	1	0	0	0	0
1	3	1	1	0	0	0	1	0	0	1	0	0	0
2	1	1	0	1	1	0	0	0	0	0	1	0	0
2	2	1	0	1	0	1	0	0	0	0	0	1	0
2	3	1	0	1	0	0	1	0	0	0	0	0	1

In the preceding matrix, main-effects columns are not linearly independent of crossed-effects columns. In fact, the column space for the crossed effects contains the space of the main effect.

When your model contains many interaction effects, you might be able to code them more parsimoniously by using the bar operator (|). The bar operator generates all possible interaction effects. For example, A | B | C expands to A B A*B C A*C B*C A*B*C. To eliminate higher-order interaction effects, use the at sign (@) in conjunction with the bar operator. For example, A | B | C | D@2 expands to A B A*B C A*C B*C D A*D B*D C*D.

Nested Effects

Nested effects are generated in the same manner as crossed effects. Hence, the design columns that are generated by the following two statements are the same (but the ordering of the columns is different):

```
model Y=A B(A);

model Y=A A*B;
```

The nesting operator in procedures in this book is more of a notational convenience than an operation that is distinct from crossing. Nested effects are typically characterized by the property that the nested variables do not appear as main effects. The order of the variables within nesting parentheses is made to correspond to the order of these variables in the CLASS statement. The order of the columns is such that variables outside the parentheses index faster than those inside the parentheses, and the rightmost nested variables index faster than the leftmost variables (Table 2.21).

Table 2.21 Example of Nested Effects

Data		I	A		B(A)					
A	B	β_0	A1	A2	B1A1	B2A1	B3A1	B1A2	B2A2	B3A2
1	1	1	1	0	1	0	0	0	0	0

Table 2.21 *continued*

Data		I	A		B(A)				
1	2	1	1	0	0	1	0	0	0
1	3	1	1	0	0	0	1	0	0
2	1	1	0	1	0	0	0	1	0
2	2	1	0	1	0	0	0	0	1
2	3	1	0	1	0	0	0	0	1

Continuous-Nesting-Class Effects

When a continuous variable nests or crosses with a classification variable, the design columns are constructed by multiplying the continuous values into the design columns for the classification effect (Table 2.22).

Table 2.22 Example of Continuous-Nesting-Class Effects

Data		I	A		X(A)	
X	A	β_0	A1	A2	X(A1)	X(A2)
21	1	1	1	0	21	0
24	1	1	1	0	24	0
22	1	1	1	0	22	0
28	2	1	0	1	0	28
19	2	1	0	1	0	19
23	2	1	0	1	0	23

This model estimates a separate intercept and a separate slope for X within each level of A.

Continuous-by-Class Effects

Continuous-by-class effects generate the same design columns as continuous-nesting-class effects. Table 2.23 shows the construction of the X*A effect. The two columns for this effect are the same as the columns for the X(A) effect in Table 2.22.

Table 2.23 Example of Continuous-by-Class Effects

Data		I	X	A		X*A	
X	A	β_0	X	A1	A2	X*A1	X*A2
21	1	1	21	1	0	21	0
24	1	1	24	1	0	24	0
22	1	1	22	1	0	22	0
28	2	1	28	0	1	0	28
19	2	1	19	0	1	0	19
23	2	1	23	0	1	0	23

You can use continuous-by-class effects together with pure continuous effects to test for homogeneity of slopes.

General Effects

An example that combines all the effects is X1*X2*A*B*C(D E). The continuous list comes first, followed by the crossed list, followed by the nested list in parentheses.

Effects might be renamed by the procedure to correspond to ordering rules. For example, B*A(E D) might be renamed A*B(D E) to satisfy the following:

- Classification variables that occur outside parentheses (crossed effects) are sorted in the order in which they appear in the CLASS statement.
- Variables within parentheses (nested effects) are sorted in the order in which they appear in the CLASS statement.

The sequencing of the parameters that are generated by an effect is determined by the variables whose levels are indexed faster:

- Variables in the crossed list index faster than variables in the nested list.
- Within a crossed or nested list, variables to the right index faster than variables to the left.

For example, suppose that a model includes four effects—A, B, C, and D—each having two levels, 1 and 2, and that the CLASS statement is as follows:

```
class A B C D;
```

Then the order of the parameters for the effect B*A(C D), which is renamed A*B(C D), is as follows:

$$
\begin{array}{llll}
A_1B_1C_1D_1 \rightarrow & A_1B_2C_1D_1 \rightarrow & A_2B_1C_1D_1 \rightarrow & A_2B_2C_1D_1 \rightarrow \\
A_1B_1C_1D_2 \rightarrow & A_1B_2C_1D_2 \rightarrow & A_2B_1C_1D_2 \rightarrow & A_2B_2C_1D_2 \rightarrow \\
A_1B_1C_2D_1 \rightarrow & A_1B_2C_2D_1 \rightarrow & A_2B_1C_2D_1 \rightarrow & A_2B_2C_2D_1 \rightarrow \\
A_1B_1C_2D_2 \rightarrow & A_1B_2C_2D_2 \rightarrow & A_2B_1C_2D_2 \rightarrow & A_2B_2C_2D_2
\end{array}
$$

Note that first the crossed effects B and A are sorted in the order in which they appear in the CLASS statement so that A precedes B in the parameter list. Then, for each combination of the nested effects in turn, combinations of A and B appear. The B effect changes fastest because it is rightmost in the cross list. Then A changes next fastest, and D changes next fastest. The C effect changes most slowly because it is leftmost in the nested list.

Nonsingular Parameterization

When a parameterization of main effects provides the same number of columns for the effects as there are degrees of freedom to estimate them, the parameterization is called *nonsingular*. A variety of nonsingular parameterizations for classification effects are available for many procedures in this book. In most of these procedures you use the PARAM= option in the CLASS statement to specify the parameterization.

Consider a model with one CLASS variable A that has four levels, 1, 2, 5, and 7. Details of the possible choices for the PARAM= option follow.

REFERENCE Three columns are created to indicate group membership of the nonreference levels. For the reference level, all three dummy variables have a value of 0. For example, if the reference level is 7 (REF=7), the design matrix columns for A are as follows.

Reference Coding			
	Design Matrix		
A	A1	A2	A5
1	1	0	0
2	0	1	0
5	0	0	1
7	0	0	0

Parameter estimates of CLASS main effects that use the reference coding scheme estimate the difference in the effect of each nonreference level compared to the effect of the reference level.

EFFECT Three columns are created to indicate group membership of the nonreference levels. For the reference level, all three dummy variables have a value of –1. For example, if the reference level is 7 (REF=7), the design matrix columns for A are as follows.

Effect Coding			
	Design Matrix		
A	A1	A2	A5
1	1	0	0
2	0	1	0
5	0	0	1
7	–1	–1	–1

Parameter estimates of CLASS main effects that use the effect coding scheme estimate the difference in the effect of each nonreference level compared to the average effect over all four levels.

ORDINAL | THERMOMETER Three columns are created to indicate group membership of the higher levels of the effect. For the first level of the effect (which for A is 1), all three dummy variables have a value of 0. The design matrix columns for A are as follows.

Ordinal Coding			
	Design Matrix		
A	A2	A5	A7
1	0	0	0
2	1	0	0
5	1	1	0
7	1	1	1

The first level of the effect is a control or baseline level. Parameter estimates of CLASS main effects, using the ORDINAL coding scheme, estimate the differences

between effects of successive levels. When the parameters have the same sign, the effect is monotonic across the levels.

POLYNOMIAL | POLY Three columns are created. The first represents the linear term (x), the second represents the quadratic term (x^2), and the third represents the cubic term (x^3), where x is the level value. If the CLASS levels are not numeric, they are translated into 1, 2, 3, ... according to their sort order. The design matrix columns for A are as follows.

Polynomial Coding			
	Design Matrix		
A	APOLY1	APOLY2	APOLY3
1	1	1	1
2	2	4	8
5	5	25	125
7	7	49	343

ORTHEFFECT The columns are obtained by applying the Gram-Schmidt orthogonalization to the columns for PARAM=EFFECT. The design matrix columns for A are as follows.

Orthogonal Effect Coding			
	Design Matrix		
A	AOEFF1	AOEFF2	AOEFF3
1	1.41421	–0.81650	–0.57735
2	0	1.63299	–0.57735
5	0	0	1.73205
7	–1.41421	–0.81649	–0.57735

ORTHORDINAL | ORTHOTHERM The columns are obtained by applying the Gram-Schmidt orthogonalization to the columns for PARAM=ORDINAL. The design matrix columns for A are as follows.

Orthogonal Ordinal Coding			
	Design Matrix		
A	AOORD1	AOORD2	AOORD3
1	–1.73205	0	0
2	0.57735	–1.63299	0
5	0.57735	0.81650	–1.41421
7	0.57735	0.81650	1.41421

ORTHPOLY The columns are obtained by applying the Gram-Schmidt orthogonalization to the columns for PARAM=POLY. The design matrix columns for A are as follows.

Orthogonal Polynomial Coding			
	Design Matrix		
A	AOPOLY1	AOPOLY2	AOPOLY5
1	–1.15311	0.90712	–0.92058
2	–0.73380	–0.54041	1.47292
5	0.52414	–1.37034	–0.92058
7	1.36277	1.00363	0.36823

ORTHREF

The columns are obtained by applying the Gram-Schmidt orthogonalization to the columns for PARAM=REFERENCE. The design matrix columns for A are as follows.

Orthogonal Reference Coding			
	Design Matrix		
A	AOREF1	AOREF2	AOREF3
1	1.73205	0	0
2	–0.57735	1.63299	0
5	–0.57735	–0.81650	1.41421
7	–0.57735	–0.81650	–1.41421

Class Variable Parameterization with Unbalanced Designs

Procedures in this book initially parameterize the CLASS variables by looking at the levels of the variables across the complete data set. If you have an *unbalanced* replication of levels across variables or BY groups, then the design matrix and the parameter interpretation might be different from what you expect. For example, suppose you have a model that has one CLASS variable A with three levels (1, 2, and 3), and another CLASS variable B with two levels (1 and 2). If the third level of A occurs only with the first level of B, if you use the EFFECT parameterization, and if your model contains the effect A(B) and an intercept, then the design for A within the second level of B is not a differential effect. In particular, the design looks like the following:

		Design Matrix			
		A(B=1)		A(B=2)	
B	A	A1	A2	A1	A2
1	1	1	0	0	0
1	2	0	1	0	0
1	3	–1	–1	0	0
2	1	0	0	1	0
2	2	0	0	0	1

Procedures in this book detect linear dependency among the last two design variables and set the parameter for A2(B=2) to 0, resulting in an interpretation of these parameters as if they were reference- or dummy-coded. The REFERENCE or GLM parameterization might be more appropriate for such problems.

Model Selection Methods

The model selection methods are specified in the METHOD= option in the SELECTION statement. The following methods are available, although specific procedures might support only a subset of these methods. Furthermore, the examples in this section refer to fit criteria that might not be supported by a specific procedure.

Full Model Fitted

When METHOD=NONE, the complete model that is specified in the MODEL statement is used to fit the model, and no effect selection is done.

Forward Selection

This section applies to the following procedures: GENSELECT, LOGSELECT, PHSELECT, QTRSELECT, and REGSELECT.

METHOD=FORWARD specifies the forward selection technique, which begins with just the intercept and then sequentially adds the effect that most improves the fit. The process terminates when no significant improvement can be obtained by adding any effect.

In the traditional implementation of forward selection, the statistic that is used to determine whether to add an effect is the significance level of a hypothesis test that reflects an effect's contribution to the model if it is included. At each step, the effect that is most significant is added. The process stops when the significance level for adding any effect is greater than some specified entry significance level.

An alternative approach to address the critical problem of when to stop the selection process is to assess the quality of the models that are produced by the forward selection method and choose the model from this sequence that "best" balances goodness of fit against model complexity. You can use several criteria for this purpose.

It is important to keep in mind that forward selection bases the decision about what effect to add at any step by considering models that differ by one effect from the current model. This search paradigm cannot guarantee reaching a "best" subset model. Furthermore, the add decision is greedy in the sense that the effect that is deemed most significant is the effect that is added. However, if your goal is to find a model that is best in terms of some selection criterion other than the significance level of the entering effect, then even this one step choice might not be optimal. For example, the effect that you would add to get a model that has the smallest value of the Mallows' $C(p)$ statistic at the next step is not necessarily the same effect that is most significant based on a hypothesis test. You can specify the criterion to optimize at each step by using the SELECT= option. For example, the following statement requests that at each step the effect that is added be the one that produces a model that has the smallest value of the Mallows' $C(p)$ statistic:

```
selection method=forward(select=CP);
```

When all effects are variables (that is, effects have one degree of freedom and no hierarchy), using ADJRSQ, AIC, AICC, BIC, CP, RSQUARE, or SBC as the selection criterion for forward selection produces the same sequence of additions. However, if the degrees of freedom contributed by different effects are not constant

or if an out-of-sample prediction-based criterion is used, then different sequences of additions might be obtained.

If you specify only the SELECT= criterion, then this criterion is also used to decide when to stop the selection process. In the previous example, not only do effects enter based on the Mallows' $C(p)$ statistic, but the selection terminates when the $C(p)$ statistic has a local minimum.

You use the CHOOSE= option to specify the criterion for selecting one model from the sequence of models produced. If you do not specify a CHOOSE= criterion, then the model at the final step is the selected model.

For example, if you specify the following statement, then forward selection terminates at the step where no effect can be added at the 0.2 significance level:

```
selection method=forward(select=SL choose=AIC SLE=0.2);
```

However, the selected model is the first one that has the minimum value of Akaike's information criterion. In some cases, this minimum value might occur at a step much earlier than the final step. In other cases, the AIC might start increasing only if more steps are performed—that is, a larger value is used for the significance level for entry. If you want to minimize AIC, then too many steps are performed in the former case and too few in the latter case. To address this issue, you can use the STOP= option to specify a stopping criterion. When you specify a stopping criterion, forward selection continues until a local extremum of the stopping criterion in the sequence of models generated is reached. To be deemed a local extremum, a criterion value at a particular step must be better than its value at the next n steps, where n is known as the "stop horizon." By default, the stop horizon is three steps, but you can change this by specifying the STOPHORIZON= option.

For example, if you specify the following statement, then forward selection terminates at the step where the effect to be added at the next step would produce a model that has an AIC statistic larger than the AIC statistic of the current model:

```
selection method=forward(select=SL stop=AIC) stophorizon=1;
```

In most cases, provided that the entry significance level is large enough that the local extremum of the named criterion occurs before the final step, specifying either of the following statements selects the same model, but more steps are done in the first case:

```
selection method=forward(select=SL choose=CRITERION);
selection method=forward(select=SL stop=CRITERION);
```

In some cases, there might be a better local extremum that cannot be reached if you specify the STOP= option but can be found if you use the CHOOSE= option. Also, you can use the CHOOSE= option in preference to the STOP= option if you want to examine how the named criterion behaves as you move beyond the step where the first local minimum of this criterion occurs.

You can specify both the CHOOSE= and STOP= options. You can also use these options together with options that specify size-based limits on the selected model. You might want to consider models that are generated by forward selection and have at most some fixed number of effects, but select from within this set based on a criterion that you specify. For example, specifying the following statements requests that forward selection continue until there are 20 effects in the final model and chooses among the sequence of models the one that has the largest value of the adjusted R-square statistic:

```
selection method=forward(stop=none maxeffects=20 choose=ADJRSQ);
```

You can also combine these options to select a model where one of two conditions is met. For example, the following statement chooses whatever occurs first between a local minimum of the sum of squares on validation data and a local minimum of the corrected Akaike's information criterion (AICC):

```
selection method=forward(stop=AICC choose=VALIDATE);
```

You can find discussion and references to studies about criteria for variable selection in Burnham and Anderson (2002), along with some cautions and recommendations.

Examples of Forward Selection Specifications

The following statement adds effects that at each step produce the lowest value of the SBC statistic and stops at the step where adding any effect would increase the SBC statistic:

```
selection method=forward stophorizon=1;
```

The following statement adds effects based on significance level and stops when all candidate effects for entry at a step have a significance level greater than the default entry significance level of 0.05:

```
selection=forward(select=SL);
```

The following statement adds effects based on significance level and stops at a step where adding any effect increases the error sum of squares computed on the validation data:

```
selection=forward(select=SL stop=validation) stophorizon=1;
```

The following statement adds effects that at each step produce the lowest value of the AIC statistic and stops at the first step whose AIC value is smaller than the AIC value at the next three steps:

```
selection=forward(select=AIC);
```

The following statement adds effects that at each step produce the largest value of the adjusted R-square statistic and stops at the step where the significance level that corresponds to the addition of this effect is greater than 0.2:

```
selection=forward(select=ADJRSQ stop=SL SLE=0.2);
```

Backward Elimination

This section applies to the following procedures: GENSELECT, LOGSELECT, PHSELECT, QTRSELECT, and REGSELECT.

METHOD=BACKWARD specifies the backward elimination technique. This technique starts from the full model, which includes all independent effects. Then effects are deleted one by one until a stopping condition is satisfied. At each step, the effect that shows the smallest contribution to the model is deleted.

In the traditional implementation of backward selection, the statistic that is used to determine whether to drop an effect is significance level. At any step, the least significant predictor is dropped and the process continues until all effects that remain in the model are significant at a specified stay significance level (SLS).

Just as with forward selection, you can use the SELECT= option to change the criterion that is used to assess effect contributions. You can also specify a stopping criterion in the STOP= option and use a CHOOSE=

option to provide a criterion for selecting among the sequence of models produced. For more information, see the discussion in the section "Forward Selection" on page 75.

Examples of Backward Selection Specifications

The following statement removes effects that at each step produce the largest value of the Schwarz Bayesian information criterion (SBC) statistic and stops at the step where removing any effect increases the SBC statistic:

```
selection method=backward stophorizon=1;
```

The following statement bases removal of effects on the corrected Akaike's information criterion (AICC) and stops at the first step whose AICC value is smaller than the AICC value at the next three steps:

```
selection method=backward(select=AICC);
```

The following statement bases removal of effects on significance level and stops when all candidate effects for removal at a step are significant at the default stay significance level of 0.05:

```
selection method=backward(select=SL);
```

The following statement bases removal of effects on significance level and stops when all effects in the model are significant at the 0.1 level. Finally, from the sequence of models generated, the chosen model is the one that produces the smallest average square error when scored on the validation data:

```
selection method=backward(select=SL choose=VALIDATE SLS=0.1);
```

The following statement applies in logistic regression models the fast backward technique of Lawless and Singhal (1978), a first-order approximation that has greater numerical efficiency than full backward selection:

```
selection method=backward(fast);
```

The fast technique fits an initial full logistic model and a reduced model after the candidate effects have been dropped. On the other hand, full backward selection fits a logistic regression model each time an effect is removed from the model.

Stepwise Selection

This section applies to the following procedures: GENSELECT, LOGSELECT, PHSELECT, QTRSELECT, and REGSELECT.

METHOD=STEPWISE specifies the stepwise method, which modifies the forward selection technique by allowing effects already in the model to be removed.

In the traditional implementation of stepwise selection method, the same entry and removal significance levels for the forward selection and backward elimination methods are used to assess contributions of effects as they are added to or removed from a model. If, at a step of the stepwise method, any effect in the model is not significant at the SLSTAY= level, then the least significant of these effects is removed from the model and the algorithm proceeds to the next step. This ensures that no effect can be added to a model while some effect currently in the model is not deemed significant. Another effect can be added to the model only after all necessary deletions have been accomplished. In this case the effect whose addition is the most significant

is added to the model and the algorithm proceeds to the next step. The stepwise process ends when none of the effects outside the model is significant at the SLENTRY= level and every effect in the model is significant at the SLSTAY= level. In some cases, neither of these two conditions for stopping is met and the sequence of models cycles. In this case, the stepwise method terminates at the end of the cycle.

Just as you can in forward selection and backward elimination, you can use the SELECT= option to change the criterion that is used to assess effect contributions. You can also use the STOP= option to specify a stopping criterion and use a CHOOSE= option to provide a criterion for selecting among the sequence of models produced. For more information, see the section "Forward Selection" on page 75.

For selection criteria other than the significance level, further modification to the stepwise method is supported. In the standard stepwise method, no effect can enter the model if removing any effect currently in the model would yield an improved value of the selection criterion. In the modification, you can use the COMPETITIVE option to specify that addition and deletion of effects should be treated competitively. The selection criterion is evaluated for all models that are produced by deleting an effect from the current model or by adding an effect to this model. The action that most improves the selection criterion is the action taken.

Examples of Stepwise Selection Specifications

The following statement requests stepwise selection based on the SBC criterion:

```
selection method=stepwise;
```

First, if removing any effect yields a model that has a lower SBC statistic than the current model, then the effect that produces the smallest SBC statistic is removed. If removing any effect increases the SBC statistic, then provided that adding some effect lowers the SBC statistic, the effect that produces the model that has the lowest SBC is added.

The following statement requests the traditional stepwise method:

```
selection=stepwise(select=SL)
```

First, if the removal of any effect in the model is not significant at the default stay level of 0.05, then the least significant effect is removed and the algorithm proceeds to the next step. Otherwise, the effect whose addition is the most significant is added, provided that it is significant at the default entry level of 0.05.

The following statement requests the traditional stepwise method, where effects enter and leave based on significance levels, but with the following extra check: if any effect to be added or removed yields a model whose SBC statistic is greater than the SBC statistic of the current model, then the stepwise method terminates at the current model.

```
selection method=stepwise(select=SL stop=SBC) stophorizon=1;
```

In this case, the entry and stay significance levels still play a role because they determine whether an effect is deleted from or added to the model. This extra check might result in the selection terminating before a local minimum of the SBC criterion is found.

The following statement selects effects to enter or drop as in the previous example except that the significance level for entry is now 0.1 and the significance level to stay is 0.08. From the sequence of models produced, the selected model is chosen to yield the minimum AIC statistic:

```
selection method=stepwise(select=SL SLE=0.1 SLS=0.08 choose=AIC);
```

The following statement requests stepwise selection that is based on the AICC criterion and treats additions and deletions competitively:

```
selection method=stepwise(select=AICC competitive);
```

Each step evaluates the AICC statistics that correspond to the removal of any effect in the current model or the addition of any effect to the current model and chooses the addition or removal that produced the minimum value, provided that this minimum is lower than the AICC statistic of the current model.

The following statement requests stepwise selection that is based on the SBC criterion, treats additions and deletions competitively, and stops based on the average square error over the validation data:

```
selection=stepwise(select=SBC competitive stop=VALIDATE);
```

At any step, SBC statistics that correspond to the removal of any effect from the current model or the addition of any effect to the current model are evaluated. The addition or removal that produces the minimum SBC value is made. The average square error on the validation data for the model with this addition or removal is evaluated. The selection stops when the average square error so produced increases for three consecutive steps.

Forward-Swap Selection

This section applies to the REGSELECT procedure.

METHOD=FORWARDSWAP specifies the forward-swap selection method, which is an extension of the forward selection method. The forward-swap selection method incorporates steps that improve a model by replacing an effect in the model with an effect that is not in the model. When the model selection criterion is R square, this method is the same as the maximum R-square improvement (MAXR) method that is implemented in the REG procedure in SAS/STAT software. You cannot use the effect significance level as the selection criterion for the forward-swap method.

The forward-swap selection method begins by finding the one-effect model that produces the best value of the selection criterion. Then another effect (the one that yields the greatest improvement in the selection criterion) is added. After the two-effect model is obtained, each of the effects in the model is compared to each effect that is not in the model. For each comparison, the forward-swap method determines whether removing one effect and replacing it with the other effect improves the selection criterion. After comparing all possible swaps, the forward-swap method makes the swap that produces the greatest improvement in the selection criterion. Comparisons begin again, and the process continues until the forward-swap method finds that no other swap could improve the selection criterion. Thus, the two-variable model that is produced is considered the “best” two-variable model that the technique can find. Another variable is then added to the model, and the comparing-and-swapping process is repeated to find the “best” three-variable model, and so on.

The difference between the stepwise selection method and the forward-swap selection method is that all swaps are evaluated before any addition is made in the forward-swap method. In the stepwise selection method, the “worst” effect might be removed without considering what adding the “best” remaining effects might accomplish. Because the forward-swap method needs to examine all possible pairwise effect swaps at

each step of the selection process, the forward-swap method is much more computationally expensive than the stepwise selection method; it might not be appropriate for models that contain a large number of effects.

Least Angle Regression

This section applies to the REGSELECT procedure.

METHOD=LAR specifies least angle regression (LAR), which was introduced by Efron et al. (2004). Not only does this algorithm provide a selection method in its own right, but with one additional modification, it can be used to efficiently produce LASSO solutions. Just like the forward selection method, the LAR algorithm produces a sequence of regression models in which one parameter is added at each step, terminating at the full least squares solution when all parameters have entered the model.

The algorithm starts by centering the covariates and response and scaling the covariates so that they all have the same corrected sum of squares. Initially all coefficients are 0, as is the predicted response. The predictor that is most correlated with the current residual is determined, and a step is taken in the direction of this predictor. The length of this step determines the coefficient of this predictor and is chosen so that some other predictor and the current predicted response have the same correlation with the current residual. At this point, the predicted response moves in the direction that is equiangular between these two predictors. Moving in this direction ensures that these two predictors continue to have a common correlation with the current residual. The predicted response moves in this direction until a third predictor has the same correlation with the current residual as the two predictors already in the model. A new direction is determined that is equiangular among these three predictors, and the predicted response moves in this direction until a fourth predictor, which has the same correlation with the current residual, joins the set. This process continues until all predictors are in the model.

As in other selection methods, the issue of when to stop the selection process is crucial. You can use the CHOOSE= option to specify a criterion for choosing among the models at each step. You can also use the STOP= option to specify a stopping criterion. These formulas use the approximation that at step k of the LAR algorithm, the model has k degrees of freedom. For a detailed discussion of this so-called simple approximation, see Efron et al. (2004).

A modification of LAR selection that is suggested in Efron et al. (2004) uses the LAR algorithm to select the set of covariates in the model at any step, but it uses ordinary least squares regression with just these covariates to obtain the regression coefficients. You can request this hybrid method by specifying the LSCOEFFS suboption of METHOD=LAR.

LASSO Selection

This section applies to the following procedures: GENSELECT, LOGSELECT, PHSELECT, and REGSELECT.

METHOD=LASSO specifies the least absolute shrinkage and selection operator (LASSO) method. LASSO arises from a constrained form of ordinary least squares regression where the sum of the absolute values of the regression coefficients is constrained to be smaller than a specified parameter. More precisely let $X = (x_1, x_2, \ldots, x_m)$ denote the matrix of covariates and let y denote the response, where the x_i have been

centered and scaled to have unit standard deviation and mean 0 and y has mean 0. Then for a particular parameter t, the LASSO regression coefficients $\beta = (\beta_1, \beta_2, \ldots, \beta_m)$ are the solution to the following constrained optimization problem:

$$\text{minimize} \|\mathbf{y} - \mathbf{X}\boldsymbol{\beta}\|^2 \qquad \text{subject to} \quad \sum_{j=1}^{m} |\beta_j| \leq t$$

Provided that the LASSO parameter t is small enough, some of the regression coefficients are exactly 0. Hence, you can view the LASSO as selecting a subset of the regression coefficients for each LASSO parameter. By increasing the LASSO parameter in discrete steps, you obtain a sequence of regression coefficients in which the nonzero coefficients at each step correspond to selected parameters.

Early implementations (Tibshirani 1996) of LASSO selection used quadratic programming techniques to solve the constrained least squares problem for each LASSO parameter of interest. Later Osborne, Presnell, and Turlach (2000) developed a "homotopy method" that generates the LASSO solutions for all values of t. Efron et al. (2004) derived a variant of their algorithm for least angle regression (called LARS algorithm) that can be used to obtain a sequence of LASSO solutions from which all other LASSO solutions can be obtained by linear interpolation. This algorithm for METHOD=LASSO is used in PROC REGSELECT. It can be viewed as a stepwise procedure with a single addition to or deletion from the set of nonzero regression coefficients at any step.

As in the other selection methods, you can use the CHOOSE= option to specify a criterion to choose among the models at each step of the LASSO algorithm. You can also use the STOP= option to specify a stopping criterion. For more information, see the discussion in the section "Forward Selection" on page 75. The model degrees of freedom used at any step of the LASSO are simply the number of nonzero regression coefficients in the model at that step. Efron et al. (2004) cite empirical evidence for doing this but do not give any mathematical justification for this choice.

A modification of LASSO selection suggested in Efron et al. (2004) uses the LASSO algorithm to select the set of covariates in the model at any step, but it uses ordinary least squares regression and just these covariates to obtain the regression coefficients. You can request this hybrid method by specifying the LSCOEFFS suboption of SELECTION=LASSO.

Adaptive LASSO Selection

This section applies to the REGSELECT procedure.

Adaptive LASSO selection is a modification of LASSO selection. In adaptive LASSO selection, weights are applied to each of the parameters in forming the LASSO constraint (Zou 2006). More precisely, suppose that the response y has mean 0 and the regressors x are scaled to have mean 0 and common standard deviation. Furthermore, suppose that you can find a suitable estimator $\hat{\beta}$ of the parameters in the true model and you define a weight vector by $w = 1/|\hat{\beta}|^{\gamma}$, where $\gamma \geq 0$. Then the adaptive LASSO regression coefficients $\boldsymbol{\beta} = (\beta_1, \beta_2, \ldots, \beta_m)$ are the solution to the following constrained optimization problem:

$$\text{minimize} \|\mathbf{y} - \mathbf{X}\boldsymbol{\beta}\|^2 \qquad \text{subject to} \quad \sum_{j=1}^{m} |w_j \beta_j| \leq t$$

The solution to the unconstrained least squares problem is used as the estimator $\hat{\beta}$. This is appropriate unless collinearity is a concern. If the regressors are collinear or nearly collinear, then Zou (2006) suggests using a ridge regression estimate to form the adaptive weights.

Adaptive LASSO enjoys the oracle properties; namely, it performs as well as if the true underlying model were given in advance.

Relaxed LASSO Selection

This section applies to the REGSELECT procedure.

Relaxed LASSO selection (Hastie, Tibshirani, and Tibshirani 2020) is a variation of the original LASSO selection method. Relaxed LASSO selection uses the LASSO algorithm to choose the set of covariates in the model at any step. However, the relaxed LASSO regression coefficients $\boldsymbol{\beta}_{\text{relaxed}}$ are a linear combination of the original LASSO coefficients $\boldsymbol{\beta}_{\text{lasso}}$ and least squares estimates $\boldsymbol{\beta}_{\text{lscoeffs}}$:

$$\boldsymbol{\beta}_{\text{relaxed}} = \kappa \boldsymbol{\beta}_{\text{lasso}} + (1 - \kappa)\boldsymbol{\beta}_{\text{lscoeffs}}$$

where κ is a mixing parameter that controls the balance between the LASSO solution and the ordinary least squares solution. If $\kappa = 1$, relaxed LASSO selection reduces to ordinary LASSO selection; if $\kappa = 0$, relaxed LASSO selection is the same as LASSO selection with the LSCOEFFS suboption.

If you have a good estimate of κ, you can specify a single value in the KAPPA= suboption. If you supply a list of κ values by using the KAPPA= suboption, PROC REGSELECT sorts the values in descending order, computes the model fit criterion by using $\boldsymbol{\beta}_{\text{relaxed}}$, and then selects candidate models. If you do not specify a value for κ, then by default PROC REGSELECT searches for a value from the series $\{0, 0.1, 0.2, \ldots, 0.9, 1\}$ that is optimal according to the current value of the CHOOSE= criterion (by default, CHOOSE=SBC).

Elastic Net Selection

This section applies to the following procedures: GENSELECT, LOGSELECT, and REGSELECT.

The METHOD=ELASTICNET option specifies the elastic net method proposed by Zou and Hastie (2005), which bridges the LASSO method and ridge regression. The elastic net method strikes a balance between having a parsimonious model and borrowing strength from correlated regressors, by solving the least squares regression problem with constraints on both the sum of the absolute coefficients and the sum of the squared coefficients.

More specifically, the elastic net coefficients $\boldsymbol{\beta} = (\beta_1, \beta_2, \ldots, \beta_m)$ are the solution to the constrained optimization problem

$$\min \|\mathbf{y} - \mathbf{X}\boldsymbol{\beta}\|^2 \qquad \text{subject to} \quad \sum_{j=1}^{m} |\beta_j| \le t_1, \ \sum_{j=1}^{m} \beta_j^2 \le t_2$$

This can be written as the equivalent Lagrangian form

$$\min \|\mathbf{y} - \mathbf{X}\boldsymbol{\beta}\|^2 + \lambda_1 \sum_{j=1}^{m} |\beta_j| + \lambda_2 \sum_{j=1}^{m} \beta_j^2$$

Elastic net can be treated as a convex combination of LASSO and ridge penalty; pure LASSO and pure ridge are two limiting cases. If t_1 is set to a very large value or, equivalently, if λ_1 is set to 0, then the elastic net method reduces to ridge regression. If t_2 is set to a very large value or, equivalently, if λ_2 is set to 0, then the elastic net method reduces to LASSO. If t_1 and t_2 are both large or, equivalently, if λ_1 and λ_2 are both set to 0, then the elastic net method reduces to ordinary least squares regression.

The elastic net method can overcome the limitations of LASSO in the following three scenarios:

- If you have more parameters than observations ($m > n$), the LASSO method selects at most n variables before it saturates, because of the nature of the convex optimization problem. This can be a defect for a variable selection method. By contrast, the elastic net method can select more than n variables in this case because of the ridge regression regularization.
- If there is a group of variables that have high pairwise correlations, then whereas LASSO tends to select only one variable from that group, the elastic net method can select more than one variable.
- If you have more observations than parameters ($n > m$), and there are high correlations between predictors, then it has been empirically observed that the prediction performance of LASSO is dominated by ridge regression. In this case, the elastic net method can achieve better prediction performance by using ridge regression regularization.

The Lagrangian form of the elastic net optimization problem can be reformulated as

$$\min \|\tilde{\mathbf{y}} - \tilde{\mathbf{X}}\boldsymbol{\beta}\|^2 + \lambda_1 \sum_{j=1}^{m} |\beta_j|$$

where the augmented design matrix $\tilde{\mathbf{X}}$ and response $\tilde{\mathbf{y}}$ are defined by

$$\tilde{\mathbf{X}}_{(n+m)\times m} = \begin{bmatrix} \mathbf{X} \\ \sqrt{\lambda_2}\mathbf{I} \end{bmatrix}, \quad \tilde{\mathbf{y}}_{(n+m)\times 1} = \begin{bmatrix} \mathbf{y} \\ \mathbf{0} \end{bmatrix}$$

This implies that for a given λ_2, the coefficients of the elastic net fit follow the same piecewise linear path as LASSO and can be solved using least angle regression (LARS) algorithm. Moreover, Zou and Hastie (2005) suggest rescaling the coefficients by $1 + \lambda_2$ to deal with the double amount of shrinkage in the elastic net fit; such rescaling is applied when you specify the ENSCALE option in the SELECTION statement.

If you have a good estimate of λ_2, you can specify the value in the L2= option. If you do not specify a value for λ_2, then by default PROC REGSELECT searches for a value between 0 and 1 that is optimal according to the current value of the CHOOSE= criterion (by default, CHOOSE=SBC).

Computing the entire solution path can be prohibitive for large problems when m is large. Instead of using the LARS algorithm, you can use other optimization techniques to solve LASSO and elastic net problems

for a reduced set of regularization parameters. You can reformulate the general elastic net objective into the following optimization problem:

$$\min_{\boldsymbol{\beta}} \frac{1}{2n}\|\mathbf{y}-\mathbf{X}\boldsymbol{\beta}\|^2 + \alpha\lambda\sum_{j=1}^{m}|\beta_j| + \frac{(1-\alpha)\lambda}{2}\sum_{j=1}^{m}\beta_j^2$$

where λ is the regularization parameter and α is the mixing parameter that controls the balance between the LASSO penalty and the ridge penalty. If $\alpha = 1$, the problem reduces to the LASSO regression; if $\alpha = 0$, the problem reduces to the ridge regression. Because the LASSO penalty is nonsmooth, the optimization is not readily solved by traditional techniques that use gradient information. To solve the problem, the REGSELECT procedure takes the following three general approaches:

- Uses the Orthant-Wise limited-memory quasi-Newton (OWL-QN) method (Andrew and Gao 2007), which is based on LBFGS and can efficiently optimize L_1 regularized objective functions. This solver efficiently handles wide data, where $m \gg n$. You can use it by specifying SOLVER=LBFGS.
- Uses the alternating direction method of multipliers (ADMM), which decomposes the objective into smooth and nonsmooth parts and solves efficiently with augmented Lagrangians (Boyd et al. 2011). This solver efficiently handles tall data, where $n \gg m$. You can use it by specifying SOLVER=ADMM. This method is only available for the REGSELECT procedure.
- Turns the nonsmooth LASSO penalty into a smooth penalty by using the reformulation of $\beta = \beta_+ - \beta_-$, and thus $|\beta| = \beta_+ + \beta_-$, where $\beta_+ = \max(\beta, 0), \beta_- = \max(-\beta, 0)$. This reformulation converts the optimization to a constrained nonlinear problem. You can use two solvers by specifying SOLVER=BFGS and SOLVER=NLP. For low-dimensional problems, both solvers can provide accurate solutions.

If you use one of these solvers to optimize the elastic net objective without supplying a list of regularization parameters or specifying the number of regularization parameters, PROC REGSELECT uses a single heuristic value for regularization:

$$\lambda = \begin{cases} 0.001\lambda_{\max} & \text{if } n > m \\ 0.1\lambda_{\max} & \text{otherwise} \end{cases}$$

where $\alpha\lambda_{\max}$ makes the lower bound of the L_1 regularization such that $\boldsymbol{\beta} = \mathbf{0}$. Note that for ridge regression when $\alpha = 0$, $\lambda_{\max}$ does not exist because the ridge penalty is not sparsity-inducing. In this case, elastic net selection computes $\lambda_{\max}$ by assuming that $\alpha = 1$ if you do not supply a list of regularization parameters.

If you supply a list of regularization parameters by using the LAMBDA= suboption, PROC REGSELECT sorts the values in descending order and then selects candidate models. If you supply only the number of regularization parameters n_λ by using the NLAMBDA= suboption, PROC REGSELECT constructs a series of λ values by using the following mechanism:

$$\lambda_k = \lambda_{\max} \cdot \rho^{k-1}, k = 1, \ldots, n_\lambda$$

You can specify ρ by using the RHO= option. Otherwise PROC REGSELECT uses

$$\rho = \begin{cases} 10^{-4/(n_\lambda-1)} & \text{if } n > m \\ 10^{-2/(n_\lambda-1)} & \text{otherwise} \end{cases}$$

The idea of penalization by using both LASSO and ridge penalty also extends to generalized linear models, including logistic regression models. For those models, the general elastic net objective function is formulated as

$$\min_{\boldsymbol{\beta}} -\frac{1}{n} L(\boldsymbol{\mu}(\boldsymbol{\beta}); \mathbf{y}) + \alpha\lambda \sum_{j=1}^{m} |\beta_j| + \frac{(1-\alpha)\lambda}{2} \sum_{j=1}^{m} \beta_j^2$$

where $L(\boldsymbol{\mu}(\boldsymbol{\beta}); \mathbf{y})$ is the log-likelihood function. If you do not supply a list of regularization parameters or do not specify the number of regularization parameters, PROC GENSELECT and PROC LOGSELECT use a default NLAMBDA= suboption value of 20 in order to choose a good candidate in a reasonable amount of time.

Adaptive Elastic Net Selection

This section applies to the REGSELECT procedure.

Adaptive elastic net selection (Zou and Zhang 2009) is an improved version of the elastic net and adaptive LASSO selection methods. Adaptive elastic net penalizes the squared error loss by using a combination of the ℓ_2 penalty and the adaptive ℓ_1 penalty.

More specifically, the adaptive elastic net coefficients $\boldsymbol{\beta} = (\beta_1, \beta_2, \ldots, \beta_m)$ are the solution to the optimization problem

$$\min \|\mathbf{y} - \mathbf{X}\boldsymbol{\beta}\|^2 + \lambda_1 \sum_{j=1}^{m} |w_j \beta_j| + \lambda_2 \sum_{j=1}^{m} \beta_j^2$$

The adaptively weighted ℓ_1 penalty achieves the oracle property, and the elastic net penalty handles the collinearity. The adaptive weights can be obtained by ridge regression estimation.

Like the naive elastic net, the adaptive elastic net can be transformed into an adaptive LASSO-type problem in some augmented space

$$\min \|\tilde{\mathbf{y}} - \tilde{\mathbf{X}}\boldsymbol{\beta}\|^2 + \lambda_1 \sum_{j=1}^{m} |w_j \beta_j|$$

where the augmented design matrix $\tilde{\mathbf{X}}$ and response $\tilde{\mathbf{y}}$ are defined by

$$\tilde{\mathbf{X}}_{(n+m)\times m} = \begin{bmatrix} \mathbf{X} \\ \sqrt{\lambda_2}\mathbf{I} \end{bmatrix}, \quad \tilde{\mathbf{y}}_{(n+m)\times 1} = \begin{bmatrix} \mathbf{y} \\ \mathbf{0} \end{bmatrix}$$

Group LASSO Selection

This section applies to the following procedures: GENSELECT, LOGSELECT, and PHSELECT.

The group LASSO method, proposed by Yuan and Lin (2006), is a variant of LASSO that is specifically designed for models defined in terms of effects that have multiple degrees of freedom, such as the main effects of CLASS variables and interactions between CLASS variables. If all effects in the model are continuous, then the group LASSO method is the same as the LASSO method.

Recall that LASSO selection depends on solving a constrained optimization problem of the form

$$\min\{-L(\boldsymbol{\mu};\mathbf{y})\} \qquad \text{subject to} \quad \sum_{j=1}^{m} |\beta_j| \le t$$

where L is the log-likelihood function. In this formulation, individual parameters can be included or excluded from the model independently, subject only to the overall constraint. In contrast, the group LASSO method uses a constraint that forces all parameters that correspond to the same effect to be included or excluded simultaneously. For a model that has k effects, let β_{G_j} be the group of linear coefficients that correspond to effect j in the model. Then group LASSO depends on solving a constrained optimization problem of the form

$$\min\{-L(\boldsymbol{\mu};\mathbf{y})\} \qquad \text{subject to} \quad \sum_{j=1}^{k} \sqrt{|G_j|}\|\beta_{G_j}\| \le t$$

where $|G_j|$ is the number of parameters that correspond to effect j, and $\|\beta_{G_j}\|$ denotes the Euclidean norm of the parameters β_{G_j},

$$\|\beta_{G_j}\| = \sqrt{\sum_{i=1}^{G_j} \beta_i^2}$$

That is, instead of constraining the sum of the absolute value of individual parameters, group LASSO constrains the Euclidean norm of groups of parameters, where groups are defined by effects.

You can write the group LASSO method in the equivalent Lagrangian form, which is an example of a penalized log-likelihood function:

$$\min\{-L(\boldsymbol{\mu};\mathbf{y})\} + \lambda \sum_{j=1}^{k} \sqrt{|G_j|}\|\beta_{G_j}\|$$

The weight $\sqrt{|G_j|}$ was suggested by Yuan and Lin (2006) in order to take the size of the group into consideration in group LASSO.

Unlike LASSO for linear models, group LASSO does not allow a piecewise linear constant solution path as generated by a LAR algorithm. Instead, the method proposed by Nesterov (2013) is adopted to solve the Lagrangian form of the group LASSO problem that corresponds to a prespecified regularization parameter λ. Nesterov's method is known to have an optimal convergence rate for first-order black-box optimization. Because the optimal λ is usually unknown, a series of regularization parameters $\rho, \rho^2, \rho^3, \ldots$ is used, where

ρ is a positive value less than 1. You can specify ρ by using the LASSORHO= option in the procedure; the default value is $\rho = 0.8$. In the ith step of group LASSO selection, the value that is used for λ is ρ^i.

A unique feature of the group LASSO method is that it does not necessarily add or remove precisely one effect at each step of the process. This is different from the forward, stepwise, and backward selection methods.

As with the other selection methods, you can specify a criterion to choose among the models at each step of the group LASSO algorithm by using the CHOOSE= option in the SELECTION statement. You can also specify a stopping criterion by using the STOP= option in the SELECTION statement. If you do not specify either the CHOOSE= or STOP= option, the model at the last LASSO step is chosen as the selected model and parameter estimates are reported for this model. These parameter estimates are used to compute predicted values for the output data tables.

For more information, see the discussion in the section "SELECTION Statement" on page 42.

The model degrees of freedom at any step of the LASSO are simply the number of nonzero regression coefficients in the model at that step. Efron et al. (2004) cite empirical evidence for doing this but do not give any mathematical justification for this choice.

Some distributions involve a dispersion parameter (the parameter ϕ in the expressions for the log likelihood). These parameters are not estimated by the LASSO optimization algorithm, and are set to either the default value or a value that you specify. You can use the PHI= option in the procedure to set the dispersion to a fixed value.

Best-Subset Selection

This section applies to the REGSELECT procedure.

The METHOD=BESTSUBSET option specifies the best-subset selection method, which uses the branch-and-bound technique (Furnival and Wilson 1974) to efficiently search for subsets of model effects that best predict the response variable. For a multiple regression model that contains m predictors, there are $2^m - 1$ candidate subset models. When m becomes large, the number of candidate submodels grows exponentially, and searching within the model space becomes impossible. By presenting all possible candidates in a tree diagram where the full model is at the root node and simple one-parameter models are at the leaf nodes, the problem becomes how to efficiently search the tree. When model B consists of a subset of model effects that are in model A a criterion $g(\cdot)$ that satisfies the inequality

$$g(A) \leq g(B)$$

so that better models have smaller value of $g(\cdot)$, enables you to avoid fitting models such as B farther down the branch when the criterion $g(A)$ is already larger than the current best criterion at one node. Thus the technique can greatly reduce the computation cost of searching for the best candidates.

Three model fit criteria are available for the search: the R-square (SELECT=RSQUARE), the adjusted R-square (SELECT=ADJRSQ), and Mallow's C_p statistic (SELECT=CP). The computation time that the analysis requires is highly dependent on the data and on the values of the BEST=, MINEFFECTS=, and MAXEFFECTS= *method-options*. In particular, for these three criteria for the SELECT= *method-option* and a large value of the BEST= *method-option*, adding one more effect to the list from which regressors are selected might significantly increase the computation time.

RSQUARE

The SELECT=RSQUARE *method-option* finds subsets of effects that best predict a dependent variable by linear regression in the given data. You can specify the largest and smallest number of effects to appear in a subset and the number of subsets of each size to be selected. This *method-option* can efficiently perform all possible subset regressions and display the models in decreasing order of R-square magnitude within each subset size. Other statistics are available for comparing subsets of different sizes.

The subset models that this SELECT=RSQUARE *method-option* selects are optimal in terms of R-square for the given data, but they are not necessarily optimal for the population from which the data sample is drawn or for any other data for which you might want to make predictions. If a subset model is selected on the basis of a large R-square value or any other criterion commonly used for model selection, then all regression statistics that are computed for that model under the assumption that the model is given a priori are biased, including all other computed statistics.

Although the SELECT=RSQUARE *method-option* is a useful tool for building exploratory models, no single statistical method can be relied on to identify the "true" model. Effective model building requires substantive theory to suggest relevant predictors and plausible functional forms for the model.

The SELECT=RSQUARE *method-option* differs from the other selection *method-options* in that it always identifies the model that has the largest R-square value for each number of effects considered. The other selection methods are not guaranteed to find the model with the largest R-square.

ADJRSQ

The SELECT=ADJRSQ *method-option* is similar to the SELECT=RSQUARE *method-option*, except that the adjusted R-square statistic is used as the criterion for selecting models, and the option finds the models with the highest adjusted R-square value within the range of sizes.

CP

The SELECT=CP *method-option* is similar to the SELECT=ADJRSQ *method-option*, except that Mallows' C_p statistic is used as the criterion for the best-subset selection. Models are listed in ascending order of C_p.

Folded Concave Penalized Selection

This section applies to the REGSELECT procedure.

Recall that adaptive LASSO selection consists of a two-stage approach that involves an initial estimator to reduce bias for large regression coefficients. An alternative single-stage approach is to use a penalty that tapers off as $\boldsymbol{\beta}$ becomes larger in absolute value.

More specifically, the folded concave penalized (FCP) selection coefficients $\boldsymbol{\beta} = (\beta_1, \beta_2, \ldots, \beta_m)^T$ are the solution to the regularized least squares

$$\min \frac{1}{2n}\|\mathbf{y} - \mathbf{X}\boldsymbol{\beta}\|^2 + \sum_{j=1}^{m} P_{\lambda,\alpha}(|\beta_j|)$$

where $P_{\lambda,\alpha}(\cdot)$ is a folded concave penalty.

Figure 2.6 Penalty Functions: LASSO, SCAD, and MCP

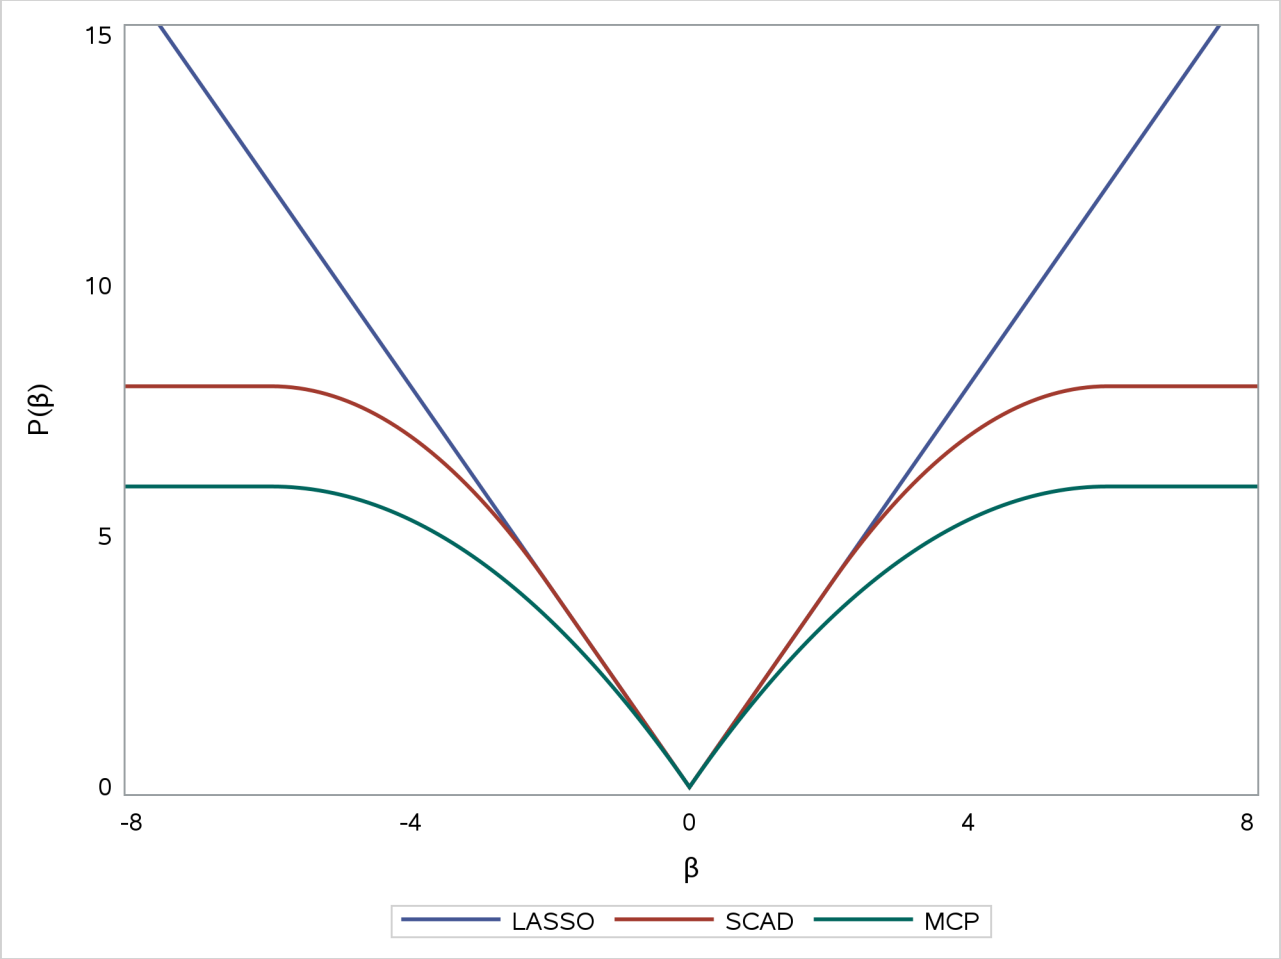

Figure 2.6 shows the penalty functions in the LASSO, SCAD, and MCP methods. When the absolute value of β becomes large, the corresponding folded concave penalty value increases much more slowly than the LASSO penalty value.

If you have a good estimate of α or λ, you can specify the value in either the ALPHA= or LAMBDA= option. If you omit the values for α and λ, then by default the procedure searches for a pair of λ, α that is optimal according to the current value of the CHOOSE= criterion (by default, CHOOSE=SBC).

A variety of nonconvex penalties have been proposed. Two of the earliest and most influential nonconvex penalties are the smoothly clipped absolute deviation (SCAD) and the minimax concave penalty (MCP).

SCAD

In SCAD selection (Fan and Li 2001), the $P_{\lambda,\alpha}(\cdot)$ takes the following form:

$$P^{\text{scad}}_{\lambda,\alpha}(\theta) = \begin{cases} \lambda\theta & \text{if} \quad 0 \le \theta \le \lambda \\ \frac{-1}{2(\alpha-1)}\left(\theta^2 - 2\alpha\lambda\theta + \lambda^2\right) & \text{if} \quad \lambda < \theta < \alpha\lambda \\ \frac{\alpha+1}{2}\lambda^2 & \text{if} \quad \theta > \alpha\lambda \end{cases}$$

The SCAD estimator $\hat{\boldsymbol{\beta}}^{\text{scad}}$ solves the following minimization problem:

$$\hat{\boldsymbol{\beta}}^{\text{scad}} = \arg\min_{\boldsymbol{\beta}} \left\{ \frac{1}{2}\|\mathbf{y} - \mathbf{X}\boldsymbol{\beta}\|_2^2 + n\sum_{j=1}^{m} P_{\lambda,\alpha}^{\text{scad}}(|\beta_j|) \right\}$$

The quadratic program (QP) reformulation of the preceding SCAD problem is given by

$$\begin{aligned} \min_{\boldsymbol{\beta},\mathbf{g},\mathbf{h}\in R^m} \quad & \frac{1}{2}\left[\boldsymbol{\beta}^T\mathbf{X}^T\mathbf{X}\boldsymbol{\beta} + n(\alpha-1)\mathbf{g}^T\mathbf{g} + 2n\mathbf{g}^T\mathbf{h}\right] - \mathbf{y}^T\mathbf{X}\boldsymbol{\beta} - n\alpha\lambda\mathbf{1}^T\mathbf{g} \\ \text{subject to} \quad & -\mathbf{h} \le \boldsymbol{\beta} \le \mathbf{h} \\ & \mathbf{0} \le \mathbf{g} \le \lambda\mathbf{1} \end{aligned} \tag{1}$$

where $\mathbf{0} = (0,\ldots,0)^T$ and $\mathbf{1} = (1,\ldots,1)^T$.

Liu, Yao, and Li (2016) show that the preceding QP (1) is equivalent to the following mixed integer linear program (MILP):

$$\begin{aligned} \min_{\boldsymbol{\beta},\mathbf{g},\mathbf{h},\{\boldsymbol{\gamma}_k\}_{k=1}^4,\{\mathbf{z}_k\}_{k=1}^4\in R^m} \quad & -\frac{1}{2}\mathbf{y}^T\mathbf{X}\boldsymbol{\beta} - \frac{1}{2}n\alpha\lambda\mathbf{1}^T\mathbf{g} - \frac{1}{2}\lambda\mathbf{1}^T\boldsymbol{\gamma}_4 \\ \text{subject to} \quad & \mathbf{X}^T\mathbf{X}\boldsymbol{\beta} - \mathbf{X}^T\mathbf{y} + \boldsymbol{\gamma}_1 - \boldsymbol{\gamma}_2 = \mathbf{0} \\ & n\mathbf{g} - \boldsymbol{\gamma}_1 - \boldsymbol{\gamma}_2 = \mathbf{0} \\ & n(\alpha-1)\mathbf{g} + n\mathbf{h} - \boldsymbol{\gamma}_3 + \boldsymbol{\gamma}_4 - n\alpha\lambda\mathbf{1} = \mathbf{0} \\ & \mathbf{0} \le \boldsymbol{\gamma}_1 \le \mathcal{M}\mathbf{z}_1, \quad \mathbf{0} \le \mathbf{h} - \boldsymbol{\beta} \le \mathcal{M}(\mathbf{1} - \mathbf{z}_1) \\ & \mathbf{0} \le \boldsymbol{\gamma}_2 \le \mathcal{M}\mathbf{z}_2, \quad \mathbf{0} \le \mathbf{h} + \boldsymbol{\beta} \le \mathcal{M}(\mathbf{1} - \mathbf{z}_2) \\ & \mathbf{0} \le \boldsymbol{\gamma}_3 \le \mathcal{M}\mathbf{z}_3, \quad \mathbf{0} \le \mathbf{g} \le \mathcal{M}(\mathbf{1} - \mathbf{z}_3) \\ & \mathbf{0} \le \boldsymbol{\gamma}_4 \le \mathcal{M}\mathbf{z}_4, \quad \mathbf{0} \le \lambda\mathbf{1} - \mathbf{g} \le \mathcal{M}(\mathbf{1} - \mathbf{z}_4) \\ & \mathbf{z}_1, \mathbf{z}_2, \mathbf{z}_3, \mathbf{z}_4 \in \{0,1\}^m \end{aligned} \tag{2}$$

where $\mathcal{M} > 0$ is a properly large constant.

MCP

In MCP selection (Zhang 2010), the $P_{\lambda,\alpha}(\cdot)$ takes the following form:

$$P_{\lambda,\alpha}^{\text{mcp}}(\theta) = \begin{cases} \lambda\theta - \frac{1}{2\alpha}\theta^2 & \text{if} \quad 0 \le \theta \le \alpha\lambda \\ \frac{\alpha}{2}\lambda^2 & \text{if} \quad \theta > \alpha\lambda \end{cases}$$

The MCP estimator $\hat{\boldsymbol{\beta}}^{\text{mcp}}$ solves the following minimization problem:

$$\hat{\boldsymbol{\beta}}^{\text{mcp}} = \arg\min_{\boldsymbol{\beta}} \left\{ \frac{1}{2}\|\mathbf{y} - \mathbf{X}\boldsymbol{\beta}\|_2^2 + n\sum_{j=1}^{m} P_{\lambda,\alpha}^{\text{mcp}}(|\beta_j|) \right\}$$

The QP reformulation of the preceding MCP problem is given by

$$\begin{aligned} \min_{\boldsymbol{\beta},\mathbf{g},\mathbf{h}\in R^m} \quad & \frac{1}{2}\left[\boldsymbol{\beta}^T\mathbf{X}^T\mathbf{X}\boldsymbol{\beta} + \frac{n}{\alpha}\mathbf{g}^T\mathbf{g} - \frac{2n}{\alpha}\mathbf{g}^T\mathbf{h}\right] - \mathbf{y}^T\mathbf{X}\boldsymbol{\beta} + n\lambda\mathbf{1}^T\mathbf{h} \\ \text{subject to} \quad & -\mathbf{h} \le \boldsymbol{\beta} \le \mathbf{h} \\ & \mathbf{0} \le \mathbf{g} \le \alpha\lambda\mathbf{1} \end{aligned} \tag{3}$$

Liu, Yao, and Li (2016) show that the preceding QP (3) is equivalent to the following MILP:

$$\begin{aligned}
\min_{\boldsymbol{\beta},\mathbf{g},\mathbf{h},\{\boldsymbol{\gamma}_k\}_{k=1}^4,\{\mathbf{z}_k\}_{k=1}^4 \in R^m} \quad & -\frac{1}{2}\mathbf{y}^T\mathbf{X}\boldsymbol{\beta} + \frac{1}{2}n\lambda\mathbf{1}^T\mathbf{h} - \frac{1}{2}\alpha\lambda\mathbf{1}^T\boldsymbol{\gamma}_4 \\
\text{subject to} \quad & \mathbf{X}^T\mathbf{X}\boldsymbol{\beta} - \mathbf{X}^T\mathbf{y} + \boldsymbol{\gamma}_1 - \boldsymbol{\gamma}_2 = \mathbf{0} \\
& \frac{n}{\alpha}\mathbf{g} + \boldsymbol{\gamma}_1 + \boldsymbol{\gamma}_2 - n\lambda\mathbf{1} = \mathbf{0} \\
& \frac{n}{\alpha}\mathbf{g} - \frac{n}{\alpha}\mathbf{h} - \boldsymbol{\gamma}_3 + \boldsymbol{\gamma}_4 = \mathbf{0} \\
& \mathbf{0} \le \boldsymbol{\gamma}_1 \le \mathcal{M}\mathbf{z}_1, \quad \mathbf{0} \le \mathbf{h} - \boldsymbol{\beta} \le \mathcal{M}(\mathbf{1} - \mathbf{z}_1) \\
& \mathbf{0} \le \boldsymbol{\gamma}_2 \le \mathcal{M}\mathbf{z}_2, \quad \mathbf{0} \le \mathbf{h} + \boldsymbol{\beta} \le \mathcal{M}(\mathbf{1} - \mathbf{z}_2) \\
& \mathbf{0} \le \boldsymbol{\gamma}_3 \le \mathcal{M}\mathbf{z}_3, \quad \mathbf{0} \le \mathbf{g} \le \mathcal{M}(\mathbf{1} - \mathbf{z}_3) \\
& \mathbf{0} \le \boldsymbol{\gamma}_4 \le \mathcal{M}\mathbf{z}_4, \quad \mathbf{0} \le \alpha\lambda\mathbf{1} - \mathbf{g} \le \mathcal{M}(\mathbf{1} - \mathbf{z}_4) \\
& \mathbf{z}_1, \mathbf{z}_2, \mathbf{z}_3, \mathbf{z}_4 \in \{0,1\}^m
\end{aligned} \tag{4}$$

where $\mathcal{M} > 0$ is a properly large constant.

SOLVER

When you specify SOLVER=MILP, the coefficients $\boldsymbol{\beta}$ are obtained by solving the minimization problem (2) or (3). Furthermore, you can also specify the BIGM= option for the $\mathcal{M}$ value and the INTTOL= option for the tolerance of integer variables $\{\mathbf{z}_k\}_{k=1}^4$. By default, $\mathcal{M} = 2|\mathbf{y}^T\mathbf{X}|_\infty$ and INTTOL=1E–7.

When you specify SOLVER=NLP, the coefficients $\boldsymbol{\beta}$ are obtained by solving the minimization problem (1) or (3).

LAMBDAGRID

When you search for the optimal model, the default values of $\lambda_{\max}$ and $\lambda_{\min}$ are, respectively,

$$\lambda_{\max} = \sigma_y\sqrt{\log(m)/m}, \quad \lambda_{\min} = \frac{\sigma_y}{20\sqrt{\log(m)}}$$

where σ_y is the standard deviation of $\mathbf{y}$, m is the length of $\boldsymbol{\beta}$, and log is the natural logarithm.

Suppose that the number of searching λ steps is n_λ. You can define the value by specifying the MAXITER-LAMBDA= option. When you specify LAMBDAGRID=LINSPACE, the values of λ series are generated as follows:

$$\lambda_i^{\text{linspace}} = \lambda_{\min} + (i-1) \times \delta_\lambda^{\text{linspace}}, \quad i = 1, 2, \ldots, n_\lambda$$

where $\delta_\lambda^{\text{linspace}} = (\lambda_{\max} - \lambda_{\min})/(n_\lambda - 1)$.

When you specify LAMBDAGRID=LOGSPACE, the values of λ series are generated as follows:

$$\log_{10}(\lambda_i^{\text{logspace}}) = \log_{10}(\lambda_{\min}) + (i-1) \times \delta_\lambda^{\text{logspace}}, \quad i = 1, 2, \ldots, n_\lambda$$

where $\delta_\lambda^{\text{logspace}} = (\log_{10}(\lambda_{\max}) - \log_{10}(\lambda_{\min}))/(n_\lambda - 1)$.

Model Selection Plots

This section describes the ODS graphical displays that you can request by using the PLOTS= option in the SELECTION statement.

This section applies to the following procedures: GENSELECT, LOGSELECT, PHSELECT, QTRSELECT, and REGSELECT.

The example plots shown in this section are produced by using the REGSELECT procedure.

The following DATA step produces simulated example data that contain a variable that you can use to assign observations to the training, validation, and testing roles. In this case, each role has 5,000 observations. These statements assume that your libref is named mylib, as in the section "Using CAS Sessions and CAS Engine Librefs" on page 7, but you can substitute any appropriately defined libref.

```
data mylib.exampleData;
   drop i j;
   array x{20} x1-x20;
   array c{5}  c1-c5;

   call streaminit(1);

 do i=1 to 15000;
    do j=1 to dim(x);
       x{j} = rand('NORMAL');
    end;

    do j=1 to dim(c);
       c{j} = 1+ int(rand('UNIFORM')*3);
    end;

    y = 1 + x1 + 2*x5 - 1.3*x10 + x20 + 5*(c1=1)+3*(c1=3) - 4*c4 + 25*rand('NORMAL');

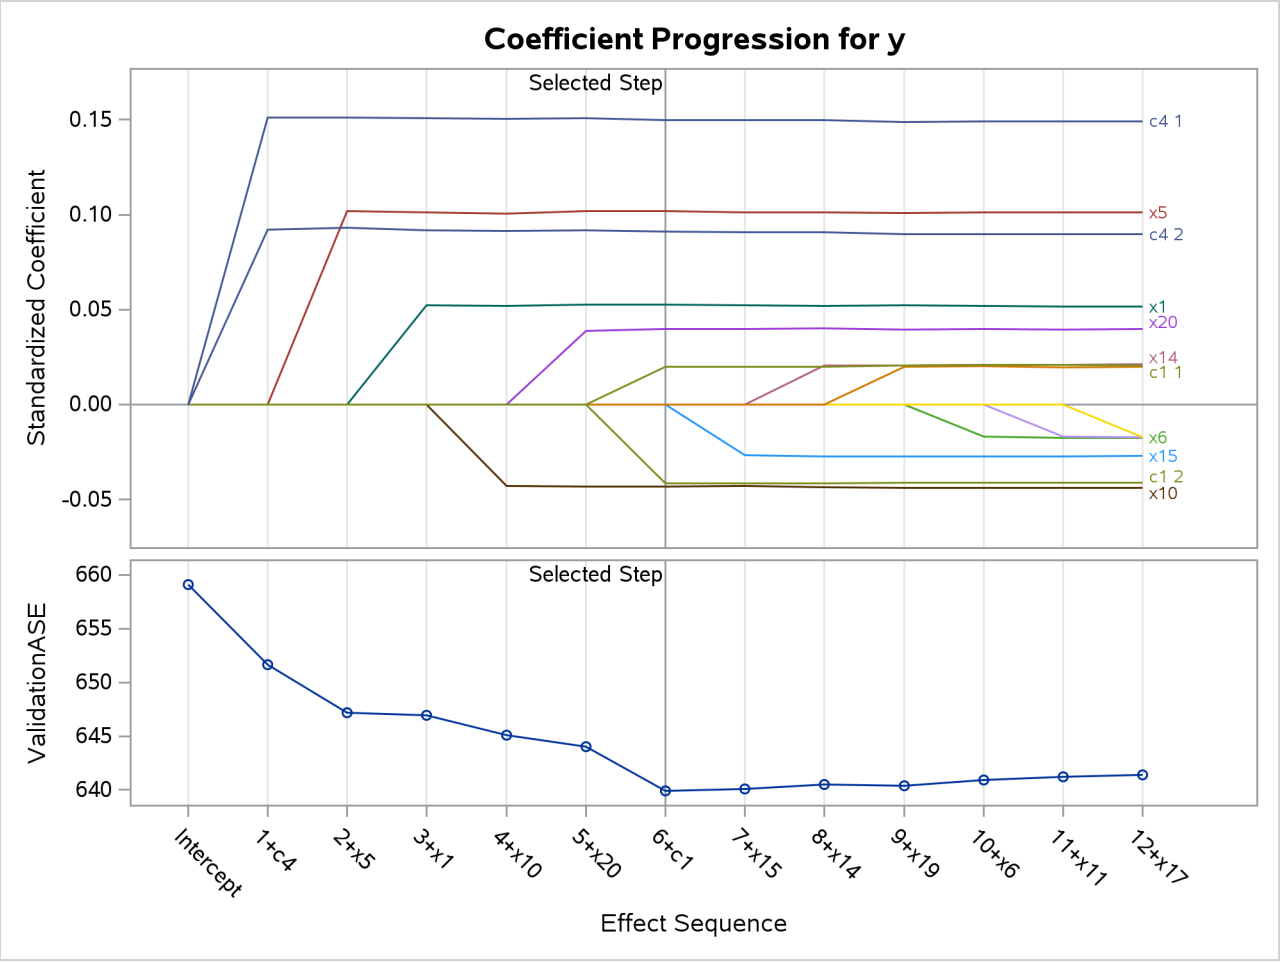
         if mod(i,3)=1 then Role = 'TRAIN';
    else if mod(i,3)=2 then Role = 'VAL';
    else                    Role = 'TEST';

    output;
 end;
run;
```

The following statements perform forward selection to obtain a parsimonious linear regression model for the response:

```
ods graphics on;

proc regselect data=mylib.exampleData;
   partition rolevar=Role(train='TRAIN' validate='VAL' test='TEST');
   class c: ;
   model y = x: c:  ;
```



```
   selection method=forward(stop=AICC CHOOSE=validate) plots=all;
run;
```

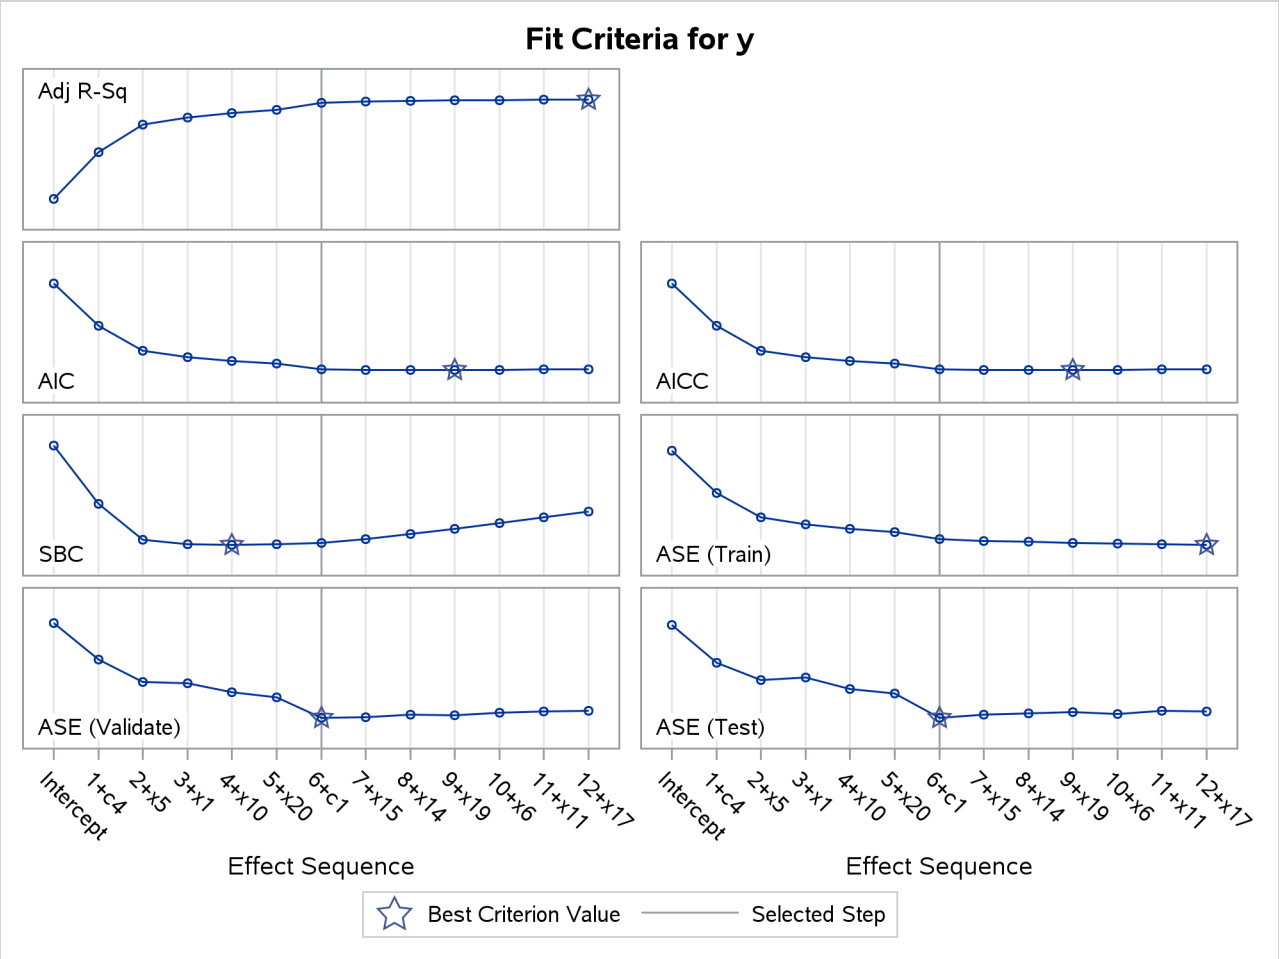
Because you specified the PLOTS=ALL option in the SELECTION statement and have enabled ODS Graphics, the plots that are described in the following sections are produced.

Coefficient Panel

Figure 2.7 shows the coefficient panel, which contains two plots that show how the standardized coefficients and the criterion used to choose the final model evolve as the selection progresses.

Figure 2.7 Coefficient Panel

The upper plot in the panel displays the standardized coefficients as a function of the step number. To help trace the changes in a parameter, the standardized coefficients for each parameter are connected by lines. Coefficients that correspond to effects not in the selected model at a step are zero and hence not observable. Parameters that are nonzero at the final step of the selection are labeled if their magnitudes are greater than 1% of the range of the magnitudes of all the nonzero parameters at this step. To avoid collision, labels that correspond to parameters that have similar values at the final step might be suppressed.



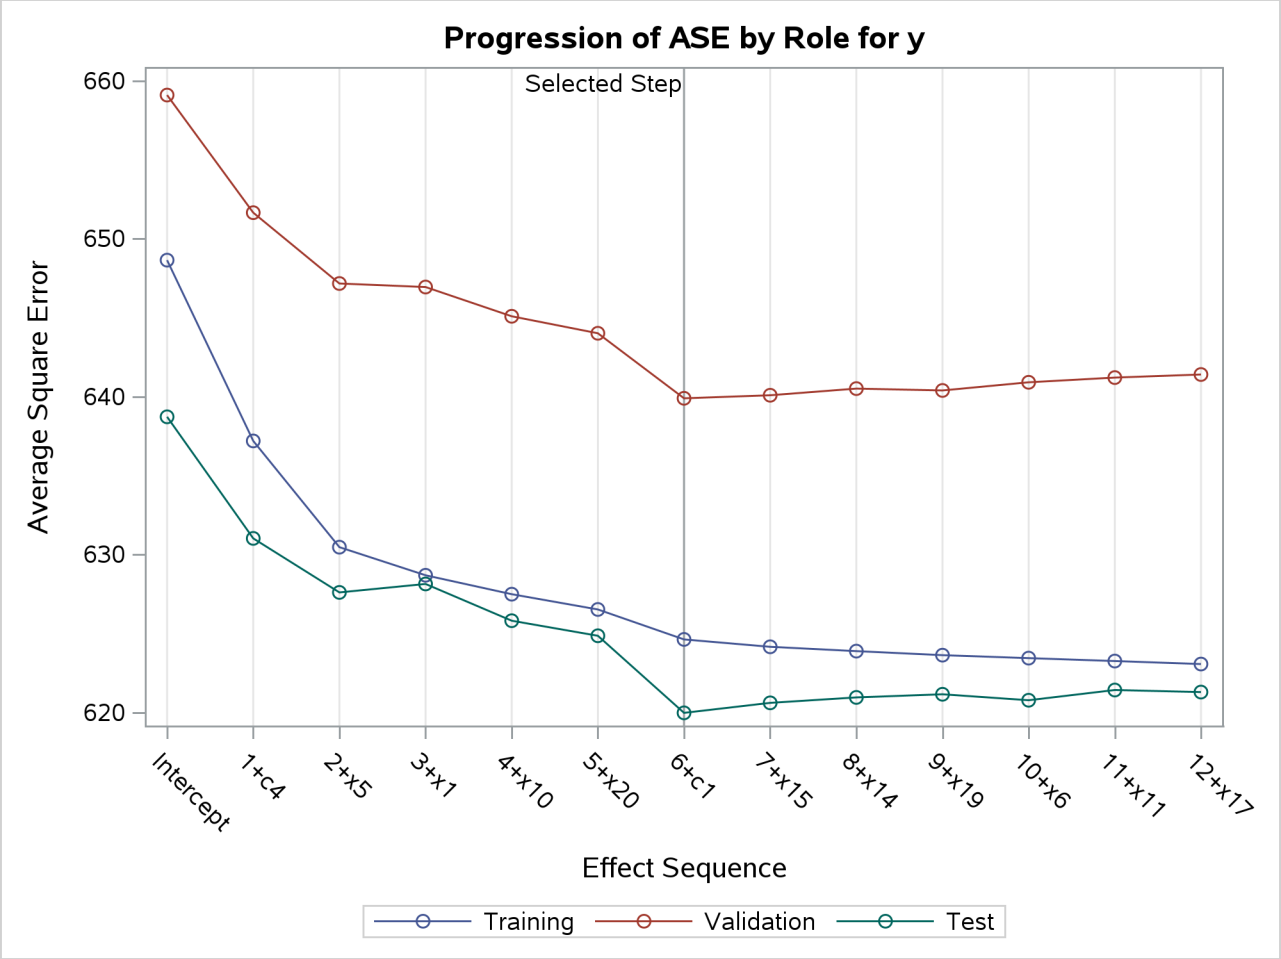
The lower plot in the panel shows how the criterion used to choose among the examined models progresses.

The selected step occurs at the optimal value of this criterion. In this example, this criterion is the average square error (ASE) on the validation data, and it achieves its minimal value at step 6 of the forward selection.

Criterion Panel

Figure 2.8 shows the criterion panel, which contains plots that show the progression of fit criteria.

Figure 2.8 Criterion Panel



The selected step is displayed as a vertical reference line on the plot of each criterion. The optimal value of each criterion is indicated with the "star" marker. Note that it is possible that a better value of a criterion might have been reached if more steps of the selection process had been done.

Fit by Role Plot

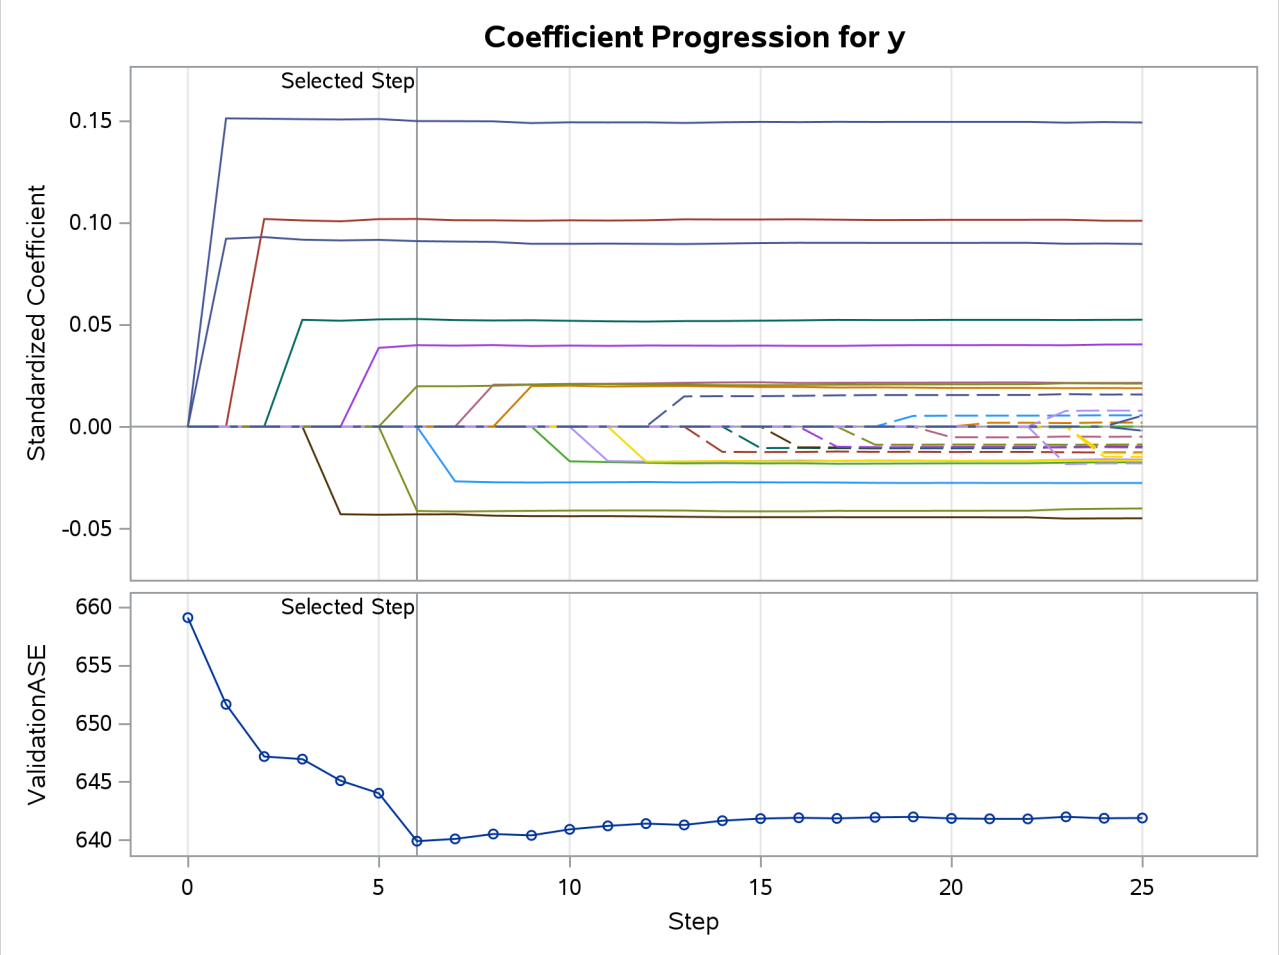
Figure 2.9 displays the fit by role plot, which shows the progression of a fit statistic evaluated separately on the training, validation, and test data. If you do not partition your data into roles by using a PARTITION statement, then the fit by role plot is not produced.

Figure 2.9 Fit by Role Plot

You use this plot to detect overfitting of the training data. For many types of regression (including the linear regression that is used in the examples in this section), the fit statistic shown in this plot is the average square error (ASE) evaluated separately for each data role. The ASE decreases monotonically on the training data as parameters are added to a model. However, the ASE on test and validation data usually starts increasing when overfitting occurs.

Using Options to Customize Plots

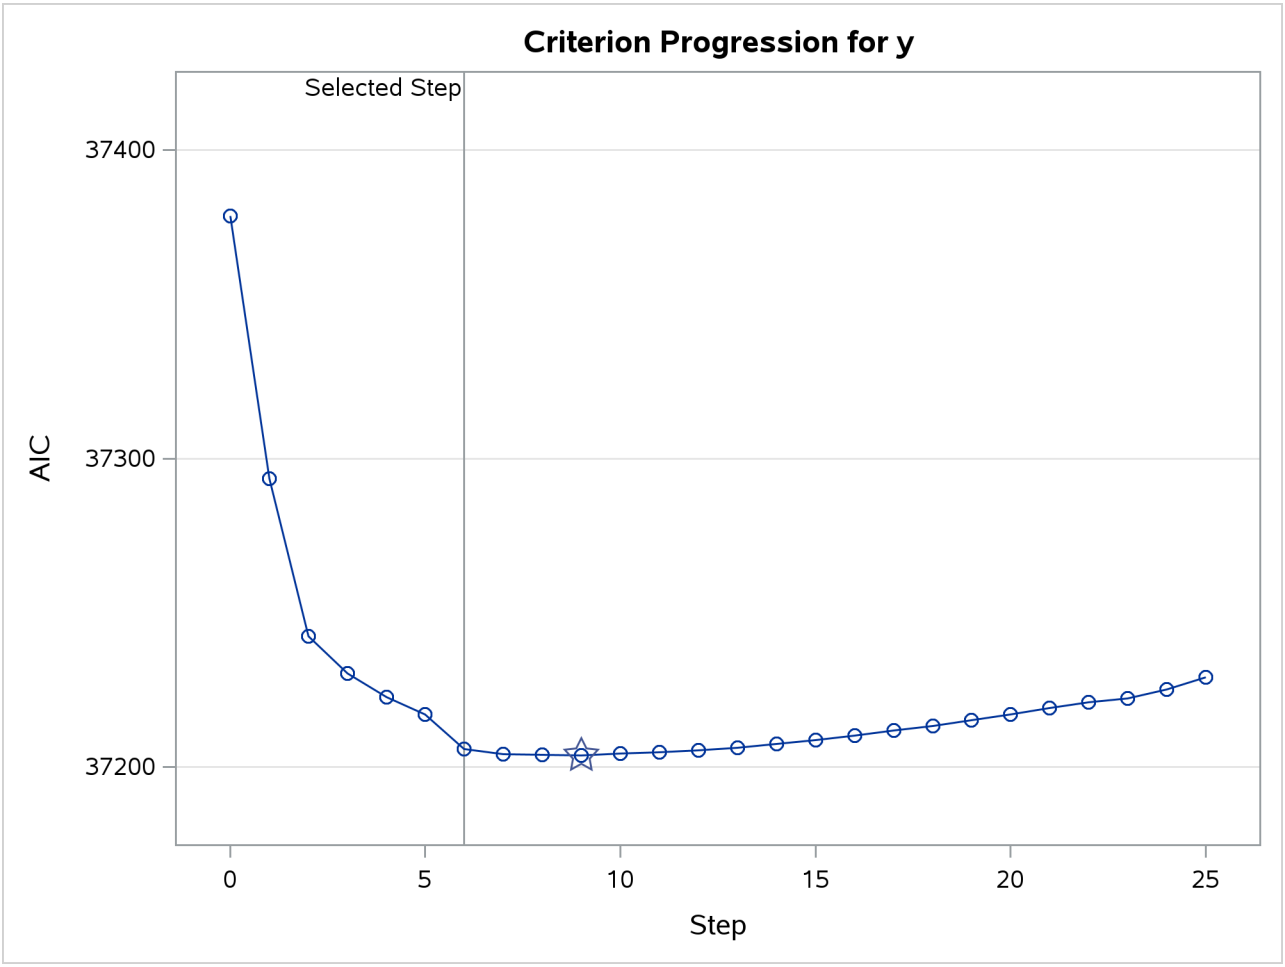
In some cases, particularly when the final step contains a large number of parameters, you might be interested in using the coefficient panel only to discern if and when the parameters in the model are essentially unchanged beyond a certain step. In such cases, you might want to suppress the labeling of the parameters and use a numeric axis on the horizontal axis of the plot. You can do this by using the STEPAXIS= and MAXPARMLABEL= global plot options. The following statements provide an example:



```
proc regselect data=mylib.exampleData;
   partition rolevar=Role(train='TRAIN' validate='VAL' test='TEST');
   class c: ;
   model y = x: c: ;
```

```
    selection method=forward(stop=none choose=validate)
              plots(maxparmlabel=1 stepaxis=number)=(coefficients criteria(unpack));
run;
```

The STEPAXIS=NUMBER option requests that a numeric horizontal axis showing step number be used on all plots. The MAXPAMLABEL=1 option suppresses the labels for the parameters in the coefficient progression panel.



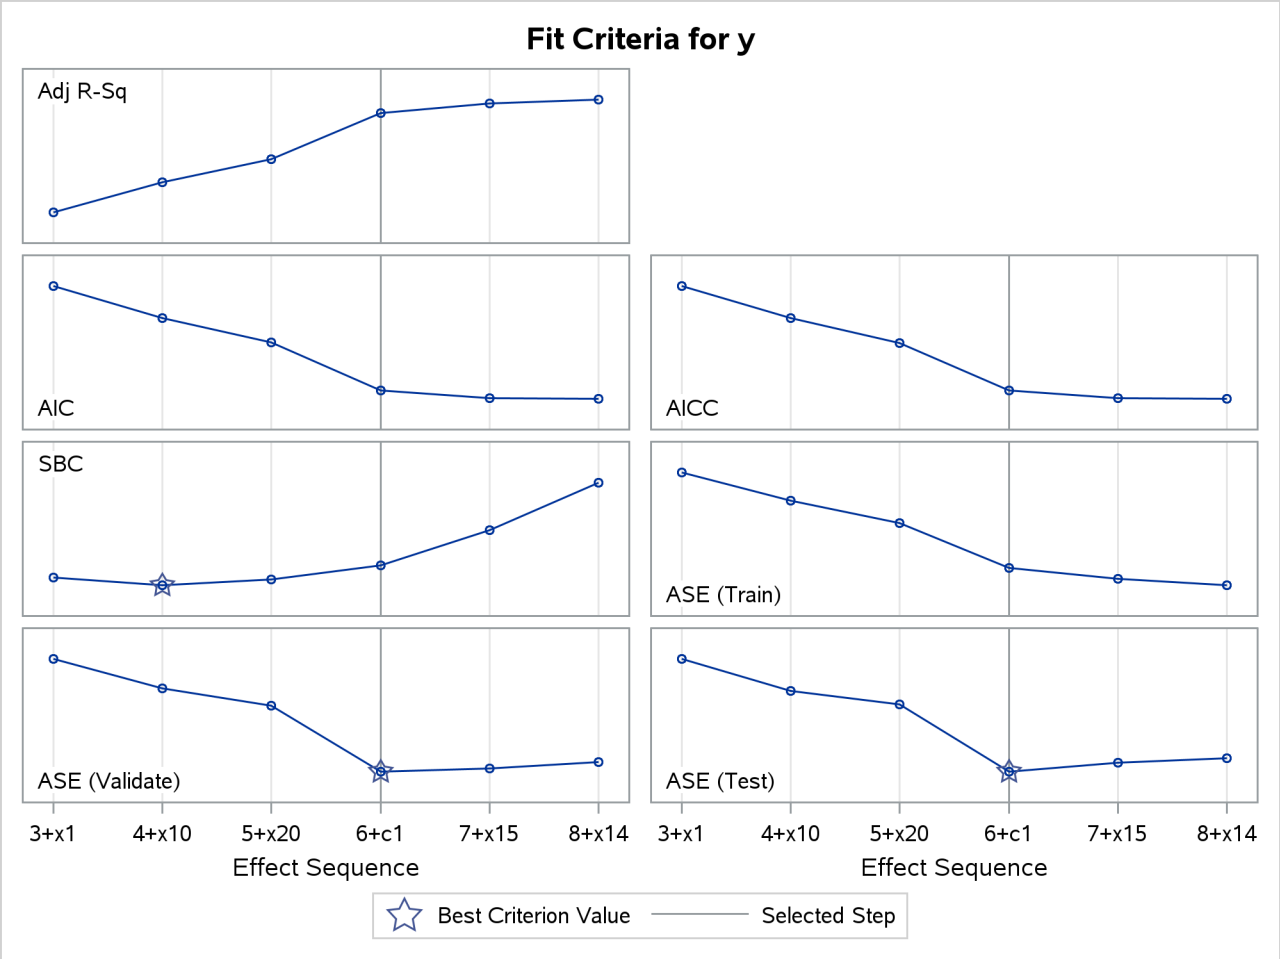
The "Coefficient Progression Panel" is shown in Figure 2.10. You can see that the standardized coefficients of the selected parameters do not vary greatly after the selected step (step 6).

Figure 2.10 Coefficient Panel

The UNPACK option for the criterion panel specifies that the individual plots in this panel be shown as separate plots. Figure 2.11 shows the plot for the AIC criterion.

Figure 2.11 AIC Criterion

Examining Specific Step Ranges



The coefficient panel, criterion panel, and average square error plot display information for all the steps examined in the selection process. In some cases, you might want to focus attention on just a particular step range. For example, it is hard to discern the variation in the criteria displayed in Figure 2.8 near the selected step because the variation in these criteria in the steps close to the selected step is small relative to the variation across all steps. You can request a range of steps to display by using the STARTSTEP= and ENDSTEP= suboptions of the PLOTS= option. The following statements provide an example:

```
proc regselect data=mylib.exampleData;
   partition rolevar=Role(train='TRAIN' validate='VAL' test='TEST');
   class c: ;
   model y = x: c: ;
   selection method=forward(stop=none choose=validate)
             plots(startstep=3 endstep=8)=criteria;
run;

ods graphics off;
```

Figure 2.12 shows the progression of the fit criteria between steps 3 and 8. Note that if the optimal value of a criterion does not occur in this specified step range, then no optimal marker appears for that criterion.

Figure 2.12 Criterion Panel for Specified Step Range

Informative Missingness

This section applies to the following procedures: GENSELECT, LOGSELECT, PHSELECT, QTRSELECT, and REGSELECT.

The concept of informative missingness is one way to account for missing values in statistical analyses and, in particular, statistical modeling. Missing values can be a problem because they reduce the amount of available data. When you work with classification variables (factors, which are levelized variables), you can treat a missing value as an actual level of the variable and allow it to participate in the analysis.

However, when continuous variables have missing values, the observation is removed from the analysis. In data that have many missing values, removing observations can reduce the amount of available data greatly,

and the sets of observations used in one model versus another model can vary based on which variables are included in the model.

Of course, there are many reasons for missing values, and substituting values for missing values has to be done with caution. For example, the famous Framingham Heart study data set contains 5,209 observations on subjects in a longitudinal study that helped understand the relationship between smoking, cholesterol, and coronary heart disease. One of the variables in the data set is AgeCHDdiag. This variable represents the age at which a patient was diagnosed with coronary heart disease (CHD). If you include this variable in a statistical model, only 1,449 observations are available, because the value cannot be observed unless a patient has experienced CHD. Including this variable acts as a filter that reduces the analysis set to the subjects who have CHD. You cannot impute the value for subjects where the variable has a missing value, because you cannot impute an age at which someone who has not had CHD would have contracted coronary heart disease.

With informative missingness, you are not so much substituting imputed values for the missing values as you are modeling the missingness. Consider a simple linear regression model:

$$y = \beta_0 + \beta_1 x + \epsilon$$

Suppose that some of the values for the regressor variable x are missing. The fitted model uses only observations for which y and x have been observed.

In order to predict the outcome y for an observation that has a missing x, either you assume that y is missing or you substitute a value (such as the average value, $\bar{x}$) for the missing x. Because the estimate for the intercept is in the simple linear regression model, the predicted value would be the average response of the nonmissing values, $\bar{y}$.

With informative missingness, you extend the model by adding extra effects for each effect that contains at least one continuous variable. In the simple linear regression model, you add one column to the model and slightly change the content of the x variable:

$$y = \beta_0 + \beta_1 x^* + \beta_2 x\_miss + \epsilon_1$$

The variable x^* contains the original values of x if they are not missing, and the average of x otherwise:

$$x^* = \begin{cases} x & \text{if } x \text{ is not missing} \\ \bar{x} & \text{otherwise} \end{cases}$$

The variable *x_miss* is a dummy variable whose value is 1 when x is missing, and 0 otherwise:

$$x\_miss = \begin{cases} 1 & \text{if } x \text{ is missing} \\ 0 & \text{otherwise} \end{cases}$$

The fitted model is not the same model that results from substituting $\bar{x}$ for the missing values during training, because the model that simply substitutes $\bar{x}$ for the missing values is

$$y = \beta_0 + \beta_1 x^* + \epsilon_2$$

The informative missing model has an extra parameter, and unless all values of *x_miss* are 0 (in which case there are no missing values), the informative missing model has a higher R-square value, because it picks up more variation.

The parameter estimate for β_2 measures the amount by which the predicted value differs from a predicted value at $\bar{x}$.

Using Validation and Test Data

This section applies to the following procedures: GAMSELECT, GENSELECT, LOGSELECT, PHSELECT, QTRSELECT, REGSELECT, and TREESPLIT.

When you have sufficient data, you can divide your data into three parts called the training, validation, and test data. During the selection process, models are fit on the training data, and the prediction errors for the models so obtained are found by using the validation data. This prediction error on the validation data can be used to decide when to terminate the selection process and to decide which model to select. Finally, after a model has been selected, the test set can be used to assess how the selected model generalizes on data that played no role in selecting the model.

In some cases, you might want to use only training and test data. For example, you might decide to use an information criterion to decide which effects to include and when to terminate the selection process. In this case, no validation data are required, but test data can still be useful in assessing the predictive performance of the selected model. In other cases, you might decide to use validation data during the selection process but forgo assessing the selected model on test data. Hastie, Tibshirani, and Friedman (2001) note that it is difficult to provide a general rule for how many observations you should assign to each role. They note that a typical split might be 50% for training and 25% each for validation and testing.

You use a PARTITION statement to logically subdivide the input data table into separate roles. You can specify the fractions of the data that you want to reserve as test data and validation data. For example, the following statements randomly divide the inData data table, reserving 50% for training and 25% each for validation and testing:

```
proc logselect data=mylib.inData;
   partition fraction(test=0.25 validate=0.25);
   ...
run;
```

You can specify the SEED= option in the PARTITION statement to create the same partition data tables for a particular number of compute nodes. However, changing the number of compute nodes changes the initial distribution of data, resulting in different partition data tables.

In some cases, you might need to exercise more control over the partitioning of the input data table. You can do this by naming both a variable in the input data table and a formatted value of that variable for each role. For example, the following statements assign roles to the observations in the inData data table that are based on the value of the variable Group in that data table. Observations whose value of Group is `'Group 1'` are assigned for testing, and those whose value is `'Group 2'` are assigned to training. All other observations are ignored.

```
proc logselect data=mylib.inData;
   partition roleVar=Group(test='Group 1' train='Group 2')
   ...
run;
```

When you have reserved observations for training, validation, and testing, a model that is fit on the training data is scored on the validation and test data, and statistics are computed separately for each of these subsets.

Using the Validation Statistic as the CHOOSE= Criterion

When you specify the CHOOSE=VALIDATE suboption of the METHOD= option in the SELECTION statement, the ASE is computed on the validation data for the models at each step of the selection process. The smallest model at any step that yields the smallest validation ASE is selected.

Using the Validation Statistic as the STOP= Criterion

When you specify the STOP=VALIDATE suboption of the METHOD= option in the SELECTION statement, the ASE is computed on the validation data for the models at each step of the selection process. At step k of the selection process, the best candidate effect to enter or leave the current model is determined and the validation ASE for this new model is computed. If this validation ASE is greater than the validation ASE for the model at step k, then the selection process terminates at step k.

Multithreading

Threading refers to the organization of computational work into multiple tasks (processing units that can be scheduled by the operating system). A task is associated with a thread. Multithreading refers to the concurrent execution of threads. When multithreading is possible, substantial performance gains can be realized compared to sequential (single-threaded) execution. The number of threads spawned by a procedure in this book is determined by your installation.

The tasks that are multithreaded by procedures in this book are primarily defined by dividing the data that are processed on a single machine among the threads—that is, the procedures implement multithreading through a data-parallel model. For example, if the input data table has 1,000 observations and the procedure is running on four threads, then 250 observations are associated with each thread. All operations that require access to the data are then multithreaded. These operations include the following (not all operations are required for all procedures):

- variable levelization
- effect levelization
- formation of the initial crossproducts matrix
- formation of approximate Hessian matrices for candidate evaluation during model selection
- objective function calculation
- gradient calculation
- Hessian calculation
- scoring of observations

In addition, operations on matrices such as sweeps can be multithreaded provided that the matrices are of sufficient size to realize performance benefits from managing multiple threads for the particular matrix operation.

Choosing an Optimization Algorithm

This section applies to the following procedures: GAMMOD, GENSELECT, LMIXED, LOGSELECT, NLMOD, and PHSELECT.

First- or Second-Order Algorithms

The factors that go into choosing a particular optimization technique for a particular problem are complex. Trial and error can be involved.

For many optimization problems, computing the gradient takes more computer time than computing the function value. Computing the Hessian sometimes takes *much* more computer time and memory than computing the gradient, especially when there are many decision variables. Unfortunately, optimization techniques that do not use some kind of Hessian approximation usually require many more iterations than techniques that do use a Hessian matrix, and as a result the total run time of these techniques is often longer. Techniques that do not use the Hessian also tend to be less reliable. For example, they can terminate more easily at stationary points than at global optima.

Table 2.24 shows which derivatives are required for each optimization technique.

Table 2.24 Derivatives Required

Algorithm	First-Order	Second-Order
TRUREG	x	x
NEWRAP	x	x
NRRIDG	x	x
QUANEW	x	-
DBLDOG	x	-
CONGRA	x	-
LBFGS	x	-
LEVMAR	x	-
NMSIMP	-	-

The second-derivative methods TRUREG, NEWRAP, and NRRIDG are best for small problems for which the Hessian matrix is not expensive to compute. Sometimes the NRRIDG algorithm can be faster than the TRUREG algorithm, but TRUREG can be more stable. The NRRIDG algorithm requires only one matrix with $p(p+1)/2$ double words; TRUREG and NEWRAP require two such matrices. Here, p denotes the number of parameters in the optimization.

The first-derivative methods QUANEW and DBLDOG are best for medium-sized problems for which the objective function and the gradient can be evaluated much faster than the Hessian. In general, the QUANEW and DBLDOG algorithms require more iterations than TRUREG, NRRIDG, and NEWRAP, but each iteration can be much faster. The QUANEW and DBLDOG algorithms require only the gradient to update an approximate Hessian, and they require slightly less memory than TRUREG or NEWRAP.

The first-derivative methods CONGRA and LBFGS are best for large problems for which the objective

function and the gradient can be computed much faster than the Hessian and for which too much memory is required to store the (approximate) Hessian. In general, the CONGRA and LBFGS algorithms require more iterations than QUANEW or DBLDOG, but each iteration can be much faster. Because CONGRA and LBFGS require only a factor of p double-word memory, many large applications can be solved only by CONGRA and LBFGS.

The no-derivative method NMSIMP is best for small problems for which derivatives are not continuous or are very difficult to compute.

The LEVMAR method is appropriate only for least squares optimization problems.

Each optimization method uses one or more convergence criteria that determine when it has converged. An algorithm is considered to have converged when any one of the convergence criteria is satisfied. For example, under the default settings, the QUANEW algorithm converges if ABSGCONV $<$ 1E–5, FCONV $< 2 \times \epsilon$, or GCONV $<$ 1E–8.

By default, procedures in this book apply the NRRIDG algorithm because it can take advantage of multi-threading in Hessian computations and inversions. If the number of parameters becomes large, specifying the QUANEW technique, which is a first-order method with good overall properties, is recommended.

Algorithm Descriptions

The following subsections provide details about each optimization technique and follow the same order as Table 2.24.

Trust Region Optimization (TRUREG)

The trust region method uses the gradient $\mathbf{g}(\boldsymbol{\beta}^{(k)})$ and the Hessian matrix $\mathbf{H}(\boldsymbol{\beta}^{(k)})$; thus, it requires that the objective function $f(\boldsymbol{\beta})$ have continuous first- and second-order derivatives inside the feasible region.

The trust region method iteratively optimizes a quadratic approximation to the nonlinear objective function within a hyperelliptic trust region with radius Δ that constrains the step size that corresponds to the quality of the quadratic approximation. The trust region method is implemented based on Dennis, Gay, and Welsch (1981), Gay (1983), and Moré and Sorensen (1983).

The trust region method performs well for small- to medium-sized problems, and it does not need many function, gradient, and Hessian calls. However, if the computation of the Hessian matrix is computationally expensive, one of the dual quasi-Newton or conjugate gradient algorithms might be more efficient.

Newton-Raphson Optimization with Line Search (NEWRAP)

The NEWRAP technique uses the gradient $\mathbf{g}(\boldsymbol{\beta}^{(k)})$ and the Hessian matrix $\mathbf{H}(\boldsymbol{\beta}^{(k)})$; thus, it requires that the objective function have continuous first- and second-order derivatives inside the feasible region. If second-order derivatives are computed efficiently and precisely, the NEWRAP method can perform well for medium-sized to large problems, and it does not need many function, gradient, and Hessian calls.

This algorithm uses a pure Newton step when the Hessian is positive-definite and when the Newton step reduces the value of the objective function successfully. Otherwise, a combination of ridging and line search is performed to compute successful steps. If the Hessian is not positive-definite, a multiple of the identity matrix is added to the Hessian matrix to make it positive-definite (Eskow and Schnabel 1991).

In each iteration, a line search is performed along the search direction to find an approximate optimum of the objective function. The line-search method uses quadratic interpolation and cubic extrapolation.

Newton-Raphson Ridge Optimization (NRRIDG)

The NRRIDG technique uses the gradient $\mathbf{g}(\boldsymbol{\beta}^{(k)})$ and the Hessian matrix $\mathbf{H}(\boldsymbol{\beta}^{(k)})$; thus, it requires that the objective function have continuous first- and second-order derivatives inside the feasible region.

This algorithm uses a pure Newton step when the Hessian is positive-definite and when the Newton step reduces the value of the objective function successfully. If at least one of these two conditions is not satisfied, a multiple of the identity matrix is added to the Hessian matrix.

Because the NRRIDG technique uses an orthogonal decomposition of the approximate Hessian, each iteration of NRRIDG can be slower than that of the NEWRAP technique, which works with a Cholesky decomposition. However, NRRIDG usually requires fewer iterations than NEWRAP.

The NRRIDG method performs well for small- to medium-sized problems, and it does not require many function, gradient, and Hessian calls. However, if the computation of the Hessian matrix is computationally expensive, one of the dual quasi-Newton or conjugate gradient algorithms might be more efficient.

Quasi-Newton Optimization (QUANEW or DUQUANEW)

The dual quasi-Newton method uses the gradient $\mathbf{g}(\boldsymbol{\beta}^{(k)})$, and it does not need to compute second-order derivatives because they are approximated. It works well for medium-sized to moderately large optimization problems, where the objective function and the gradient can be computed much faster than the Hessian. However, in general the QUANEW technique requires more iterations than the TRUREG, NEWRAP, and NRRIDG techniques, which compute second-order derivatives. The QUANEW technique provides an appropriate balance between the speed and stability required for most nonlinear mixed model applications.

The QUANEW technique implemented by procedures in this book is the dual quasi-Newton algorithm, which updates the Cholesky factor of an approximate Hessian.

In each iteration, a line search is performed along the search direction to find an approximate optimum. The line-search method uses quadratic interpolation and cubic extrapolation to obtain a step size α that satisfies the Goldstein conditions (Fletcher 1987). One of the Goldstein conditions can be violated if the feasible region defines an upper limit of the step size. Violating the left-side Goldstein condition can affect the positive-definiteness of the quasi-Newton update. In that case, either the update is skipped or the iterations are restarted with an identity matrix, resulting in the steepest descent or ascent search direction.

Double-Dogleg Optimization (DBLDOG)

The double-dogleg optimization method combines the ideas of the quasi-Newton and trust region methods. In each iteration, the double-dogleg algorithm computes the step $\mathbf{s}^{(k)}$ as the linear combination of the steepest descent or ascent search direction $\mathbf{s}_1^{(k)}$ and a quasi-Newton search direction $\mathbf{s}_2^{(k)}$:

$$\mathbf{s}^{(k)} = \alpha_1 \mathbf{s}_1^{(k)} + \alpha_2 \mathbf{s}_2^{(k)}$$

The step is requested to remain within a prespecified trust region radius (Fletcher 1987, p. 107). Thus, the DBLDOG subroutine uses the dual quasi-Newton update but does not perform a line search.

The double-dogleg optimization technique works well for medium-sized to moderately large optimization problems, where the objective function and the gradient can be computed much faster than the Hessian. The implementation is based on Dennis and Mei (1979) and Gay (1983), but it is extended for dealing with boundary and linear constraints. The DBLDOG technique generally requires more iterations than the TRUREG, NEWRAP, and NRRIDG techniques, which require second-order derivatives; however, each of the DBLDOG iterations is computationally cheap. Furthermore, the DBLDOG technique requires only gradient calls for the update of the Cholesky factor of an approximate Hessian.

Conjugate Gradient Optimization (CONGRA)

Second-order derivatives are not required by the CONGRA algorithm and are not even approximated. The CONGRA algorithm can be expensive in function and gradient calls, but it requires only $O(p)$ memory for unconstrained optimization. In general, many iterations are required to obtain a precise solution, but each of the CONGRA iterations is computationally cheap.

The CONGRA subroutine should be used for optimization problems with large p. For the unconstrained or boundary-constrained case, CONGRA requires only $O(p)$ bytes of working memory, whereas all other optimization methods require order $O(p^2)$ bytes of working memory. During p successive iterations, uninterrupted by restarts or changes in the working set, the conjugate gradient algorithm computes a cycle of p conjugate search directions. In each iteration, a line search is performed along the search direction to find an approximate optimum of the objective function. The line-search method uses quadratic interpolation and cubic extrapolation to obtain a step size α that satisfies the Goldstein conditions. One of the Goldstein conditions can be violated if the feasible region defines an upper limit for the step size.

Levenberg-Marquardt Optimization (LEVMAR)

The LEVMAR algorithm performs a highly stable optimization; however, for large problems, it consumes more memory and takes longer than the other techniques. The Levenberg-Marquardt optimization technique is a slightly improved variant of the Moré (1978) implementation.

Nelder-Mead Simplex Optimization (NMSIMP)

The Nelder-Mead simplex method does not use any derivatives and does not assume that the objective function has continuous derivatives. The objective function itself needs to be continuous. This technique is quite expensive in the number of function calls, and it might be unable to generate precise results for $p \gg 40$.

The original Nelder-Mead simplex algorithm is implemented and extended to boundary constraints. This algorithm does not compute the objective for infeasible points, but it changes the shape of the simplex adapting to the nonlinearities of the objective function. This change contributes to an increased speed of convergence and uses a special termination criterion.

Limited-Memory BFGS Optimization (LBFGS)

The limited-memory BFGS (LBFGS) method is a variation of the Broyden-Fletcher-Goldfarb-Shanno quasi-Newton (BFGS) method. In the BFGS method, a full $n \times n$ dense approximation of the inverse Hessian matrix, H, is maintained and updated at each iteration. The line-search direction d is obtained from $d = -Hg$, where g is the current gradient. However, in the LBFGS method, only the update information from the most recent m iteration histories is kept; this requires storing only $2 \times m \times n$ doubles in memory. The line-search direction d is constructed from the saved update information and current gradient. The LBFGS method is preferred for solving large-scale problems, because it uses a limited amount of computer memory and less computing time to find a line-search direction. Currently, the LBFGS method supports only two convergence criteria: FCONV and GCONV.

OutputCasTables Table

The OutputCasTables table is a special table that has information about each CAS table that is created during a CAS action execution. The information for each CAS table consists of the CAS table name, the caslib in which the table resides, and the number of columns and rows in the CAS table. Because this table is not a typical ODS table that contains analytical results, you cannot include it in the *table-spec-list* in the DISPLAYOUT statement.

The APPLYROWORDER Option

This section applies to the following procedures: BART, GENSELECT, KCLUS, LOGSELECT, MVOUTLIER, PARTITION, SUPERLEARNER, and TREESPLIT.

Procedures in this book require the input data to reside on a CAS server. Some of these procedures are sensitive to the order of the data on the CAS server, and they might provide different results when the order of the data changes or the distribution of the data across workers changes, even when options (including the seed) are the same. The listed procedures include the APPLYROWORDER option, which enables you to use a prespecified ordering of the data and a prespecified distribution of observations to threads when you perform an analysis of the data.

The APPLYROWORDER option requires you to use the **partition** action in the **table** action set. The **partition** action distributes the data to threads and workers in your distributed system according to a partition variable that you specify. All rows of data that have the same partition key value reside on the same worker and the same thread in your distributed system. In addition to the partition key, an order-by key enables you to specify the order of the rows of data on each thread of the worker. This key must be unique to each row in order to provide reproducible row ordering.

For example, you can use the CAS procedure as follows to run the **partition** action:

```
proc cas;
   action table.partition /
      table={name="inData",
        groupby={"partitionKey"},
        orderby={"orderbyKey"}
      },
      casout={name="inData2", replace=True};
run;
```

The **partition** action redistributes the data that are specified by the inData table according to the variables that are specified in the **groupby** and **orderby** parameters. The redistributed data are saved in the data table named inData2. The **groupby** parameter specifies the partition key, and the **orderby** parameter specifies the order-by key.

Only procedures that support the APPLYROWORDER option can use the data ordering that the **partition** action provides. If you want the procedure to use this data ordering, specify the APPLYROWORDER option in the PROC statement. For example, the following PROC FOREST statement indicates that you want to use the ordered inData2 data table, making use of the row order that you previously applied:

```
proc forest data=mycas.inData2 applyroworder;
   ...
run;
```

If you have not previously run the **partition** action along with the **groupby** and **orderby** parameters before running a procedure with the APPLYROWORDER option, then the procedure issues a warning and the option has no other effect.

Finally, note that even if you have the same data with the same partition keys and order-by keys, the distribution will be different between systems that have different numbers of threads or different numbers of workers.

References **129**

Overview: ASSESS Procedure

The ASSESS procedure assesses and compares supervised learning models in SAS Viya. For a supervised learning model that has a nominal target, the ASSESS procedure produces lift information and receiver operating characteristic (ROC) information. For a regression model, the ASSESS procedure performs a quantile binning of the predictions and then returns the summary statistics of the response variable for each bin. PROC ASSESS also calculates fit statistics such as average square error, mean square logarithmic error, mean absolute error, mean consequential error, and multiclass log loss.

The expected input to the ASSESS procedure is score data from supervised learning models.

PROC ASSESS Features

The ASSESS procedure can be used to select a champion model from several models or to evaluate a certain model during the model assessment phase. The following list summarizes some basic features of PROC ASSESS:

- executes analysis in parallel on multiple machines
- is multithreaded
- calculates lift and gain in each bucket based on percentile
- calculates ROC information based on cut size
- calculates popular fit statistics for regression and classification models
- performs analysis for each partition

Using CAS Sessions and CAS Engine Librefs

SAS Cloud Analytic Services (CAS) is the analytic server and associated cloud services in SAS Viya. This section describes how to create a CAS session and set up a CAS engine libref that you can use to connect to the CAS session. It assumes that you have a CAS server already available; contact your system administrator if you need help starting and terminating a server. This CAS server is identified by specifying the host on which it runs and the port on which it listens for communications. To simplify your interactions with this CAS server, the host information and port information for the server are stored as SAS option values that are retrieved automatically whenever this CAS server needs to be accessed. You can examine the host and port values for the server at your site by using the following statements:

```
proc options option=(CASHOST CASPORT);
run;
```

In addition to starting a CAS server, your system administrator might also have created a CAS session and a CAS engine libref for your use. You can define your own sessions and CAS engine librefs that connect to the CAS server as shown in the following statements:

```
cas mysess;
libname mylib cas sessref=mysess;
```

The CAS statement creates the CAS session named mysess, and the LIBNAME statement creates the mylib CAS engine libref that you use to connect to this session. It is not necessary to explicitly name the CASHOST and CASPORT of the CAS server in the CAS statement, because these values are retrieved from the corresponding SAS option values.

If you have created the mysess session, you can terminate it by using the TERMINATE option in the CAS statement as follows:

```
cas mysess terminate;
```

For more information about the CAS and LIBNAME statements, see the section "Introduction to Shared Concepts" on page 6 in Chapter 2, "Shared Concepts."

Getting Started: ASSESS Procedure

(View the complete code for this example at https://github.com/sascommunities/doc-supplement-casstat/tree/main/Examples/assess_gs.sas.)

NOTE: Input data must be in a CAS table that is accessible in your CAS session. You must refer to this table by using a two-level name. The first level must be a CAS engine libref, and the second level must be the table name. For more information, see the sections "Using CAS Sessions and CAS Engine Librefs" on page 7 and "Loading a SAS Data Set onto a CAS Server" on page 7 in Chapter 2, "Shared Concepts."

This example demonstrates how to use the ASSESS procedure to compute lift regression information and fit statistics.

The following SAS DATA step creates the SAS data table mylib.score, which is similar to score data from a linear regression, and loads the table into your CAS session:

```
data mylib.score;
   input _PartInd_ good p_good;
   datalines;
0 0.8224 0.7590
0 0.6538 0.4632
0 0.7693 0.7069
0 0.7491 0.7087
0 0.7779 0.7209
1 0.7161 0.8389
1 0.6779 0.6209
1 0.6392 0.6077
1 0.8090 0.9096
1 0.6064 0.7355
;
```

These statements assume that your CAS engine libref is named mylib, but you can substitute any appropriately defined CAS engine libref.

In this data table, the variable good is the ground truth and the variable p_good is the prediction from modeling. The variable _PartInd_ assigns each observation to one of two partitions for the analysis.

The following statements call the ASSESS procedure to compute lift regression information and fit statistics.

```
proc assess data=mylib.score nbins=2;
   var p_good;
   target good;
   by _PartInd_;
run;
```

The VAR statement specifies that the variable p_good should be analyzed in the model assessment. The TARGET statement specifies that the variable good is the response variable. The BY statement specifies that PROC ASSESS should perform the analysis separately for each value of _PartInd_.

Figure 3.1 shows the minimum, maximum, and mean of the actual and predicted values for _PartInd_=0.

Syntax: ASSESS Procedure

The following statements are available in the ASSESS procedure:

PROC ASSESS < *options* > **;**
BY *variable* **;**
FITSTAT PVAR=*variables* / **PEVENT=***"event-list"* < **DLM=***"character"* > **;**
FREQ *variable* **;**
INPUT *variable* **;**
TARGET *variables* < */options* > **;**
WEIGHT *variable* **;**

The PROC ASSESS, INPUT, and TARGET statements are required.

The following sections describe the PROC ASSESS statement and then describe the other statements in alphabetical order.

PROC ASSESS Statement

PROC ASSESS < *options* > **;**

The PROC ASSESS statement invokes the ASSESS procedure.

You can specify the following *options*:

DATA=*libref.data-table*
names the input data table for PROC ASSESS to use. The default is the most recently created data table. *libref.data-table* is a two-level name, where

libref refers to a collection of information that is defined in the LIBNAME statement and includes the library, which includes a path to the data, and a session identifier, which defaults to the active session but which can be explicitly defined in the LIBNAME statement. For more information about *libref*, see the section "Using CAS Sessions and CAS Engine Librefs" on page 112.

data-table specifies the name of the input data table.

FITSTATOUT=*libref.data-table*
specifies the name of the fit statistics results table. *libref.data-table* is a two-level name, where *libref* refers to the library, and *data-table* specifies the name of the output data table. For more information about this two-level name, see the DATA= option and the section "Using CAS Sessions and CAS Engine Librefs" on page 112.

If you specify this option, all ODS tables are suppressed. This option is valid only if you also include a FITSTAT statement.

LIFTOUT=*libref.data-table*
specifies the name of the lift results table. *libref.data-table* is a two-level name, where *libref* refers to the library, and *data-table* specifies the name of the output data table. For more information about this two-level name, see the DATA= option and the section "Using CAS Sessions and CAS Engine Librefs" on page 112.

If you specify this option, all ODS tables are suppressed.

MAXITER=*integer*
specifies the maximum number of iterations for the percentile algorithm, where *integer* must be an integer greater than or equal to 1. By default, MAXITER=5 times the value of the NBINS= option.

METHOD=EXACT | ITERATIVE
specifies the analytic method to use to compute the percentile for binning in the lift analysis.

You can specify the following values:

EXACT uses smart technology to perform an exact count to compute the percentile without global sorting in the distributed environment.

ITERATIVE uses the iterative approach to approximate the percentile in the distributed environment.

If you specify METHOD=EXACT, the MAXITER= option is ignored. By default, METHOD=ITERATIVE.

NBINS=*integer*
specifies the number of bins to use in the lift calculation, where *integer* must be an integer greater than or equal to 2.

By default, NBINS=20.

NCUTS=*integer*
specifies the number of cuts to use in the ROC calculation, where *integer* must be an integer greater than or equal to 2. The inverse of *integer* represents the step size of the quantile. For example, NCUTS=10 generates 10 intervals for ROC analysis, with each step size 0.1. You cannot specify this option when the response variable that is specified in the TARGET statement is interval.

By default, NCUTS=100.

NOMISSINGTARGET
excludes the observations that have missing values of a nominal target from assessment analysis.

NTHREADS=*number*
specifies the number of threads to use in the computation, where *number* must be an integer between 1 and 64, inclusive. The default value is the number of CPUs available in the machine.

QUANTILEBIN
improves binning allocations in the lift analysis in certain situations where data are not evenly distributed, with spikes in some intervals.

ROCOUT=*libref.data-table*
specifies the name of the ROC results table. *libref.data-table* is a two-level name, where *libref* refers to the library, and *data-table* specifies the name of the output data table. For more information about this two-level name, see the DATA= option and the section "Using CAS Sessions and CAS Engine Librefs" on page 112.

If you specify this option, all ODS tables are suppressed. This option is valid only for a nominal target (LEVEL=NOMINAL option in the TARGET statement).

USERCUTOFF=*ratio*
specifies a user-defined threshold for events, where *ratio* must be between 0 and 1, exclusive.

If you specify this option, the ROC table includes only one row, which contains the user-defined cutoff value, and the NCUTS= option is ignored.

USEDATARANGE(NROCBINS=*number* **LB=***number* **UB=***number***)**
computes the ROC-related statistics on the basis of the specified range of the input data.

You can specify the following additional suboptions:

NROCBINS=*number*
specifies the number of bins to apply when you compute ROC-related statistics on the basis of the range of the input data.

By default, NROCBINS=5000.

LB=*number*
specifies the lower-bound value of the range of the input data to apply when you compute ROC-related statistics, where *number* must be between 0 and 1, inclusive.

By default, LB=0.

UB=*number*
specifies the upper-bound value of the range of the input data to apply when you compute ROC-related statistics, where *number* must be between 0 and 1, inclusive.

By default, UB=1.

If neither the LB= option nor UB= option is specified, the ROC-related statistics are computed on the basis of the range of the input data.

BY Statement

BY *variable* **;**

The BY statement specifies one partition *variable* to be used in the predictive model. If you specify the BY statement, PROC ASSESS performs the analysis separately for each value of the BY variable. If you do not specify the BY statement, PROC ASSESS treats the entire input data as one group for analysis.

FITSTAT Statement

FITSTAT PVAR=*variables* / **PEVENT=***"event-list"* < **DLM=***"character"*> **;**

The FITSTAT statement reports the following error metrics for a nominal target: average square error, divisor of average square error, root average square error, mean consequential error, and multiclass log loss. (For an interval target, PROC ASSESS creates the following metrics by default, without your specifying the FITSTAT statement: average square error, divisor of average square error, root average square error, mean absolute error, root mean absolute error, mean square logarithmic error, and root mean square logarithmic error.)

You must specify the following options:

PVAR=*variables*
specifies the posterior probability for each level in model prediction except the variable that you specify in the INPUT statement. Duplicate *variables* are not allowed. If you specify the *variable* that is specified in the INPUT statement, it is ignored.

PEVENT="*event-list***"**
specifies the events that correspond to each *variable* in the PVAR= option. The "*event-list*" cannot include the event that corresponds to the variable in the TARGET statement. You must specify the PEVENT= and PVAR= options one after the other, in this order, and the same number of times. The maximum length of the "*event-list*" is 5,000 characters.

You can also specify the following option:

DELIMITER="*character***"**

DLM="*character***"**

specifies the delimiter that is used to separate events that you specify in the PEVENT= option. You use a delimiter when event names contain embedded spaces (for example, "Fuel Oil") or special characters (for example, ";" or "*"). You must specify the quotation marks around the "*character*". You can specify only one delimiter; combinations of delimiters are not supported. The valid values of the DELIMITER= option are " " (space), ";" (semicolon), "*" (asterisk), "." (period), and "," (comma).

By default, DELIMITER=" " (space).

If you specify a delimiter other than " " (space), PROC ASSESS treats any spaces, including empty spaces, as valid characters. You are responsible for mapping events correctly in order to obtain correct results.

FREQ Statement

FREQ *variable* **;**

The *variable* in the FREQ statement identifies a numeric variable in the input data table that contains the frequency of occurrence of each observation. PROC ASSESS treats each observation as if it appears f times, where f is the value of the FREQ *variable* for the observation. If f is not an integer, it is truncated to an integer. If f is less than 1 or missing, the observation is not used in the analysis. When you omit the FREQ statement, each observation is assigned a frequency of 1.

INPUT Statement

INPUT *variable* **;**

VAR *variable* **;**

The INPUT statement specifies the name of one *variable* to be analyzed in model assessment. When the variable specified in the TARGET statement is nominal, *variable* is the posterior probability of the event to be analyzed; when the variable specified in the TARGET statement is interval, *variable* is the predicted value.

TARGET Statement

TARGET *variable* < */options* > **;**

The TARGET statement specifies the response *variable* in supervised learning. You can specify the following *options*:

EVENT=“*string*”

specifies the formatted value of the response *variable* that represents the event. For an interval target (LEVEL=INTERVAL), the EVENT= option is ignored. For a nominal target (LEVEL=NOMINAL), the EVENT= option is required.

LEVEL=INTERVAL | NOMINAL
specifies the *variable* type.

You can specify the following values:

INTERVAL specifies that the response *variable* is interval, which must be numeric.

NOMINAL specifies that the response *variable* is nominal, also known as a classification variable, which can be numeric or character.

By default, LEVEL=INTERVAL.

WEIGHT Statement

WEIGHT *variable* **;**

The *variable* in the WEIGHT statement is used as a weight to perform a weighted analysis of ROC information and fit statistics. If specified, the WEIGHT statement is ignored for lift analysis. If you analyze ROC information and fit statistics, nonpositive or missing weights are ignored in the analysis. When the WEIGHT statement is omitted, all observations that are used in the analysis are assigned a weight of 1.

Details: ASSESS Procedure

Lift Information

In the lift information table, the number of events are first allocated to each bin based on a percentile analysis of the probability of the event. In distributed mode, the percentile analysis is based on a heuristic, so it is an estimation of the precise percentile cutoff points that are used for binning. Consequently, the resulting cutoff points might be different from the cutoff points that are based on sorting the whole data set. This difference is more likely to happen when the data set is small. If specified, the weight variable is ignored for lift analysis.

Events are allocated to bins in two ways in order to perform the analysis. One way is the baseline case, which allocates events evenly to bins with the assumption that no analytic models are applied. The second way is the predicted case, which allocates events to each bin based on probabilities from modeling. In each case, the following metrics are calculated independently:

- captured response percentage, which is the number of events in each bin divided by the total number of events
- cumulative captured response percentage, which accumulates the captured response percentages over bins
- response percentage, which is the number of events divided by the number of observations in each bin
- cumulative response percentage, which accumulates the response percentages over bins

Lift is defined as the ratio of the captured response percentage from the predicted case to the captured response percentage from the baseline case. Gain is defined as the ratio of the cumulative response percentage from the predicted case to the cumulative response percentage from the baseline case, minus one.

ROC Information

In the receiver operating characteristic (ROC) information table, the confusion matrix is calculated on the basis of the event in each cutoff point. If weight or frequency is specified, it is included in the confusion matrix computation. More terminology and the derivation of a confusion matrix are available in Fawcett (2006), Powers (2011), and Derby (2013).

The following notation is necessary for discussion of ROC information:

- m is the number of cutoff points
- n is the number of observations
- N is the sum of observation frequencies with weight in the data
- w_i is the frequency of observation i and r_i is the weight of observation i, so

$$N = \sum_{i=1}^{n} w_i r_i$$

- a_k is true positive at cutoff point k, $k \in [0, m-1]$
- b_k is false positive at cutoff point k, $k \in [0, m-1]$
- c_k is false negative at cutoff point k, $k \in [0, m-1]$

The definitions of C (area under the curve), Gini, gamma, and tau are as follows:

$$\text{C} = \frac{\mu + \frac{\theta}{2}}{\rho}$$

$$\text{Gini} = \frac{\mu - \omega}{\rho}$$

$$\text{gamma} = \frac{\mu - \omega}{\mu + \omega}$$

$$\text{tau} = \frac{\mu - \omega}{\frac{N}{2}(N-1)}$$

where:

$$\theta = \sum_{k=1}^{m} ((a_{k-1} - a_k)(b_{k-1} - b_k))$$

$$\mu = \sum_{k=2}^{m} \left((a_{k-1} - a_k) \sum_{j=1}^{k-1} (b_{j-1} - b_j) \right)$$

$$\omega = \sum_{k=1}^{m-1} \left((a_{k-1} - a_k) \sum_{j=k+1}^{m} (b_{j-1} - b_j) \right)$$

$$\rho = a_0 b_0, a_m = 0 \text{ and } b_m = 0$$

The F0.5 score at cutoff point k is extended from F1 and is defined as follows:

$$(1 + \beta^2) \frac{pr}{\beta^2 p + r}$$

where $p = \frac{a_k}{a_k + b_k}$, $r = \frac{a_k}{a_k + c_k}$, and $\beta = 0.5$. For more information about F0.5, see Kaggle Inc. (2015). The Kolmogorov-Smirnov chart and other metrics are available in Derby (2013).

Fit Statistics

The following notation is necessary for discussion of fit statistics:

- n is the number of observations
- r is the number of levels for a nominal target
- N is the sum of observation frequencies in the data
- M is the sum of observation frequencies with weight in the data
- w_i is the frequency of observation i, so

$$N = \sum_{i=1}^{n} w_i$$

- v_i is the weight of observation i, so

$$M = \sum_{i=1}^{n} w_i v_i$$

- y_i is the actual target value of observation i
- $\hat{y}_i$ is the predicted target value of observation i
- t_i is the level from the target in observation i
- $\hat{t}_i$ is the predicted level from the target in observation i
- $y_{i,j}$ is 1 if observation i is assigned to target level j; otherwise it is 0
- $p_{i,j}$ is the predicted probability that observation i is assigned to target level j

For interval targets, PROC ASSESS calculates the following metrics:

- average square error

$$\text{ASE} = \frac{1}{N}\sum_{i=1}^{n}(y_i - \hat{y}_i)^2 w_i v_i$$

- root average square error

$$\text{RASE} = \sqrt{\text{ASE}}$$

- mean square logarithmic error

$$\text{MSLE} = \frac{1}{N}\sum_{i=1}^{n}\left(\log(\hat{y}_i + 1) - \log(y_i + 1)\right)^2 w_i v_i$$

- mean absolute error

$$\text{MAE} = \frac{1}{N}\sum_{i=1}^{n}|y_i - \hat{y}_i| w_i v_i$$

For nominal targets, PROC ASSESS calculates the following metrics:

- average square error

$$\text{ASE} = \frac{1}{rN}\sum_{i=1}^{n}\sum_{j=1}^{r}(y_{i,j} - p_{i,j})^2 w_i v_i$$

- root average square error

$$\text{RASE} = \sqrt{\text{ASE}}$$

- mean consequential error (misclassification)

$$\text{MCE} = \frac{1}{M}\sum_{t_i \neq \hat{t}_i} w_i v_i$$

- multiclass log loss

$$\text{logloss} = -\frac{1}{N}\sum_{i=1}^{n}\sum_{j=1}^{r} y_{i,j}\log(p_{i,j}) w_i v_i$$

Displayed Output

The following sections describe the output that PROC ASSESS produces. The output is organized into various tables, which are discussed in the order of their appearance.

Fit Statistics

The "Fit Statistics" table contains the following error metrics for a nominal target if you specify the FITSTAT statement: average square error, divisor of average square error, root average square error, mean consequential error, and multiclass log loss.

For an interval target, the following metrics are created without specifying the FITSTAT statement: average square error, divisor of average square error, root average square error, mean absolute error, root mean absolute error, mean square logarithmic error, and root mean square logarithmic error.

Lift Information

The "Lift Information" table contains information about the lift and gain of each partition for a nominal target.

ROC Information

The "ROC Information" table contains information about the receiver operating characteristic (ROC) of each partition for a nominal target.

Lift Regression Information

The "Lift Regression Information" table contains information about lift regression for each partition for an interval target.

ODS Table Names

Each table created by the ASSESS procedure has a name associated with it, and you must use this name to refer to the table when you use ODS statements. The names of each table and a short description of the contents are listed in Table 3.1.

Table 3.1 ODS Tables Produced by PROC ASSESS

Table Name	Description	Statement	Option
FitStat	Fit statistics	FITSTAT	PVAR= and PEVENT= for a nominal target; default for interval target
LIFTInfo	Lift information	PROC ASSESS	Default for nominal target
LIFTRegInfo	Lift regression information	PROC ASSESS	Default for interval target

Table 3.1 *continued*

Table Name	Description	Statement	Option
ROCInfo	ROC information	PROC ASSESS	Default for nominal target

Examples: ASSESS Procedure

The examples in this chapter are available in the GitHub repository located at https://github.com/sascommunities/doc-supplement-casstat.

NOTE: Input data must be in a CAS table that is accessible in your CAS session. You must refer to this table by using a two-level name. The first level must be a CAS engine libref, and the second level must be the table name. For more information, see the sections "Using CAS Sessions and CAS Engine Librefs" on page 7 and "Loading a SAS Data Set onto a CAS Server" on page 7 in Chapter 2, "Shared Concepts."

Example 3.1: Assess a Model That Has a Binary Target

(View the complete code for this example (assess_ex1.sas) in the example repository.)

The following example demonstrates how to use the ASSESS procedure to compute ROC information, lift information, and fit statistics for a model that has a nominal target.

The following DATA step creates a score data table from a previously trained model. For example, the model could be a tree-based model, a neural network, or a support vector machine.

```
data mylib.score2;
   length good_bad $4;
   input _PartInd_ good_bad p_good p_bad;
   datalines;
0 good 0.6675 0.3325
0 good 0.5189 0.4811
0 good 0.6852 0.3148
0 bad  0.0615 0.9385
0 bad  0.3053 0.6947
0 bad  0.6684 0.3316
0 good 0.6422 0.3578
0 good 0.6752 0.3248
0 good 0.5396 0.4604
0 good 0.4983 0.5017
0 bad  0.1916 0.8084
0 good 0.5722 0.4278
0 good 0.7099 0.2901
0 good 0.4642 0.5358
0 good 0.4863 0.5137
1 bad  0.4942 0.5058
1 bad  0.4863 0.5137
```

```
1 bad  0.4942 0.5058
1 good 0.6118 0.3882
1 good 0.5375 0.4625
1 good 0.8132 0.1868
1 good 0.6914 0.3086
1 good 0.5700 0.4300
1 good 0.8189 0.1811
1 good 0.2614 0.7386
1 good 0.1910 0.8090
1 good 0.5129 0.4871
1 good 0.8417 0.1583
1 good 0.5500 0.4500
;
```

The following PROC ASSESS call uses five bins to do lift analysis and uses 0.2 as the incremental step size for ROC analysis:

```
proc assess data=mylib.score2 ncuts=5 nbins=5;
   var p_good;
   target good_bad / event="good" level=nominal;
   fitstat pvar=p_bad / pevent="bad" ;
   by _PartInd_;
run;
```

Output 3.1.1 shows the lift and gain for each bin in the first partition.

Output 3.1.1 Lift Regression Information for the First Partition

Overview: BART Procedure

The BART procedure fits Bayesian additive regression trees (BART) models in SAS Viya for response variables that follow a normal or binary distribution.

A BART model uses a sum-of-trees ensemble to approximate the conditional mean of a response variable (also called a target variable), given a vector of input variables (also called predictor variables). Training a BART model requires you to specify a sum-of-trees ensemble, a likelihood function, and a prior distribution on the model parameters. The BART procedure uses a Bayesian backfitting Markov chain Monte Carlo (MCMC) algorithm to generate posterior samples of the sum-of-trees ensemble and to fit the model. Predictions from the BART model are obtained by averaging predictions from the posterior samples. You can assess uncertainty in the BART model predictions by examining the variability of the posterior samples. PROC BART supports models of normally distributed response variables and probit models of binary response variables.

The sum-of-trees ensemble that is used in a BART model consists of multiple binary decision trees. A decision tree is a type of predictive model that has been developed independently in the statistics community and the machine learning community. The predictor variables that a tree model uses can be categorical or continuous. The set of all possible combinations of the predictor variables is called the predictor space. A single decision tree partitions the predictor space into a set of nonoverlapping segments. In the terminology of the tree metaphor, segments in the partition correspond to the terminal nodes, or leaves, of the tree. The partition is described by a series of splitting rules that are used to route an observation, starting from the root node of the tree, to one of the terminal nodes. The data in a leaf are used to estimate parameters that enable you to predict the value of the response.

In the terminology of machine learning, BART models are predictive models. A predictive model defines a relationship between the input variables and a target variable. The purpose of a predictive model is to predict a target value from the inputs. You create a predictive model by using training data in which the target values are known. You can then apply the model to observations in which the target is unknown. If the predictions fit the new data well, the model is said to generalize well. Good generalization is the primary goal of predictive modeling. BART models use a regularization prior for the sum-of-trees ensemble in order to limit overfitting of the training data and obtain good generalization. The regularization prior controls the complexity of the trees in the ensemble and limits the contribution of an individual tree to the ensemble prediction.

For more information about BART models, see the section “Details: BART Procedure” on page 154.

PROC BART Features

PROC BART has the following basic features:

- trains Bayesian additive regression trees (BART) models for normally distributed response data and probit models for binary response data
- provides a STORE statement to create an analytic store for the model and saves it as a binary object in a data table
- provides a FREQ statement for grouped analysis
- provides an OUTPUT statement to produce a data table that contains predicted values and other observationwise statistics
- provides a PARTITION statement to divide data into training data and test data roles
- provides a TREEPRIOR statement to specify the BART prior parameters for the sum-of-trees ensemble
- provides a GAUSSPRIOR statement to specify the BART prior parameters for a model that is fitted to normally distributed data

Because the BART procedure runs on SAS Cloud Analytic Services (CAS), it also does the following:

- enables you to run on a cluster of machines that distribute the data and the computations
- enables you to run in single-machine mode
- exploits available cores and concurrent threads

PROC BART Compared with Other SAS Procedures

The GRADBOOST and FOREST procedures both fit predictive models by using ensembles of decision trees. Although Bayesian additive regression trees (BART) are also predictive models that consist of tree ensembles, BART models differ substantially from the models that the GRADBOOST and FOREST procedures fit in terms of what you must specify to train the model, how you train the model, and how you obtain predictions from the model.

The GRADBOOST procedure uses a gradient boosting algorithm to construct a sum-of-trees ensemble (Friedman 2001). In the gradient boosting algorithm, trees are added sequentially to the ensemble. The algorithm determines the target value to use for training a new tree by evaluating the gradient of a loss function, given the current ensemble fit. Each tree that the algorithm adds to the ensemble is subject to a "learning rate" that limits the contribution of a single tree to the overall ensemble prediction. You can impose further regularization by applying penalties to the loss function and by constraining the complexity of the individual trees. Predictions from the fitted model are obtained by summing the predictions from each tree in the ensemble and multiplying the total by the learning rate. For more information about the boosting algorithm that PROC GRADBOOST implements, see the section "Boosting" (Chapter 17, *SAS Viya: Machine Learning Procedures*).

The FOREST procedure uses a bagging algorithm to construct a tree ensemble (Breiman 1996, 2001). The bagging algorithm trains each tree in the model on a sample of the input data that it takes with replacement. In addition, when you grow a tree, the input variables that are considered for splitting a node are randomly selected from all available inputs. You can impose further forms of regularization by constraining the complexity of the individual trees. Predictions from the ensemble are obtained by averaging the predictions from each tree. For more information about the bagging algorithm that PROC FOREST implements, see the section "Bagging the Data" (Chapter 11, *SAS Viya: Machine Learning Procedures*).

Bayesian additive regression trees (BART) models consist of samples of a sum-of-trees ensemble that you produce by using a Bayesian backfitting MCMC algorithm. This algorithm uses a form of Gibbs sampling to obtain posterior samples of the sum-of-trees ensemble. In contrast with the gradient boosting or bagging algorithm, when you use this algorithm to train a BART model, trees are not added to the ensemble. Instead, the Gibbs sampler successively modifies each tree in the ensemble. In BART models, you achieve regularization by using a regularization prior that places greater prior probability on simpler tree structures and applies shrinkage to the leaf parameters through the choice of their prior mean and variance. The algorithm obtains predictions from the final BART model by averaging the predictions from the posterior samples of the ensemble, and you can assess uncertainty in the model predictions on the basis of variability of the posterior samples. For more information about sampling from the posterior for a normal response model, see the section "Sampling the Posterior" on page 156.

When you train a model by using either the GRADBOOST or FOREST procedure, you must specify hyperparameters that control the process of training the individual trees. You can tune the hyperparameters manually, or you can use the AUTOTUNE statement to search for a best configuration of hyperparameter values. Training a BART model requires you to specify a prior for the sum-of-trees ensemble and rules for sampling modifications to the tree structures. As discussed by Chipman, George, and McCulloch (2010), the default BART prior can produce models that, in terms of model fit, are comparable to models that you produce by using alternative techniques, including random forests and gradient boosted trees, which are implemented using hyperparameter tuning.

Using CAS Sessions and CAS Engine Librefs

SAS Cloud Analytic Services (CAS) is the analytic server and associated cloud services in SAS Viya. This section describes how to create a CAS session and set up a CAS engine libref that you can use to connect to the CAS session. It assumes that you have a CAS server already available; contact your system administrator if you need help starting and terminating a server. This CAS server is identified by specifying the host on which it runs and the port on which it listens for communications. To simplify your interactions with this CAS server, the host information and port information for the server are stored as SAS option values that are retrieved automatically whenever this CAS server needs to be accessed. You can examine the host and port values for the server at your site by using the following statements:

```
proc options option=(CASHOST CASPORT);
run;
```

In addition to starting a CAS server, your system administrator might also have created a CAS session and a CAS engine libref for your use. You can define your own sessions and CAS engine librefs that connect to the CAS server as shown in the following statements:

```
cas mysess;
libname mylib cas sessref=mysess;
```

The CAS statement creates the CAS session named mysess, and the LIBNAME statement creates the mylib CAS engine libref that you use to connect to this session. It is not necessary to explicitly name the CASHOST and CASPORT of the CAS server in the CAS statement, because these values are retrieved from the corresponding SAS option values.

If you have created the mysess session, you can terminate it by using the TERMINATE option in the CAS statement as follows:

```
cas mysess terminate;
```

For more information about the CAS and LIBNAME statements, see the section "Introduction to Shared Concepts" on page 6 in Chapter 2, "Shared Concepts."

Getting Started: BART Procedure

(View the complete code for this example at https://github.com/sascommunities/doc-supplement-casstat/tree/main/Examples/bartgs1.sas.)

NOTE: Input data must be in a CAS table that is accessible in your CAS session. You must refer to this table by using a two-level name. The first level must be a CAS engine libref, and the second level must be the table name. For more information, see the sections "Using CAS Sessions and CAS Engine Librefs" on page 7 and "Loading a SAS Data Set onto a CAS Server" on page 7 in Chapter 2, "Shared Concepts."

This section illustrates some of the basic features of the BART procedure by analyzing data about city-cycle fuel efficiency—that is, the gas mileage of vehicles driven in urban conditions. The data can be downloaded from the UCI Machine Learning Repository (Asuncion and Newman 2007). The following DATA step creates the table autompg in your CAS session:

```
title 'Automobile MPG Study';
data mylib.Autompg;
   input MPG Cylinders Displacement Horsepower Weight
         Acceleration Year Origin Name $35.;
   datalines;

;
```

These statements assume that your CAS engine libref is named mylib, but you can substitute any appropriately defined CAS engine libref.

The data table contains nine variables. The response variable MPG is city-cycle mileage per gallon (MPG). Seven predictor variables (Cylinders, Displacement, Horsepower, Weight, Acceleration, Year, and Origin) provide vehicle attributes. Among them, Cylinders, Year, and Origin are categorical variables. The last variable, Name, contains the specific name of each vehicle model.

The following statements fit a Bayesian additive regression trees (BART) model:

```
proc bart data= mylib.autompg seed=246810;
   class cylinders year origin;
   model mpg = cylinders displacement horsepower
               weight acceleration year origin;
run;
```

The MODEL statement is required when you use the BART procedure to fit a model. If you specify a CLASS statement, it must precede the MODEL statement. The output from this analysis is presented in Figure 4.1 through Figure 4.6. Note that this example is run on a single machine with a single chain. If you run PROC BART in a distributed mode, multiple chains are used by default, and the model fit depends on the number of chains that you run.

The "Model Information" in Figure 4.1 summarizes important information about the model that you fit. Information includes the input data source, response (target) variable, bin method, missing rule, simulation size, thinning rate, and random number seed.

Figure 4.1 Model Information

Automobile MPG Study

The BART Procedure

Model Information	
Data Source	AUTOMPG
Target Variable	MPG
Distribution	Normal
Number of Trees	200
Number of Bins	50
Bin Method	Quantiles
Missing Rule	Separate
Burn-In Size	100
Simulation Size	1000
Thinning Rate	1
Random Number Seed	246810

Figure 4.2 displays the "Class Level Information" and "Number of Observations" tables. The "Class Level Information" table lists the levels of the classification variables that you specify in the CLASS statement and the ordering of the levels. The "Number of Observations" table displays the number of observations that are used in the analysis.

Figure 4.2 Class Level Information and Number of Observations

Class Level Information		
Class	**Levels**	**Values**
Cylinders	5	3 4 5 6 8
Year	13	70 71 72 73 74 75 76 77 78 79 80 81 82
Origin	3	1 2 3

Number of Observations Read	398
Number of Observations Used	398

Figure 4.3 displays the "Prior Information" table. The table summarizes the parameters that define the BART prior for the tree structure and the variance of the response variable. The BART prior parameters typically do not require hyperparameter tuning, because the default BART model tends to perform well in terms of model fit, and this performance does not change significantly if there are small changes in the prior parameters.

Figure 4.3 Prior Information

Prior Information	
Depth Zero Node Split Probability	0.95
Node Depth Power	2
Split Operation Probability	0.5
Prune Operation Probability	0.5
Leaf Variance Multiplier	2
Variance Prior Degrees of Freedom	3
Variance Prior Scale	1.522001
Variance Prior Quantile Level	0.9
Initial Variance Estimate	7.517741

Figure 4.4 displays the "Sample Information" table. This table summarizes basic information about the posterior samples of the sum-of-trees ensemble, such as the number of samples saved, the proportion of tree-modifying operations accepted, and information about the size of the trees.

Figure 4.4 Sample Information

Sample Information	
Number of Samples Kept	1000
Proportion of Burn-In Operations Accepted	0.22735
Proportion of Sampling Operations Accepted	0.21987
Minimum Number of Tree Nodes	1
Maximum Number of Tree Nodes	15
Average Number of Tree Nodes	3.5521
Minimum Tree Depth	0
Maximum Tree Depth	5
Minimum Number of Leaves	1
Maximum Number of Leaves	8
Average Number of Leaves	2.27605
Minimum Leaf Size	5
Maximum Leaf Size	398
Average Leaf Size	174.8643

Figure 4.5 displays the fit statistics for the fitted model. In this case, there is only one: the average square error (ASE).

Figure 4.5 Fit Statistics

Fit Statistics	
Average Square Error	2.89472

Finally, PROC BART displays the table shown in Figure 4.6, which shows the amount of time (in seconds) that it took to perform the various tasks in the analysis.

Figure 4.6 Procedure Timing

Task Timing		
Task	**Seconds**	**Percent**
Parsing	0.01	0.08%
Data Preparation	0.05	0.84%
Burn-In Iterations	0.55	9.07%
MCMC Sampling	5.42	89.81%
Miscellaneous	0.01	0.19%
Cleaning Up	0.00	0.01%
Total	6.04	100.00%

Syntax: BART Procedure

The following statements are available in the BART procedure:

PROC BART < *options* > **;**
BY *variables* **;**
CLASS *variable*. . . < *variable* > **;**
DISPLAY < *table-list* > < */options* > **;**
DISPLAYOUT *table-spec-list* < */options* > **;**
FREQ *variable* **;**
GAUSSPRIOR *prior-options* < */option* > **;**
MARGIN '*name*' *variable* **=** '*value*' < . . . *variable* **=** '*value*' > < / **LABEL =** '*label*' > **;**
MARGINDIFF EVENT='*margin-name*' **REF=**'*margin-name*' / < **NAME=***name* > < **LABEL=***label* > **;**
MODEL *response*=*variables* < */model-options* > **;**
OUTPUT OUT=*libref.data-table*
< **SAMPLEPRED** >< **ALPHA=***number* > < **COPYVARS=(***variables***)** >
< *keyword* < **=***name* > >. . . < *keyword* < **=***name* > > **;**
OUTPUTMARGINS *libref.data-table* **;**
PARTITION *partition-options* **;**
SAMPSUMMARY OUT=*libref.data-table* < *keyword*=*name* >. . . < *keyword*=*name* > **;**
STORE < **OUT=** >*libref.data-table* **;**
TREEPRIOR < *prior-options* > **;**

The PROC BART statement and one MODEL statement are required; you can specify only one MODEL statement. The CLASS statement can appear multiple times. If you specify a CLASS statement, it must

precede the MODEL statement. The following sections describe the PROC BART statement and then describe the other statements in alphabetical order.

PROC BART Statement

PROC BART < *options* > **;**

The PROC BART statement invokes the procedure. Table 4.1 summarizes the available options in the PROC BART statement by function. The options are described fully after the table.

Table 4.1 PROC BART Statement Options

Option	Description
Basic Options	
ALPHA=	Specifies the level for the construction of equal-tail credible intervals
APPLYROWORDER	Uses group and order information from the input data table
DATA=	Specifies the input data table
LEAFSIGMAK=	Specifies the value used to determine the prior variance for the leaf parameter
MAXTRAINTIME=	Specifies the maximum time (in seconds) for training
NOCLPRINT	Limits or suppresses the display of classification variable levels
NTREE=	Specifies the number of trees in the sum-of-trees model
RESTORE=	Specifies the input analytic store
SEED=	Sets the seed for pseudorandom number generation
MCMC Options	
NBI=	Specifies the number of burn-in iterations
NDISTCHAINS=	Specifies the number of distributed chains to run
NMC=	Specifies the number of MCMC iterations, excluding the burn-in iterations
NMCDIST=	Specifies the number of MCMC iterations for each chain, excluding the burn-in iterations, when chains are distributed
NTHIN=	Specifies the thinning rate
Memory Options	
MAPINMEM	Stores a mapping of each observation to terminal nodes in memory when the model is trained
TRAININMEM	Stores data in memory when the model is trained
Splitting Options	
ASSIGNMISSING=	Specifies how to handle missing values in predictor variables
BINMETHOD=	Specifies the method to use for binning continuous variables
MINLEAFSIZE=	Specifies the minimum number of observations per leaf
NBINS=	Specifies the number of bins to use for binning continuous variables
ORDERSPLIT=	Specifies the minimum cardinality of a categorical input for which to use splitting rules based on level ordering

ALPHA=*number*

specifies the level for the construction of equal-tail credible limits. The level is 1 – *number*. The value of *number* must be between 0 and 1, exclusive. The level applies to the credible limits for all predictive margins. The level also applies to credible limits for predictions in the output data table unless you specify a different level by using the ALPHA= option in the OUTPUT statement.

By default, ALPHA=0.05.

APPLYROWORDER

uses group and order information from the input data table. You can add this information to the input table by using the **`partition`** action in the **`table`** action set. For more information, see the section "The APPLYROWORDER Option" on page 107 in Chapter 2, "Shared Concepts." The APPLYROWORDER option is applicable to models that require the simulation of latent variables, and by default it is not enabled. If you specify this option but the table does not contain group and order information, the procedure terminates with an error.

ASSIGNMISSING=MACBIG | MACSMALL | NONE | SEPARATE

specifies how to handle missing values during the training and scoring phases.

During the training phase, PROC BART samples a primary splitting rule for a node as described in the section "Splitting Rules" on page 158. During the scoring phase, observations are assigned to a node in a tree according to the primary splitting rule if it can be applied. If the primary rule cannot be applied because of missing values or unknown categorical predictor levels, a default splitting rule is applied that assigns an observation to the larger branch of the split. An unknown level of a categorical predictor is a level that was not encountered in the training data but is encountered during scoring. The default splitting rule enables all data to be scored.

You can specify one of the following values:

MACBIG during the training phase, treats missing values for continuous predictors as the largest machine value and treats missing values for categorical predictors as a separate level. In the scoring phase, observations that have missing continuous predictor values are assigned to the right branch of the split, and observations that have an unknown categorical predictor level are assigned to the larger branch of the split.

MACSMALL during the training phase, treats missing values for continuous predictors as the smallest machine value and treats missing values for categorical predictors as a separate level. In the scoring phase, observations that have missing continuous predictor values are assigned to the left branch of the split, and observations that have an unknown categorical predictor level are assigned to the larger branch of the split.

NONE during the training phase, excludes all observations that have a missing predictor value. In the scoring phase, observations that have missing values or observations whose unknown categorical predictor level is unknown are assigned to the larger branch of the split.

SEPARATE during the training phase, treats missing values for continuous predictors as a separate group and treats missing values for categorical predictors as a separate level. In the training phase, when a split operation is sampled for a continuous predictor and there are observations that have a missing value of the splitting

variable on the node, a primary rule for routing missing values is sampled before the primary splitting rule for nonmissing values is sampled. If a continuous predictor does not have a missing value on the node that you are splitting, a primary rule for routing missing values is not sampled. In the scoring phase, observations that have an unknown categorical predictor level or have a missing continuous predictor value for a node without a primary rule for routing missing values are assigned to the larger branch of the split.

By default, ASSIGNMISSING=SEPARATE.

BINMETHOD=EVEN | QUANTILE
specifies how to bin continuous input variables before training the model. The number of bins that are created is determined by the value of the NBINS= option.

You can specify one of the following values:

EVEN discretizes continuous input variables into fixed-width bins. The width of each bin for a particular variable is calculated by subtracting the smallest value among all observations from the largest value among all observations, and then dividing the result by the number of bins.

QUANTILE discretizes continuous input variables into bins according to their quantile. The width of the bins for a particular variable is not fixed, but the number of observations in the various bins is approximately equal.

By default, BINMETHOD=QUANTILE.

DATA=*libref.data-table*
names the input data table for PROC BART to use. The default is the most recently created data table. *libref.data-table* is a two-level name, where

libref refers to a collection of information that is defined in the LIBNAME statement and includes the library, which includes a path to the data, and a session identifier, which defaults to the active session but which can be explicitly defined in the LIBNAME statement. For more information about *libref*, see the section "Using CAS Sessions and CAS Engine Librefs" on page 134.

data-table specifies the name of the input data table.

LEAFSIGMAK=*number*
specifies the *number* to be used to determine the prior variance for the leaf parameters. For more information about the tree prior, see the section "Tree Prior" on page 155.

By default, LEAFSIGMAK=2.

MAPINMEM

OBSLEAFMAPINMEM
stores a mapping of each observation to terminal nodes, or leaves, in memory when the model is trained. Storing the observation-to-leaf map in memory eliminates the need to route observations through trees when tree-modifying operations are sampled, and it can improve performance. However,

the observation-to-leaf map requires memory allocations that are, in total, proportional to the number of observations times the value of the NTREE= option.

By default, the observation-to-leaf map is not stored in memory.

MAXTRAINTIME=*number*
specifies the maximum time (in seconds) to use for model training.

By default, there is no time limit.

MINLEAFSIZE=*number*
specifies the minimum *number* of observations that each child of a split must contain in the training data in order for the split to be considered.

By default, MINLEAFSIZE=5.

NBI=*number*
specifies the *number* of burn-in iterations to perform before the procedure starts to save samples for prediction.

By default, NBI=100.

NBINS=*number*
specifies the *number* of bins to use for binning the continuous input variables.

By default, NBINS=50.

NDISTCHAINS=*number*
specifies a distributed mode that divides the MCMC sampling in a grid environment. This mode distributes training data to workers so that the specified *number* of workers have a full copy of the training data and run a separate chain. Using this option can reduce the cost of communication over the grid and allows multiple chains to be run in parallel. However, distributed mode requires more memory space for each worker. This option is not applicable when you are in single-machine mode. When NDISTCHAINS=0, a single chain is run, and each worker node is assigned a portion of the training data. Note that the fit of a BART model depends on the number of chains that you run.

By default, the *number* of chains is equal to the number of worker nodes.

NMC=*number*
specifies the *number* of iterations in the main simulation loop. This is the MCMC sample size if NTHIN=1. This option is ignored if you specify the NMCDIST= option.

By default, NMC=1000.

NMCDIST=*number*
specifies the number of MCMC iterations for each chain, excluding the burn-in iterations, when multiple chains are used. This option is not applicable when you are in single-machine mode or when NDISTCHAINS=0.

By default, the number of MCMC iterations is evenly distributed across chains, and the total number is equal to the value of the NMC= option.

NOCLPRINT<=*number*>
suppresses the display of the "Class Level Information" table if you do not specify *number*. If you specify *number*, the values of the classification variables are displayed for only those variables whose number of levels is less than *number*. Specifying a *number* helps reduce the size of the "Class Level Information" table if some classification variables have a large number of levels.

NTHIN=*number*
specifies the thinning rate of the simulation. PROC BART keeps every *number*th simulation sample and discards the rest. All the posterior statistics are calculated using the thinned samples.

By default, NTHIN=1.

NTREE=*number*
specifies the *number* of trees in a sample of the sum-of-trees ensemble.

By default, NTREE=200.

ORDERSPLIT=*number*
specifies the minimum *number* of levels for which a categorical input uses splitting rules according to level ordering. For more information about the sampling of splitting rules, see the section "Splitting Rules" on page 158.

By default, ORDERSPLIT=50.

RESTORE=*libref.data-table*
specifies the name of the analytic store that contains a model that is fitted and stored from a previous analysis. The analytic store is created by a STORE statement from a previous PROC BART call or by a **`store`** parameter that is specified in a previous **`bartGauss`** or **`bartProbit`** action call.

You can use the previously fitted model to either score data or compute predictive margins. For each task, you use the DATA= option to specify the input data table to be used. To score the input data, you specify the OUTPUT statement to create a data table that contains the observationwise predictions and statistics. To compute predictive margins relative to the covariate distribution in the input data, you specify one or more MARGIN statements. When you compute predictive margins, you can also use the MARGINDIFF statement to specify a contrast between predictive margins that is defined by different MARGIN statements. You can use the OUTPUTMARGINS statement to create an output data table that contains the predicted marginal mean for each saved sample of the ensemble.

Because the previously fitted model is stored, you cannot use statements and options specific to training a model. In particular, the CLASS, FREQ, GAUSSPRIOR, MODEL, PARTITION, STORE, and TREEPRIOR statements are not available when you specify the RESTORE= option. When you use this option, you cannot specify both the OUTPUT statement and the MARGIN statement. You must use separate PROC BART calls to score data and compute predictive margins when you use a previously fitted model.

For more information about using a previously fitted model to score new data or compute predictive margins, see "Example 4.1: Storing and Scoring" on page 164.

SEED=*number*

specifies the initial seed for random number generation for model building. The value of *number* must be an integer. If you do not specify a seed or you specify a *number* less than or equal to 0, the seed is generated by reading the time of day from the computer's clock.

TRAININMEM

stores data in memory when the model is trained. Storing the data in memory can improve performance, but it requires memory allocations that are, in total, proportional to the number of observations times the size of a row of predictors.

By default, the data are not stored in memory.

BY Statement

BY *variables* **;**

You can specify a BY statement in PROC BART to obtain separate analyses of observations in groups that are defined by the values of the BY variables. If you specify more than one BY statement, only the last one specified is used. For more information, see the discussion of BY-group processing in the "Grouping Data" section of *SAS Programmers Guide: Essentials*.

CLASS Statement

CLASS *variable. . .* < *variable* > **;**

The CLASS statement names the classification variables to be used as explanatory variables in the analysis.

DISPLAY Statement

DISPLAY < *table-list* > < / *options* > **;**

The DISPLAY statement enables you to specify a list of display tables to display or exclude. This statement is similar to the ODS SELECT, ODS EXCLUDE, and ODS TRACE statements. However, the DISPLAY statement can improve performance when a large number of tables could be generated (such as in BY-group processing). The procedure processes the DISPLAY statement on a CAS server and thus sends only a subset of ODS tables to the SAS client. Because ODS statements are processed on a SAS client, first all the generated display tables are sent to the client, and then the client creates a subset.

If you use both DISPLAY and ODS statements together, the DISPLAY statement takes precedence over the ODS statements. Note that the ODS EXCLUDE statement processes tables that are sent to the client after they have been filtered by the DISPLAY statement. In some cases, it might appear that the ODS EXCLUDE statement is taking precedence because it can further filter the tables. For more information about ODS, see *SAS Output Delivery System: Procedures Guide*.

You can specify the *table-list* as a list of table names, paths, partial pathnames, and regular expressions.

The table names that you can specify are listed in the section "ODS Table Names" on page 163. A path is a table name that is prefixed with dot-separated grouping information. For example, a

SelectionSummary table that a procedure produces during a selection routine might have the path *Bygroup1.Summary.SelectionSummary*. A partial pathname does not include all groups; for example, *SelectionSummary* and *Summary.SelectionSummary* are partial pathnames for *Bygroup1.Summary.SelectionSummary*.

When you specify a table name or partial pathname, all display tables whose paths end in the specified name are selected for display or exclusion. For example, both *SelectionSummary* and *Summary.SelectionSummary* select *Bygroup1.Summary.SelectionSummary*.

A regular expression is enclosed in forward slashes (/). For example, specifying "/tions/" selects all pathnames that contain the substring "tions"; in particular, the *Bygroup1.Summary.SelectionSummary* table is selected. Specifying "!/tions/" selects all pathnames that do not contain the substring "tions"; in particular, the *Bygroup1.Summary.SelectionSummary* table is not selected.

You can specify the following *options* after a slash (/):

CASESENSITIVE
performs a case-sensitive comparison of table names in the *table-list* to display table names when tables are subsetted for display. To preserve case, you must enclose table names in the *table-list* in quotation marks.

EXCLUDE
displays all display tables except those that you specify in the *table-list*.

EXCLUDEALL
suppresses display of all tables. This option takes precedence over the other options.

TRACE
displays the display table names, labels, and paths.

DISPLAYOUT Statement

DISPLAYOUT *table-spec-list* < / *options* > **;**

The DISPLAYOUT statement enables you to create output tables from your displayed output. This statement is similar to the ODS OUTPUT statement. For more information about ODS, see *SAS Output Delivery System: Procedures Guide*.

The *table-spec-list* specifies a list of output tables to create. Each entry in the list has either a *key=value* format or a *key* format:

key=value specifies *key* as the ODS table name, path, or partial pathname, and specifies *value* as the output table name.

key specifies *key* as the ODS table name and also as the output table name.

The ODS table names that you can specify are listed in the section "ODS Table Names" on page 163. You cannot specify the ODS table named OutputCasTables in the *table-spec-list*.

Table names and partial pathnames are discussed under the DISPLAY statement. The DISPLAYOUT statement does not support regular expressions.

You can specify the following *options* after a slash (/):

INCLUDEALL
creates output tables for all display tables. The name of the created output table is the same as the name of the corresponding display table. If you specify this option, the *table-spec-list* specification is ignored.

NOREPLACE
does not replace any existing output table of the same name.

REPEATED
replicates all output tables on all nodes.

FREQ Statement

FREQ *variable* **;**

The *variable* in the FREQ statement identifies a numeric variable in the input data table that contains the frequency of occurrence of each observation. PROC BART treats each observation as if it appears f times, where f is the value of the FREQ *variable* for the observation. If f is not an integer, it is truncated to an integer. If f is less than 1 or missing, the observation is not used in the analysis. When you omit the FREQ statement, each observation is assigned a frequency of 1.

GAUSSPRIOR Statement

GAUSSPRIOR *prior-options* < */option* > **;**

The GAUSSPRIOR statement enables you to specify the prior parameters for a model that is fitted to a normally distributed response variable. Bayesian additive regression trees (BART) models for normal data use an inverse chi square prior for the variance parameter. For more information about the BART prior for a normal data, see the section "Variance Prior" on page 156. You can use the following *prior-options* to specify the prior for the variance parameter and the initial variance estimate:

SIGMADF=*number*
specifies the degrees of freedom of the scaled inverse chi-square prior for the variance parameter. The value of *number* must be greater than or equal to 1.

By default, SIGMADF=3.

SIGMALAMBDA=*number*
specifies the scale parameter of the scaled inverse chi-square prior for the variance parameter. The value of *number* must be positive. You cannot specify both this option and the SIGMAQUANTILE= option.

By default, the scale parameter value is determined by the value of the SIGMAQUANTILE= option.

SIGMAQUANTILE=*number*
specifies the quantile level to be used to determine the scale parameter of the scaled inverse chi-square prior for the variance parameter. The value of *number* must be between 0 and 1, exclusive. You cannot specify both this option and the SIGMALAMBDA= option.

By default, SIGMAQUANTILE=0.9.

VAREST=*number*
specifies the initial value for the variance. The value of *number* must be positive.

By default, the initial variance value is determined by a least squares regression of the response variable on the predictor variables.

You can also specify the following *option*:

VARAUTOCORR=*numeric-list*
specifies the autocorrelation lags for the variance parameter.

By default, autocorrelations are computed at lags of 1, 5, 10, and 50.

MARGIN Statement

MARGIN '*name*' *variable*='*value*' < . . . *variable* = '*value*' > < / **LABEL=**'*label*' > **;**

The MARGIN statement computes a predictive margin (Lane and Nelder 1982). A predictive margin is obtained by fixing the *value* of one or more input *variables* and averaging the predicted response values over the distribution of covariates in an input data table.

The elements of the MARGIN statement are as follows:

name
identifies the predictive margin. The *name* is used in output tables, to specify event and reference levels in a MARGINDIFF statement, and to name variables in an output data table that is created by a OUTPUTMARGIN statement.

variable **=** '*value*'
identifies an input *variable* and the *value* that it is set to when you compute the predictive margin. The *variable* can be either continuous or categorical. For a categorical variable, you must specify the *value* in quotes. You can specify multiple input *variables* and the *values* that they are set to when computing the predictive margin.

In addition to the required *name* for the predictive margin, you can provide an optional *label* that is displayed in output tables when you specify the LABEL= option after a slash (/).

If you specify both the MARGIN and MODEL statements, then the predictive margins are computed by averaging the predictions from the fitted model for all observations in the training data. If you specify the MARGIN statement and the RESTORE= option in the PROC BART statement, then the predictive margins are computed by averaging the predictions from the previously fitted model that is saved in the specified analytic store for all observations in the input data table that you specify in the DATA= option in the PROC BART statement. For more information about using a previously fitted model to score and compute predictive margins, see "Example 4.1: Storing and Scoring" on page 164.

MARGINDIFF Statement

MARGINDIFF EVENT='*margin-name*' **REF=**'*margin-name*' / < **LABEL=***label* > < **NAME=***name* > **;**

The MARGINDIFF statement computes the difference between two predictive margins. You must specify the event predictive margin by using the EVENT= option and specify the reference predictive margin by using the REF= option. You identify the event and reference predictive margins by using a *margin-name* that you specify in a MARGIN statement.

You can specify the following options after a slash (/):

LABEL=*label*
labels the difference between predictive margins in output tables.

NAME=*name*
names the difference in predictive margins. A name for the difference is required if you use the OUTPUTMARGINS statement to create an output data table of the predictive margins and their differences.

MODEL Statement

MODEL *response*=*variables* < / *model-options* > **;**

The MODEL statement specifies the *response* (dependent or target) variable and the predictor (independent or explanatory) *variables*. You can specify only one MODEL statement.

You can specify the following *model-options*:

DIST=*keyword*
DISTRIBUTION=*keyword*
specifies the response distribution for the model. The *keywords* and their associated distributions are shown in Table 4.2.

Table 4.2 Built-In Distribution Functions

DISTRIBUTION=	Distribution Function
BINARY | BERNOULLI	Binary
NORMAL | GAUSSIAN | GAUSS	Normal

If you do not specify a response distribution, the BART procedure determines the response distribution as follows. If you specify a GAUSSPRIOR statement, then a Gaussian response model is used. If the response variable is a character variable or included in the CLASS statement, then a binary response model is used. A Gaussian response model is used by default if none of these conditions are met.

OFFSET=*variable*
specifies a *variable* to use as an offset for the binary response model. For more information about the BART model for binary response data, see the section "BART Model for Binary Data" on page 159.

OUTPUT Statement

OUTPUT OUT=*libref.data-table*
< **SAMPLEPRED** >< **ALPHA=***number* > < **COPYVARS=(***variables***)** >
< *keyword* < **=***name* > >. . . < *keyword* < **=***name* > > **;**

The OUTPUT statement creates a data table that contains observationwise statistics that PROC BART computes after fitting the model. To avoid data duplication when you have large data tables, the variables in the input data table are *not* included in the output data table unless you specify them in the COPYVARS= option.

The computation of the output statistics is based on the final fitted estimates. If an error occurs in fitting the model, then the output data table is not created.

You must specify the following option:

OUT=*libref.data-table*
names the output data table for PROC BART to use. You must specify this option before any other options. *libref.data-table* is a two-level name, where

libref refers to a collection of information that is defined in the LIBNAME statement and includes the library, which includes a path to where the data table is to be stored, and a session identifier, which defaults to the active session but which can be explicitly defined in the LIBNAME statement. For more information about *libref*, see the section "Using CAS Sessions and CAS Engine Librefs" on page 134.

data-table specifies the name of the output data table.

You can also specify the following syntax elements:

ALPHA=*number*
specifies the level for the construction of equal-tail credible limits. The level is 1 – *number*. The value of *number* must be between 0 and 1, exclusive.

By default, ALPHA=0.05.

COPYVAR=*variable*
COPYVARS=(*variables***)**
transfers one or more *variables* from the input data table to the output data table.

INTO< (*cutpoint***) >=<** *name* **>**
names the variable that contains the level of the response into which an observation is classified for binary response models. The default *name* is _INTO_. If the predicted probability of an observation equals or exceeds the *cutpoint*, the observation is classified as an event; otherwise it is classified as a nonevent. You can specify the *cutpoint* value as a number between 0 and 1, exclusive. The default value is 0.5.

LCL<=*name*>
computes the equal-tail lower credible limit. The default *name* is Lcl. You can set the credible limit by specifying the ALPHA= option.

PRED<=*name*>

PREDICTED<=*name*>

P<=*name*>
computes predicted values for the response variable. For observations in which the response variable is missing, the predicted values are computed even though these observations do not affect the model fit. The default *name* is Pred.

RESIDUAL<=*name*>

RESID<=*name*>

R<=*name*>
computes the raw residual, $y - \mu$, where μ is the estimate of the predicted mean. The default *name* is Residual.

ROLE<=*name*>
specifies the numeric variable that indicates the role that each observation plays in fitting the model. The default *name* is _ROLE_. Table 4.3 shows how this variable is interpreted for each observation.

Table 4.3 Role Interpretation

Value	Observation Role
0	Not used
1	Training
3	Testing

If you do not partition the input data by specifying a PARTITION statement, then the role variable value is 1 for observations that are used to fit the model and 0 for observations that are not used.

SAMPLEPRED
produces predicted values and raw residuals for each posterior sample saved for prediction if you specify the PRED and RESIDUAL keywords.

UCL<=*name*>
computes the equal-tail upper credible limit. The default *name* is Ucl. You can set the credible level by specifying the ALPHA= option.

OUTPUTMARGIN Statement

OUTPUTMARGIN *libref.data-table* **;**

The OUTPUTMARGIN statement creates an output data table that contains the predicted marginal means and differences for each posterior sample that is saved for prediction. Each row of the table contains the predicted marginal means and differences for a saved sample of the ensemble. The column name for each predictive margin is the name that you specify in a MARGIN statement, and the column name for each difference is the name that you specify in a MARGINDIFF statement.

libref.data-table is a two-level name, where *libref* refers to the library, and *data-table* specifies the name of the output data table. For more information about this two-level name, see the section "Using CAS Sessions and CAS Engine Librefs" on page 134.

PARTITION Statement

PARTITION *partition-options* **;**

The PARTITION statement specifies how to logically partition observations in the input data set into disjoint subsets for model training and testing. For more information, see the section "Using Validation and Test Data" on page 101 in Chapter 2, "Shared Concepts." Either you can designate a variable in the input data table and a set of formatted values of that variable to determine the role of each observation, or you can specify proportions to use for randomly assigning observations to each role.

You must specify exactly one of the following *partition-options*:

FRACTION(< TEST=*fraction* **>< SEED=***number* **>)**
randomly assigns specified proportions of the observations in the input data table to the roles. You specify the proportions for testing by using the TEST= suboption. The specified *fraction* must be between 0 and 1. The remaining fraction is the proportion of the observations that are assigned to the training role. The SEED= option specifies an integer that is used to start the pseudorandom number generator for random partitioning of data for training, testing, and validation. If you omit the SEED= option, or if the SEED= option value is less than or equal to 0, the seed is generated by reading the time of day from the computer's clock.

ROLE=*variable***(< TEST='***value***' >< TRAIN='***value***' >)**

ROLEVAR=*variable***(< TEST='***value***' >< TRAIN='***value***' >)**
names the *variable* in the input data table whose values are used to assign roles to each observation. You cannot also use this variable as an analysis variable in other statements or options. The TEST= and TRAIN= suboptions specify the formatted values of this variable that are used to assign observation roles. If you omit the TRAIN= suboption, then all observations whose role is not determined by the TEST= suboption are assigned to the training role. If you omit both the TEST= and TRAIN= suboptions, data partitioning is not performed.

SAMPSUMMARY Statement

SAMPSUMMARY OUT=*libref.data-table* < *keyword*=*name*>. . . < *keyword*=*name*> ;

The SAMPSUMMARY statement creates a data table that contains a summary of the sum-of-trees ensemble samples.

You must specify the following option:

OUT=*libref.data-table*
names the output data table for PROC BART to use. You must specify this option before any other options. *libref.data-table* is a two-level name, where

libref refers to a collection of information that is defined in the LIBNAME statement and includes the library, which includes a path to where the data table is to be stored, and a session identifier, which defaults to the active session but which can be explicitly defined in the LIBNAME statement. For more information about *libref*, see the section "Using CAS Sessions and CAS Engine Librefs" on page 134.

data-table specifies the name of the output data table.

You can also specify the following *keywords*:

AVGNODE< =*name* **>**
names the variable that contains the average number of nodes per tree in the sample. The default *name* is AvgNode.

PROPACCEPTED< =*name* **>**
names the variable that contains the proportion of accepted tree modifications for the sample. The default *name* is PropAccepted.

SAMPSAVED< =*name* **>**
names the variable that contains an indicator for whether the sample is saved for prediction. The default *name* is SampSaved.

VARIANCE< =*name* **>**
names the variable that contains the sampled variance for the normal response model. The default *name* is Variance.

STORE Statement

STORE < **OUT=** >*libref.data-table* **;**

The STORE statement saves the context and results of the statistical analysis. The resulting analytic store has a binary file format that you cannot modify. An example of analytic store technology is to perform a time-consuming analysis and to store its results by using the STORE statement. Later you can perform specific statistical analysis tasks that are based on the saved results of the previous analysis, without having to fit the model again. You can process the contents of the analytic store by using the RESTORE= option, the ASTORE procedure, the **`bartScore`** and **`bartScoreMargin`** actions in the **`bart`** action set, or the **`score`** action in the **`aStore`** action set.

libref.data-table is a two-level name, where *libref* refers to the library, and *data-table* specifies the name of the output data table. For more information about this two-level name, see the section "Using CAS Sessions and CAS Engine Librefs" on page 134.

TREEPRIOR Statement

TREEPRIOR < *prior-options* > **;**

The TREEPRIOR statement enables you to specify the regularization prior for the sum-of-trees ensemble. For more information about the regularization prior, see the section "Tree Prior" on page 155. You can use the following *prior-options* to specify the regularization prior for the sum-of-trees ensemble:

DEPTHBASE=*number*
specifies the base probability for splitting an internal node as a function of its depth from the root. A larger base probability value makes splitting a node more likely. The value of *number* must be between 0 and 1, exclusive.

By default, DEPTHBASE=0.95.

DEPTHPOWER=*number*
specifies the power parameter to be used to compute the probability of splitting an internal node as a function of its depth from the root. A larger depth power value decreases the probability of splitting a node. The value of *number* must be positive.

By default, DEPTHPOWER=2.

PPRUNE=*number*
specifies the probability of sampling the operation of pruning a terminal node for the tree sampling algorithm. The value of *number* must be between 0 and 1, exclusive, and if you specify both the PSPLIT= and PPRUNE= options, their values must sum to 1. If you specify the PSPLIT= option but not the PPRUNE= option, the PPRUNE= option is set to 1 minus the PSPLIT= option value.

By default, PPRUNE=0.5.

PSPLIT=*number*

specifies the probability of sampling the operation of splitting a terminal node for the tree sampling algorithm. The value of *number* must be between 0 and 1, exclusive, and if you specify both the PSPLIT= and PPRUNE= options, their values must sum to 1. If you specify the PPRUNE= option but not the PSPLIT= option, the PSPLIT= option is set to 1 minus the PPRUNE= option value.

By default, PSPLIT=0.5.

Details: BART Procedure

Missing Values

Any observation that has missing values for the response or frequency variable is excluded from training and evaluating the model. The ASSIGNMISSING= option determines how PROC BART handles observations that have missing input values. By default, during the training phase missing values for a categorical predictor are treated as a separate level. When a node is split on a continuous predictor, by default if there are observations in which the splitting variable has missing values, a separate rule for routing missing values is sampled before the splitting rule for nonmissing values is sampled. An alternative strategy is to exclude observations that have missing input values from the training phase, or to treat a continuous predictor that has a missing value as either the smallest or largest machine value.

In the scoring phase, observations whose values are not covered by a node's primary splitting rule are assigned to the larger branch of the split. An observation can have a value that is not covered by a primary splitting rule for the following reasons. For a node that is split by using a categorical predictor, an observation that has a level that did not occur in the training data is always uncovered by the splitting rule. In addition, when a node is split on a categorical predictor by using an unordered splitting rule, any observation with a level of the splitting variable that did not occur in the training data on that node is uncovered by the splitting rule. When ASSIGNMISSING=NONE, any observation that has a missing predictor value is uncovered by the splitting rule.

For a node that is split by using a continuous predictor, when ASSIGNMISSING=SEPARATE, an observation that has a missing continuous predictor value is uncovered by the splitting rule if there is no separate rule for missing values. A separate rule for missing values is not sampled when, in the training data, all observations on the node have nonmissing values of the splitting variable.

For more information about how splitting rules are sampled, see the section "Splitting Rules" on page 158.

BART Model for Normal Data

For a response y assumed to follow a normal distribution,

$$y = f(\boldsymbol{x}) + \epsilon \quad \epsilon \sim N(0, \sigma^2)$$

a Bayesian additive regression trees (BART) model uses a sum-of-trees ensemble to approximate $f(\boldsymbol{x})$, the conditional mean of y given the vector of predictors $\boldsymbol{x}$ (Chipman, George, and McCulloch 2010). In addition to requiring you to specify the vector of predictors and the number of trees to use in the ensemble, the BART model requires you to specify a prior for the tree structure, the tree parameters, and the variance parameter σ^2.

The following definitions describe components of the BART prior:

- m denotes the number of trees in the ensemble.
- T_j denotes the structure of the jth tree.
- M_j denotes the set of terminal node, or leaf, parameters in the jth tree.
- b_j denotes the number of terminal nodes in the jth tree.
- $\mu_{\ell j}$ denotes the terminal node parameter associated with the ℓth terminal node in the jth tree.

The BART prior is assumed to be of the following form:

$$\begin{aligned} p\left(T_1, M_1, \ldots, T_m, M_m, \sigma^2\right) &= \prod_{j=1}^{m} p\left(T_j, M_j\right) p(\sigma^2) \\ &= \prod_{j=1}^{m} p\left(M_j \mid T_j\right) p\left(T_j\right) p(\sigma^2) \\ &= \prod_{j=1}^{m} \prod_{\ell=1}^{b_j} p\left(\mu_{\ell j} \mid T_j\right) p\left(T_j\right) p(\sigma^2) \end{aligned}$$

Priors of this form assume independence between the tree structures and conditionally independent terminal node parameters, given the tree structure. The priors for the tree structure $p\left(T_j\right)$, the terminal node parameters $p\left(\mu_{\ell j} \mid T_j\right)$, and the variance term $p\left(\sigma^2\right)$ are chosen to form a regularization prior that limits the contribution of a single tree to the model fit. The use of a regularization prior enforces the so-called weak learner property on the individual trees (Chipman, George, and McCulloch 2010).

Tree Prior

The tree prior $p\left(T_j\right)$ is based on the recommendations of Chipman, George, and McCulloch (1998). For a node η that has depth d from the root node, the probability of the node being split is given by

$$\alpha(1+d)^{-\beta} \quad \alpha \in (0,1),\ \beta \in [0, \infty)$$

As part of the regularization prior, the base split probability α and depth power parameter β are chosen to assign higher prior probability to smaller trees. The recommended distribution for sampling the split

rule is determined by two components: first, a distribution for selecting which variable is used to split the node; and second, a distribution for selecting the split criterion, given the selected variable. When you train the model, you can restrict the set of feasible splitting rules by requiring each terminal node to contain a minimum number of observations. The BART procedure uses a uniform distribution to sample both the splitting variable and the splitting criterion. You can specify the parameters of the tree prior by using the TREEPRIOR statement.

The leaf parameters $p\left(\mu_{\ell j} \mid T_j\right)$ use a normal prior that has mean μ_μ and variance σ_μ^2. Given the assumed form of the BART prior, the conditional mean of the response, given the predictor variables, $f(\boldsymbol{x}) = E\left[Y \mid \boldsymbol{X}\right]$, is the sum of m independent and identically distributed (iid) normal random variables and has mean $m\mu_\mu$ and variance $m\sigma_\mu^2$. As described by Chipman, George, and McCulloch (2010), the parameters μ_μ and σ_μ^2 are chosen to assign high probability to values within the range of the training data. In particular, given a value of $k > 0$ the parameters μ_μ and σ_μ^2 are chosen to satisfy $y_{\max} = m\mu_\mu + k\sqrt{m}\sigma_\mu$ and $y_{\min} = m\mu_\mu - k\sqrt{m}\sigma_\mu$. For $k = 2$, these parameters result in an approximately 95% prior probability for the event $f(\boldsymbol{x}) \in (y_{\min}, y_{\max})$.

For a specified value of k, you can simplify identifying the values of μ_μ and σ_μ^2 by considering a linear transformation of the response variable that results in a new range of $(-0.5, 0.5)$. After such a transformation, the leaf parameter prior would be given by a normal prior that has mean 0 and variance $\frac{0.5}{k\sqrt{m}}$. As noted by Chipman, George, and McCulloch (2010), these choices of parameter values limit the contribution of a single tree and result in a decreasing prior variance for $\mu_{\ell j}$ as the number of trees in the ensemble m or the choice of parameter k increases. You can specify the value of k that is used to determine the prior variance of the leaf parameter by using the LEAFSIGMAK= option in the PROC BART statement.

Variance Prior

The prior for the variance $p\left(\sigma^2\right)$ is chosen to follow a scaled inverse chi-square distribution that has degrees of freedom υ and scale parameter λ. As described by Chipman, George, and McCulloch (2010), the choice of parameters υ and λ can be informed by the training data. Namely, for specified degrees of freedom υ, quantile level q, and estimate for the variance $\hat{\sigma}^2$, you can choose the scale parameter to satisfy $p\left(\sigma^2 < \hat{\sigma}^2\right) = q$. You can specify the parameters that are used to determine the prior for the variance parameter by using the GAUSSPRIOR statement.

Sampling the Posterior

Given a training data set, a Bayesian backfitting MCMC algorithm is used to draw samples from the posterior distribution (Chipman, George, and McCulloch 2010). This algorithm is a form of Gibbs sampling that can be described as follows. Let $\boldsymbol{y}$ denote the vector of training data response values, and let $\boldsymbol{T}_{-j}$ denote the tree structures for the $m-1$ trees in the ensemble, excluding the jth tree. Similarly, let $\boldsymbol{M}_{-j}$ denote the set of all leaf parameters, excluding the jth tree parameters. Each iteration of the sampling algorithms takes m consecutive draws, $j = 1, \ldots, m$, from

$$T_j, M_j \mid \boldsymbol{T}_{-j}, \boldsymbol{M}_{-j}, \boldsymbol{y}, \sigma^2$$

followed by a draw from

$$\sigma^2 \mid T_1, M_1, \ldots, T_m, M_m, \boldsymbol{y}$$

As described by Chipman, George, and McCulloch (2010), the draws for the tree structures T_j and leaf parameters M_j are simplified by observing that their conditional distribution depends on $\boldsymbol{T}_{-j}$, $\boldsymbol{M}_{-j}$, and $\boldsymbol{y}$

only through the partial residuals for the fit excluding the jth tree. Moreover, the choice of the conjugate normal prior for the leaf parameters allows for the sampling of T_j and M_j to be carried out in two steps. Let $\boldsymbol{r}_j$ denote the partial residuals that are based on the fit, excluding the jth tree. You then obtain the samples for T_j and M_j by taking successive draws from

$$T_j \mid \boldsymbol{r}_j, \sigma^2$$
$$M_j \mid T_j, \boldsymbol{r}_j, \sigma^2$$

The draws for the tree structure T_j are obtained by using the Metropolis-Hastings sampling algorithm described by Chipman, George, and McCulloch (1998). This algorithm considers sampling from four operations that modify the tree structure—namely, pruning a pair of terminal nodes, splitting a terminal node, changing the splitting rule of an internal node, or swapping a splitting rule between a parent node and a child node. The BART procedure considers only pruning and splitting operations. As described in Pratola et al. (2014), although the changing and swapping operations significantly improve the fit of single-tree models, these operations have less impact on the sum-of-trees ensemble BART models. Limiting the tree modifications to only pruning and splitting operations was observed to have a limited effect on model fit while providing a significant computational benefit.

Let T_{new} denote the sampled modification to the tree structure T_j, and let $q(\cdot \mid \cdot)$ denote the proposal density. The proposed modification is then accepted with the probability

$$\alpha = \min\left\{ \frac{q(T_j \mid T_{\text{new}})\, p\left(\boldsymbol{r}_j \mid T_{\text{new}}, \sigma^2\right)\, p\left(T_{\text{new}}\right)}{q\left(T_{\text{new}} \mid T_j\right)\, p\left(\boldsymbol{r}_j \mid T_j, \sigma^2\right)\, p\left(T_j\right)}, 1 \right\}$$

After the proposed operation is accepted or rejected, a draw is taken for the set of leaf parameters M_j, and the partial residuals $\boldsymbol{r}_{j+1}$ are then updated for sampling the $j+1$th tree structure T_{j+1} and the $j+1$th set of leaf parameters M_{j+1}.

To begin the sampling, the BART procedure initializes the ensemble with m single-node trees, or stumps. By default, 100 burn-in iterations are performed before the main simulation loop of 1,000 iterations. Samples from the main simulation loop are saved for prediction and computing posterior statistics. You can use the NTHIN= option to specify a thinning rate for the main simulation. Thinning is often used to reduce the correlation among posterior sample draws. When you apply thinning, the number of samples that are saved for prediction is $\left\lceil \frac{\text{NMC}}{\text{NTHIN}} \right\rceil$. For more information about Markov chain sample size, burn-in, and thinning, see the section "Burn-In, Thinning, and Markov Chain Samples" (Chapter 8, *SAS/STAT User's Guide*) in Chapter 8, "Introduction to Bayesian Analysis Procedures" (*SAS/STAT User's Guide*).

When you run PROC BART on a cluster of machines, you can use a distributed mode that divides the MCMC samples. By default, each worker node in the cluster has a full copy of the training data and runs a separate chain. You can specify the number of separate chains by using the NDISTCHAINS= option in the PROC BART statement. Specifying NDISTCHAINS=0 requests the use of a single chain in which each worker node is assigned a portion of the training data. Each chain performs the number of burn-in iterations that you specify in the NBI= option in the PROC BART statement. By default, the size of the main simulation loop for each chain is set so that the total number of samples that are saved across chains is equal to $\left\lceil \frac{\text{NMC}}{\text{NTHIN}} \right\rceil$, the number of samples that would be saved if you used a single chain. Alternatively, you can use the NMCDIST= option in the PROC BART statement to specify the main simulation loop size for each chain. Thinning is applied separately to each chain. Note that the fit of a BART model depends on the number of chains that you run.

Predictions from the trained model are obtained by averaging predictions from each of the saved posterior samples. Uncertainty in the model predictions can be assessed on the basis of variability of the posterior samples.

Splitting Rules

PROC BART samples proposed splitting operations by first sampling a terminal node to split, then sampling a variable to split on, and finally sampling a splitting rule for that variable. At each step, the samples are taken uniformly from the set of feasible options. Feasibility of a split is determined by the MINLEAFSIZE= option in the PROC BART statement, which specifies the minimum number of training observations per leaf. The following sections describe how splitting rules for continuous and categorical predictors are sampled.

Continuous Predictors

Splitting rules for a continuous predictor x are of the form $x < c$. PROC BART bins continuous predictors and samples the values of c from the right bin endpoints. You specify the number of bins and the method that is used to bin continuous predictors by using the NBINS= and BINMETHOD= options, respectively, in the PROC BART statement. Observations that have missing values do not contribute to the computation of the bin endpoints.

The ASSIGNMISSING= option in the PROC BART statement determines how to handle missing values during the training and scoring phases. During the training phase, by default observations with missing values are treated as a separate group. If the node that is being split has observations with missing values of the split variable x, a separate splitting rule is sampled for the missing group before the splitting rule for nonmissing values is sampled. During the scoring phase, if an observation has a missing value and the node has a rule for routing the missing group, that rule is applied. If the node does not have a separate rule for routing the missing group, observations with missing values are assigned to the larger branch of the split. Alternatively, observations with missing values could be treated as the largest machine value or the smallest machine value, or they could be excluded from the training phase. For more information about how PROC BART handles missing values, see the section "Missing Values" on page 154.

Categorical Predictors

Splitting rules for categorical predictors x can be either ordered or unordered. Which type of splitting rules the procedure uses for a categorical predictor is determined by the cardinality of the predictor and the value of the ORDERSPLIT= option in the PROC BART statement. Categorical predictors whose cardinality is greater than or equal to the value of the ORDERSPLIT= option use ordered splitting rules, and predictors whose cardinality is less than the value of the ORDERSPLIT= option use unordered splitting rules.

Ordered splitting rules are based on the sorted level ordering of the variable as determined by the levelization process. These rules are of the form $x < l$, where x denotes the observed level order and l is an integer value. Unordered splitting rules are of the form $x \in C$, where C denotes a set of levels. The set C is determined by randomly assigning levels to the left or right branch of a split. Assuming that a categorical predictor has n levels on a node, each with a frequency greater than the minimum leaf size, there are $n - 1$ possible ordered splitting rules and 2^{n-1} unordered splitting rules. The use of ordered or unordered splitting rules is determined by the cardinality of the variable, not the number of levels that occur on the node that is being split. The use of ordered splitting rules can significantly decrease the amount of memory that is needed to represent the fitted model when there are high-cardinality input variables.

The ASSIGNMISSING= option in the PROC BART statement determines how to handle missing values during the training and scoring phases. By default, during the training phase, missing values are treated as a separate level. During the scoring phase, an observation whose level is unknown is assigned to the larger branch of the split. An observation has an unknown level if the level does not occur in the training data or does not occur in the training data on a node that has an unordered splitting rule. Alternatively, observations that have missing values could be excluded from the training phase. For more information about how missing values are handled, see the section "Missing Values" on page 154.

BART Model for Binary Data

As described by Chipman, George, and McCulloch (2010), a probit BART model can be used to analyze binary response data.

The probit BART model has the following components:

- Φ denotes the standard normal cumulative distribution function
- $g_j(\boldsymbol{x})$ denotes the prediction function that corresponds to the jth tree defined by T_j and M_j
- $G(\boldsymbol{x})$ denotes the sum-of-trees prediction function
- c denotes an offset variable

The BART probit model assumes that the probability of an event is given by

$$P\left(Y = 1 \mid \boldsymbol{x}\right) = \Phi\left(G(\boldsymbol{x}) + c\right)$$

The regularization prior for the probit model inherits many properties of the prior for the Gaussian model. For more information about the regularization prior for Gaussian BART models, see the section "BART Model for Normal Data" on page 155.

Like the Gaussian BART model, the probit BART model assumes independent tree structures and conditionally independent terminal node parameters, given the tree structure. The prior probability of a node being split is also given by the same function of the node's depth. For more information about the tree prior, see the section "Tree Prior" on page 155. The differences between the Gaussian and probit BART models are related to the variance parameter σ^2, the prior that is used for the leaf parameters $\mu_{\ell j}$, the presence of an offset variable c, and the algorithm that is used to generate posterior samples of the sum-of-trees ensemble. The remainder of this section elaborates on these differences.

As described by Chipman, George, and McCulloch (2010), samples of the sum-of-trees ensemble for probit models are produced by a Gibbs sampling algorithm that is similar to the algorithm that is used for Gaussian models but involves the addition of latent variables $Z_i, i = 1, \ldots, n$. The latent variables Z_i are assumed to be independent and identically distributed (iid) normal random variables with mean $G(\boldsymbol{x}_i) + c$ and variance 1. Moreover, the latent variables are assumed to be related to the observed response y_i by

$$y_i = 1 \text{ if } Z_i > 0 \quad \text{and} \quad y_i = 0 \text{ if } Z_i \leq 0$$

Conditional on the observed response values, the latent variables Z_i therefore follow the truncated normal distributions

$$Z_i \mid y_i = 1 \sim \max\left\{N(G(\boldsymbol{x}_i + c), 1), 0\right\} \quad \text{and} \quad Z_i \mid y_i = 0 \sim \min\left\{N(G(\boldsymbol{x}_i + c), 1), 0\right\}$$

With these assumptions, the latent variables are used to sample updates to the tree structures and leaf parameters. The algorithm for sampling these updates follows the same process that is used for Gaussian models, but the observed response values are replaced by the sampled values of the latent variables. For more information about the sampling algorithm that is used for Gaussian models, see the section "Sampling the Posterior" on page 156.

For the latent variables, the probit BART model assumes a prior of the form

$$p\left(T_1, M_1, \ldots, T_m, M_m\right) = \prod_{j=1}^{m} \prod_{\ell=1}^{b_j} p\left(\mu_{\ell j} \mid T_j\right) p\left(T_j\right)$$

Like the Gaussian model, the probit model uses a normal prior for the leaf parameters μ_{ℓ_j} that enforces the weak learner property. But in contrast to the Gaussian model, the prior mean and variance do not depend on the range of the observed data. For a value of $k > 0$, the prior mean and variance for the probit model leaf parameters are

$$\mu_\mu = 0 \quad \text{and} \quad \sigma_\mu = \frac{3}{k\sqrt{m}}$$

This choice for the prior mean and variance places a greater prior probability on values of $G(\boldsymbol{x})$ within the range $(-3, 3)$ and applies regularization to $G(\boldsymbol{x})$, shrinking its values toward 0. You can specify the value of k that determines the prior variance of the leaf parameter by using the LEAFSIGMAK= option in the PROC BART statement.

Each iteration of the Gibbs sampling algorithm for probit models begins by sampling values of $z_i \mid y_i$ for each observation $i = 1, \ldots, n$. Let $\boldsymbol{z}$ denote the vector of sampled values, and let $\boldsymbol{T}_{-j}$ denote the tree structures for the $m - 1$ trees in the ensemble, excluding the jth tree. Similarly, let $\boldsymbol{M}_{-j}$ denote the set of all leaf parameters, excluding the jth tree parameters. Then, for each tree T_j and set of leaf parameters M_j, $j = 1, \ldots, m$, samples are taken from

$$T_j, M_j \mid \boldsymbol{T}_{-j}, \boldsymbol{M}_{-j}, \boldsymbol{z}$$

As with the algorithm that is used for Gaussian models, the updates for the tree structure T_j and M_j can be made in two steps. First, an update to the tree structure is sampled, and then an update to the leaf parameters, given the updated tree structure, is sampled. The proposal density for modifying the tree structure and the probability of accepting a proposed modification to the tree structure are determined by using the same expressions that are described in the section "Sampling the Posterior" on page 156.

By default, for probit models, the BART procedure determines the value of the offset variable c on the basis of the proportion of events $y_i = 1$ that occur in the training data. Alternatively, you can use the OFFSET= option in the MODEL statement to specify an offset variable, in which case the offset values can be different for each observation.

Computational Resources

The Bayesian additive regression trees (BART) algorithm is computationally intensive. For each posterior sample, the modifications to each tree are sampled sequentially, and each tree modification requires at least one pass through the data. As a result, for large data sets the time that PROC BART spends generating the posterior samples and training the model can be significant. You can use the MAXTRAINTIME= option in the PROC BART statement to specify a maximum time (in seconds) for training to model.

PROC BART also supports options that you can use to reduce the time that it takes to train the model. However, each of these options can require a significant amount of memory and might not be suitable for very large data sets.

You can use the TRAININMEM option in the PROC BART statement to store the data in memory when the model is trained. Storing the data in memory can reduce the time that it takes to access data during the sampling of tree modifications. This option requires memory allocations that are in total proportional to the number of observations times the size of an input row. By default, the data are not stored in memory during model training.

You can use the MAPINMEM option in the PROC BART statement to store a mapping of each observation to terminal nodes, or leaves, in memory during model training. Storing a mapping of each observation to the terminal nodes that it corresponds to removes the need to route an observation through a tree when you are sampling updates to a tree's structure and its leaf parameters. This option requires memory allocations that are in total proportional to the number of observations times the number of trees. By default, the observation-to-leaf mapping is not stored in memory during model training.

When PROC BART is run on a cluster of machines, you can run multiple chains and divide the MCMC samples across worker nodes. In addition to allowing for multiple chains to be run in parallel, distributed mode can reduce the time that it takes for communications across the cluster of machines. This mode requires distributing the training data to each worker so that each worker that runs a separate chain has a full copy of the training data. This option is not applicable in single-machine mode. By default, distributed mode is used when PROC BART is run on a cluster of machines. You can use the NDISTCHAINS= option in the PROC BART statement to specify the number of distributed chains to use. When NDISTCHAINS=0, a single chain is run, and each worker node is assigned a portion of the training data. Note that the fit of a BART model depends on the number of chains that you run.

Displayed Output

The following sections describe the output that PROC BART produces. The output is organized into various tables, which are discussed in order of their appearance.

Model Information

The "Model Information" table displays basic information about the model, such as the input data, response variable, frequency variable, MCMC burn-in size, simulation size, thinning rate, and number of trees in the ensemble samples.

Class Information

The "Class Level Information" table lists the levels of every variable that you specify in the CLASS statement. You should check this information to make sure that it is correct. You can suppress the "Class Level Information" table completely or partially by specifying the NOCLPRINT= option in the PROC BART statement.

Number of Observations

The "Number of Observations" table displays the number of observations that are read from the input data table and the number of observations that are used in the analysis. If you specify a FREQ statement, the table displays the sum of the frequencies that are read and used.

Response Profile

The "Response Profile" table displays the ordered value from which the BART procedure determines the probability that is being modeled as an event in a binary model. For each response category level, the frequency that is used in the analysis is reported. For a binary model, the note that follows the "Response Profile" table indicates which outcome is modeled as the event. If you specify a PARTITION statement, the table displays the values for each role.

Prior Information

The "Prior Information" table displays basic information about the model prior, such as the parameters for the tree prior and the prior for the variance parameter for a normal response variable.

Chain Information

The "Chain Information" table displays information about the number of MCMC samples that are saved from each chain. This table is produced only when you run multiple chains.

Sample Information

The "Sample Information" table displays basic information about the posterior samples of the sum-of-trees ensemble, such as the number of samples saved, the proportion of operations accepted, and information about the size of the trees.

Variance Autocorrelations

The "Variance Autocorrelations" table displays the first-order autocorrelations of the posterior samples for the variance parameter of a normally distributed response. By default, PROC BART displays lag 1, 5, 10, and 50 estimates for the autocorrelations. You can request different autocorrelations by specifying the VARAUTOCORR= option in the GAUSSPRIOR statement.

Fit Statistics

The "Fit Statistics" table displays the average square error (ASE) that is computed on the basis of the final selected model. If you specify a PARTITION statement, the table displays the ASE for each role.

Classification

The "Classification" table displays information about both the observed and predicted values for a binary response. The table includes columns for the observed response, the predicted event count, the predicted nonevent count, and the total number of events and nonevents. If you specify a PARTITION statement, the table displays the values for each role.

Margins

The "Margins" table displays predictive margin estimates. Each row of the table corresponds to a predictive margin that you define in a MARGIN statement.

MarginDiffs

The "Margin Differences" table displays differences between predictive margin estimates. Each row of the table corresponds to a difference between predictive margins that you specify in a MARGINDIFF statement.

Timing

The "Timing" table displays the amount of time (in seconds) that it took PROC BART to perform different tasks in the analysis.

OutputCasTables Table

The OutputCasTables table is a special table that has information about each CAS table that is created during a CAS action execution. The information for each CAS table consists of the CAS table name, the caslib in which the table resides, and the number of columns and rows in the CAS table. Because this table is not a typical ODS table that contains analytical results, you cannot include it in the *table-spec-list* in the DISPLAYOUT statement.

ODS Table Names

Each table that the BART procedure creates has a name that is associated with it. You must use this name to refer to the table when you use ODS statements. Table 4.4 lists the name of each table and a short description of its contents.

Table 4.4 ODS Tables Produced by PROC BART

Table Name	Description	Statements	Option
ChainInfo	Information about samples per chain	Default for distributed chains	
Classification	Classification matrix	Default output for binary data	

Table 4.4 *continued*

Table Name	Description	Statements	Option
ClassInfo	Level information from the CLASS statement	CLASS	
FitStatistics	Fit statistics	Default output	
MarginDiffs	Differences in predictive margins	MARGINDIFF	
Margins	Predictive margins	MARGIN	
ModelInfo	Information about the modeling environment	Default output	
NObs	Number of observations read and used	Default output	
PriorInfo	Information about the model prior	Default output	
OutputCasTables	See the section "OutputCasTables Table" on page 163	OUTPUT DISPLAYOUT SAMPSUMMARY	OUT=
ResponseProfile	Response categories for binary data	Default output for binary data	
ScoreInfo	Information about the stored model used for scoring	PROC BART	RESTORE=
SampleInfo	Information about the posterior samples	Default output	
Timing	Absolute and relative times for tasks performed by the procedure	Default output	
VarAutoCorr	Autocorrelation statistics for normal response variance	Default output	

Examples: BART Procedure

The examples in this chapter are available in the GitHub repository located at `https://github.com/sascommunities/doc-supplement-casstat`.

Example 4.1: Storing and Scoring

(View the complete code for this example (bartex1.sas) in the example repository.)

When you use PROC BART to fit a model, you can use the STORE statement to save the model. For example, you can score new observations or define interventions on predictors and score marginal means for the interventions. This example uses the RESTORE= option in PROC BART to do subsequent scoring. Note that because scoring a new observation for a Bayesian additive regression trees (BART) model requires routing the observation through each tree for all the saved samples of the sum-of-trees ensemble, scoring large data sets can be time-consuming.

The following statements generate the data table inputData, which consists of 10,000 observations on a continuous response variable (y) and 40 continuous variables (x1–x40), in your CAS session:

```
data mylib.inputData / single =yes;
   drop  j w1-w40;

  array x{40};
  array w{40};
  call streaminit(6524);
  pi=constant("pi");

   do i=1 to 10000;
      u = rand("Uniform");
      do j=1 to dim(x);
         w{j} = rand("Uniform");
         x{j} = (w{j} + u)/2;
      end;

      f1 = sin(pi * x1 * x2 );
      f2 = (x3-0.5)**2;
      f3 = x4;
      f4 = x5;
      fb = 10*f1 +20*f2+10*f3+5*f4;

      y = fb +  rand("Normal");
      output;
   end;

run;
```

For the simulation, only the variables x1–x5 affect the outcome y, and the variables x1–x40 are all positively correlated.

In the following program, because the input data are not large, the TRAININMEM and MAPINMEM options store the data and elements of the model in memory when the model is trained:

```
proc bart data=mylib.inputData seed=9181 trainInMem mapInMem;
   model y = x1-x40;
   store mylib.modelFit;
run;
```

The mylib.modelFit store contains a representation of the model that you can use to score new observations. The fit statistics for the fitted model are displayed in the "Fit Statistics" table in Output 4.1.1.

Output 4.1.1 Fit Statistics

The BART Procedure

Fit Statistics	
Average Square Error	0.97290

The following statements create a new data table of observations to score using the same data-generating process that generated the training data:

```
data mylib.toScoreData / single =yes;
   drop  j w1-w40;

  array x{40};
  array w{40};
  call streaminit(1972);
  pi=constant("pi");

   do i=1 to 1000;
      u = rand("Uniform");
      do j=1 to dim(x);
         w{j} = rand("Uniform");
         x{j} = (w{j} + u)/2;
      end;

      f1 = sin(pi * x1 * x2 );
      f2 = (x3-0.5)**2;
      f3 = x4;
      f4 = x5;
      fb = 10*f1 +20*f2+10*f3+5*f4;

      y = fb +  rand("Normal");
      output;
   end;

run;
```

The following statements show how to use PROC BART to score the new data by using the previously fitted model. The saved model mylib.modelFit is specified in the RESTORE= option. You use the DATA= option to specify the data table of observations to score, and you use the OUTPUT statement to designate the output data table that contains the results. The PRED= keyword names the variable in the output data table that contains the predicted response value. Note that because the toScoreData data table also contains the response variable y, residuals for the predicted values can also be computed. The RESID= keyword names the variable in the output data table that contains the residuals. The RESTORE= option and OUTPUT statement are both required when you use PROC BART to score data by using a previously fitted model.

```
proc bart data=mylib.toScoreData restore=mylib.modelFit;
   output out = mylib.scoredData pred = predResp resid = residual;
run;
```

The following statements compute the average square error (ASE) for the scored observations:

```
data fitCheck;
   set mylib.scoredData;
   SquareError = residual * residual;
run;

proc means data=fitCheck mean;
   var SquareError;
run;
```

The ASE for the scored observations in Output 4.1.2 is similar to the ASE for the training data in Output 4.1.1,

indicating that the fitted model generalizes well.

Output 4.1.2 ASE for the Scored Data

The MEANS Procedure

Analysis Variable : SquareError
Mean
1.0628698

You can also use the saved model mylib.modelFit to compute predictive margins. You can use the MARGIN statement to define predictive margins that intervene on one or more of the input variables. Observations in an input data table are scored according to the specified interventions, and means of the predicted values are reported along with equal-tail credible intervals. When you want to compare the difference between predicted margins, you can use the MARGINDIFF statement to specify a contrast of predictive margins that are defined in MARGIN statements.

The following statements show how you can compute predictive margins by using PROC BART and the previously fitted model that is saved in the analytic store mylib.modelFit. The saved model mylib.modelFit is specified in the RESTORE= option, and the data table of observations to score is specified in the DATA= option. Five predictive margins are specified in the MARGIN statement. The first scenario intervenes on x2 and sets its value to 0.25, and the second scenario intervenes on both x2 and x3 and sets their values to 0.25 and 0.5, respectively. The remaining three predictive margins intervene on x1 and set its level to 0.25, 0.5, and 0.75, respectively. These three predictive margins are then used in MARGINDIFF statements to request differences between these predictive margins.

```
proc bart restore = mylib.modelFit data=mylib.inputData;
   margin "Scenario1" x2 = 0.25;
   margin "Scenario2" x2 = 0.25 x3 = 0.5;
   margin "x1Ref"     x1 = 0.25;
   margin "x1Evt1"    x1 = 0.5;
   margin "x1Evt2"    x1 = 0.75;
   margindiff event = "x1Evt1" ref = "x1Ref" / label= "x1:0.5 - 0.25";
   margindiff event = "x1Evt2" ref = "x1Ref" / label= "x1:0.75 - 0.25";
run;
```

The "Score Information" table in Output 4.1.3 displays information about the saved model, the data table that is used to train the model, the data table of scored observations, and the number of scored observations.

Output 4.1.3 Score Information

The BART Procedure

Scoring Information	
Store	MODELFIT
Scoring Table	INPUTDATA
Training Table	INPUTDATA
Target Variable	y
Missing Rule	Separate
MCMC Sample Size	1000
Number of Observations	10000

The "Predictive Margins" table in Output 4.1.4 displays the means for the predicted margin estimates and the equal-tail credible intervals for the interventions that are specified by a MARGIN statement.

Output 4.1.4 Predictive Margins

Predictive Margins

Description	Estimate	95% Equal-Tail Interval	
Scenario1	12.14185	11.97984	12.31817
Scenario2	11.36423	11.20431	11.55277
x1Ref	12.22552	12.07488	12.42200
x1Evt1	15.13663	15.01155	15.25285
x1Evt2	16.54028	16.39544	16.66414

The "Predictive Margin Differences" table in Output 4.1.5 displays the mean difference between predictive margins that is specified in the MARGINDIFF statement along with equal-tail credible intervals.

Output 4.1.5 Predictive Margin Differences

Predictive Margin Differences

Description	Estimate	95% Equal-Tail Interval	
x1:0.5 - 0.25	2.9111	2.6998	3.1283
x1:0.75 - 0.25	4.3148	4.0424	4.5075

Example 4.2: Probit Model for Binary Data

(View the complete code for this example (bartex2.sas) in the example repository.)

This example uses the junk email available in the Sashelp.JunkMail data set. The data set comes from a study that classifies whether an email is junk email (coded as 1) or not (coded as 0). The data were collected by Hewlett-Packard Labs and donated by George Forman. The data table, which is specified in the following DATA step, contains 4,601 observations, with two binary variables and 57 continuous explanatory variables. The response variable, Class, is a binary indicator of whether an email is considered spam or not. The partitioning variable, Test, is a binary indicator that is used to divide the data into training and testing parts. The 57 explanatory variables are continuous variables that represent the frequencies of some common words and characters and the lengths of uninterrupted sequences of capital letters in emails.

```
data mylib.JunkMail;
   set Sashelp.JunkMail;
run;
```

In the following program, the PARTITION statement divides the data into two parts: the training data have a Test value of 0 and contain about two-thirds of the data, and the rest of the data are used to evaluate the fit. You use the DIST= option in the MODEL statement to indicate that the response is binary.

```
proc bart data=mylib.JunkMail seed=210124;
   model Class = Make Address All _3d Our Over Remove
         Internet Order Mail Receive Will People Report Addresses Free Business
         Email You Credit Your Font _000 Money HP HPL George _650 Lab Labs
         Telnet _857 Data _415 _85 Technology _1999 Parts PM Direct CS Meeting
         Original Project RE Edu Table Conference Semicolon Paren Bracket
         Exclamation Dollar Pound CapAvg CapLong CapTotal
   / dist=binary;
   partition rolevar=Test(train='0' test='1');
run;
```

The "Number of Observations" and "Response Profile" tables in Output 4.2.1 are divided into training and testing columns.

Output 4.2.1 Partitioned Counts

The BART Procedure

Number of Observations Read	4601
Number of Observations Used	4601
Number of Observations Used for Training	3065
Number of Observations Used for Testing	1536

Response Profile		
Class	**Training**	**Testing**
1	1218	595
0	1847	941

Probability modeled is Class = 0.

The fit statistics for the selected model are displayed in the "Fit Statistics" table in Output 4.2.2. The misclassification rate and average square error are similar for the training and testing data, indicating that the fitted model generalizes well.

Output 4.2.2 Partitioned Fit Statistics

Fit Statistics		
	Training	**Testing**
Average Square Error	0.03995	0.04744
Misclassification Rate	0.04698	0.06055

To enable you to further assess the performance of the model, the "Classification Matrix" table in Output 4.2.3 displays information about the observed and predicted values for both the training and test data.

Output 4.2.3 Partitioned Classification Matrix

Classification Matrix						
	Training Prediction			Testing Prediction		
Observed	0	1	Total	0	1	Total
0	1790	57	1847	901	40	941
1	87	1131	1218	53	542	595
Total	1877	1188	3065	954	582	1536

Overview: BINNING Procedure

The BINNING procedure performs binning in SAS Viya. Binning is a common step in the data preparation stage of the model-building process. You can use binning to classify missing variables, reduce the impact of outliers, and generate multiple effects. The generated effects are useful and contain certain nonlinear information about the original variables.

The BINNING procedure supports several binning methods, which are described in the following subsections. The BINNING procedure can also calculate the weight of evidence (WOE) and information value (IV) based on binning results.

Bucket Binning

Bucket binning creates equal-length bins and assigns each observation in the data to one of these bins. You can choose the number of bins during the binning; the default number of bins (the binning level) is 16. Only interval input variables are supported for this binning method.

Winsorized Binning

Winsorized binning is similar to bucket binning except that both tails are cut off to obtain a smooth binning result. This technique is often used to remove outliers during the data preparation stage. Only interval input variables are supported for this binning method.

Quantile Binning

PROC BINNING calculates the quantile (or percentile) cutpoints and uses them as the lower bound and upper bound in creating bins. As a result, each bin should have a similar number of observations. Because PROC BINNING always assigns observations that have the same value to the same bin, quantile binning might create unbalanced bins if any variable has tied values. Only interval input variables are supported for this binning method. For more information, see the section "Binning Computation and Formulas" on page 184.

Cutpoint Binning

The cutpoint binning method enables you to create bins by specifying the bin upper bound. Only interval input variables are supported for this binning method.

Tree-Based Binning

The tree-based binning method enables you to create bins by creating decision trees or regression trees. This technique requires you to specify a target variable. If the target variable is nominal, PROC BINNING creates decision trees; if the target variable is interval, PROC BINNING creates regression trees.

PROC BINNING Features

The BINNING procedure has the following features:

- provides a bucket (equal-length) binning method
- provides a Winsorized binning method and Winsorized statistics
- provides a quantile binning method
- provides a cutpoints binning method
- provides a tree-based binning method
- calculates the weight of evidence (WOE) and information value (IV) based on binning results

Using CAS Sessions and CAS Engine Librefs

SAS Cloud Analytic Services (CAS) is the analytic server and associated cloud services in SAS Viya. This section describes how to create a CAS session and set up a CAS engine libref that you can use to connect to the CAS session. It assumes that you have a CAS server already available; contact your system administrator if you need help starting and terminating a server. This CAS server is identified by specifying the host on which it runs and the port on which it listens for communications. To simplify your interactions with this CAS server, the host information and port information for the server are stored as SAS option values that are retrieved automatically whenever this CAS server needs to be accessed. You can examine the host and port values for the server at your site by using the following statements:

```
proc options option=(CASHOST CASPORT);
run;
```

In addition to starting a CAS server, your system administrator might also have created a CAS session and a CAS engine libref for your use. You can define your own sessions and CAS engine librefs that connect to the CAS server as shown in the following statements:

```
cas mysess;
libname mylib cas sessref=mysess;
```

The CAS statement creates the CAS session named mysess, and the LIBNAME statement creates the mylib CAS engine libref that you use to connect to this session. It is not necessary to explicitly name the CASHOST and CASPORT of the CAS server in the CAS statement, because these values are retrieved from the corresponding SAS option values.

If you have created the mysess session, you can terminate it by using the TERMINATE option in the CAS statement as follows:

```
cas mysess terminate;
```

For more information about the CAS and LIBNAME statements, see the section "Introduction to Shared Concepts" on page 6 in Chapter 2, "Shared Concepts."

Getting Started: BINNING Procedure

Bucket Binning

(View the complete code for this example at https://github.com/sascommunities/doc-supplement-casstat/tree/main/Examples/binning_gs.sas.)

NOTE: Input data must be in a CAS table that is accessible in your CAS session. You must refer to this table by using a two-level name. The first level must be a CAS engine libref, and the second level must be the table name. For more information, see the sections "Using CAS Sessions and CAS Engine Librefs" on page 7 and "Loading a SAS Data Set onto a CAS Server" on page 7 in Chapter 2, "Shared Concepts."

The following DATA step creates the data table mylib.bucket, which consists of 1,000 observations of an ID variable (id) and three continuous variables (x1–x3), in your CAS session:

```
data mylib.bucket;
   length id 8;
   call streaminit(12345);
   do id=1 to 1000;
      x1 = rand("Uniform");
      x2 = rand("Uniform") * 10;
      x3 = rand("Uniform") * 100;
      output;
   end;
run;
```

These statements assume that your CAS engine libref is named mylib, but you can substitute any appropriately defined CAS engine libref.

The following statements show how you can use the BINNING procedure to perform bucket binning:

```
proc binning data=mylib.bucket numbin=10 method=bucket;
   input x1-x3;
   output out=mylib.out;
run;
```

The DATA= option specifies the input data table. The NUMBIN= option requests that 10 bins be created for all binning variables. The METHOD= option requests that the bucket binning method be used. The INPUT statement names three continuous variables (x1–x3) as input variables for binning. The OUTPUT statement creates an OUTPUT data table to contain the results of PROC BINNING.

Figure 5.1 displays the "Bin Details" table. This table shows the binning variable, bin ID, bin lower bound, bin upper bound, bin width, number of observations in that bin, and some statistics of that bin (such as mean, standard deviation, minimum, and maximum).

Figure 5.1 Bin Details

The BINNING Procedure

Bin Details

Syntax: BINNING Procedure

The following statements are available in the BINNING procedure:

PROC BINNING < *options* > **;**
CODE FILE=*filename* **;**
FREQ *variable* **;**
INPUT *variables* < *options* > **;**
OUTPUT OUT=*libref.data-table* < *options* > **;**
TARGET *variable* / < *options* > **;**
WEIGHT *variable* **;**

The PROC BINNING statement and at least one INPUT statement are required. You can specify multiple INPUT statements. The TARGET statement is required to calculate the weight of evidence (WOE) and information value (IV) when the value of the METHOD= option is BUCKET, QUANTILE, WINSOR, or CUTPTS. The TARGET statement is also required when the value of the METHOD= option is TREE.

The following sections describe the PROC BINNING statement and then describe the other statements in alphabetical order.

PROC BINNING Statement

PROC BINNING < *options* > **;**

The PROC BINNING statement invokes the procedure. Table 5.1 summarizes important *options* in the PROC BINNING statement by function.

Table 5.1 PROC BINNING Statement Options

Option	Description
Basic Option	
DATA=	Specifies the input data table
Precision Option	
FUZZYCOMPARE=	Specifies the fuzzy comparison threshold that is used to determine the distinctness of numeric values
Binning Level Options	
DISTINCTCOUNTLIMIT=	Specifies the maximum number of distinct levels for interval variables in order for them to be treated as nominal variables
NUMBIN=	Specifies the global number of bins for all binning variables
Binning Method Option	
METHOD=	Specifies which binning method to use
Tolerance Option	
PERCENTILETOLERANCE=	Specifies the tolerance for percentile computation

Table 5.1 *continued*

Option	Description
Maximum Iterations Option	
PERCENTILEMAXITERATIONS=	Specifies the maximum iterations for percentile computation
Weight-of-Evidence Option	
WOE(WOEADJUST=)	Computes the weight of evidence and information values
Missing Value Handling Options	
BINMISSING=	Specifies whether to use missing values of the input variables for the binning process
MISSINGBINSTATS=	Specifies whether to use the bin that contains the missing values for binning analysis
MISSINGEVALNONEVENT=	Specifies whether to consider missing values of the target variable as nonevents
Format Option	
RAW=	Specifies whether to process variables by using their raw values or formatted values

You can specify the following *options*:

BINMISSING=TRUE | FALSE
specifies whether to use missing values of the input variables for the binning process. You can specify either of the following values:

TRUE places all missing values into a bin whose binId=0.

FALSE ignores all missing values.

By default, BINMISSING=TRUE.

DATA=*libref.data-table*
names the input data table for PROC BINNING to use. The default is the most recently created data table. *libref.data-table* is a two-level name, where

libref refers to a collection of information that is defined in the LIBNAME statement and includes the library, which includes a path to the data, and a session identifier, which defaults to the active session but which can be explicitly defined in the LIBNAME statement. For more information about *libref*, see the section "Using CAS Sessions and CAS Engine Librefs" on page 173.

data-table specifies the name of the input data table.

FUZZYCOMPARE=*value*
specifies the fuzzy comparison threshold that is used to determine the distinctness of numeric values. The range for this option is 0 to 1E–5.

By default, FUZZYCOMPARE=1E–10.

METHOD=BUCKET | CUTPTS(*numlist***) | QUANTILE | TREE <***options***> | WINSOR(RATE=***rate***)**
specifies which binning method to use.

You can specify one of the following methods:

BUCKET
uses the bucket binning method. Only interval input variables are supported for this binning method.

CUTPTS(*numlist***)**
uses the cutpoints binning method and specifies the lower and upper bounds of the bin. The numbers in *numlist* specify the upper bounds of each bin except the last bin (whose upper bound is positive infinity). Each number in *numlist* also implies the lower bound of the next bin; the lower bound of the first bin is negative infinity. Only interval input variables are supported for this binning method.

QUANTILE
uses the quantile binning method. Only interval input variables are supported for this binning method.

TREE <*options***>**
uses the tree-based binning method. Both interval and nominal input variables are supported for this binning method. You can specify the following *options*:

CRITERIA <*options***>**
specifies the criteria for growing the tree for the tree-based binning method. You can specify the following *options*:

GAIN

ENTROPY
uses the gain in information (decrease in entropy) as the tree-growing criterion. This criterion is available only for a nominal target.

GAINRATIO

ENTROPYRATIO
uses the gain ratio in information (decrease in entropy ratio) as the tree-growing criterion. This criterion is available only for a nominal target. This is the default criterion for a nominal target.

GINI
uses the Gini statistic as the tree-growing criterion. This criterion is available only for a nominal target.

SSE
uses the sum of squared error as the tree-growing criterion. This criterion is available only for an interval target. This is the default criterion for an interval target.

DISTINCTCOUNTLIMIT=*integer*

MAXDISTINCTLEVELS=*integer*
specifies the maximum number of distinct levels that interval variables can have in order for them to be treated as nominal variables, where *integer* can be any integer between 2 and 30,000, inclusive. You can use the LEVEL= option in the INPUT statement to treat interval variables as nominal variables as long as their levels are less than *integer*.

By default, DISTINCTCOUNTLIMIT=5000.

INITBIN=*integer*
specifies the initial number of bins for interval input variables to start the tree-based binning process. The final number of bins created by PROC BINNING might be different than the number you specify. The value of *integer* can be any integer between 1 and 10,000, inclusive. By default, INITBIN=100.

INITMETHOD=BUCKET | QUANTILE
specifies the method to initialize the tree-based binning for interval input variables. You can specify either of the following values:

BUCKET uses the bucket binning method.

QUANTILE uses the quantile binning method.

By default, the bucket binning method is used.

LEAFSIZE=*integer*

MINNOBSINBIN=*integer*
specifies the allowed minimum number of observations per leaf for tree-based binning. The value of *integer* can be any integer between 1 and 30,000. There is no default. If you specify this option, the number of observations in each leaf will be larger than the specified *integer*.

MAXNBINS=*integer*
specifies the desired maximum number of bins for all variables. The value of *integer* can be any integer between 2 and 10,000, inclusive. If this option is specified, PROC BINNING tries to make sure that the final number of bins for all variables is no more than the specified *integer*. By default, MAXNBINS=5.

MINNBINS=*integer*
specifies the desired minimum number of bins for all variables. The value of *integer* can be any integer between 1 and 10,000, inclusive. If this option is specified, PROC BINNING tries to make sure that the final number of bins for all variables is no less than the specified *integer*. By default, MINNBINS=1.

WINSOR(RATE=*rate*)
uses the Winsorized binning method and specifies the *rate* that it uses. You must specify a *rate* between 0 and 0.5, exclusive. Only interval input variables are supported for this binning method.

MISSINGBINSTATS=TRUE | FALSE
specifies whether to use the bin that contains the missing values for binning analysis such as WOE and IV. You can specify either of the following values:

TRUE uses the bin that contains the missing values (binId=0) for binning analysis.

FALSE ignores the bin that contains the missing values.

By default, MISSINGBINSTATS=TRUE.

MISSINGEVALNONEVENT=TRUE | FALSE
specifies whether to consider missing values of the target variable as nonevents. You can specify either of the following values:

TRUE considers missing values of the target variable to be nonevents.

FALSE excludes missing values of the target variable from analysis.

By default, MISSINGEVALNONEVENT=FALSE.

NUMBIN=*integer*
specifies the global number of binning levels for all binning variables. The value of *integer* can be any integer between 2 and 1000, inclusive.

By default, NUMBIN=16.

In tree-based binning, this option is ignored.

PERCENTILETOLERANCE=*value*
specifies the tolerance for percentile computation.

By default, PERCENTILETOLERANCE=1E–5.

PERCENTILEMAXITERATIONS=*value*
specifies the maximum number of iterations for percentile computation.

By default, PERCENTILEMAXITERATIONS=10.

RAW=TRUE | FALSE
specifies whether to process variables by using their raw values or formatted values. You can specify either of the following values:

TRUE processes variables by using their raw values.

FALSE if a variable has format, processes it by using a formatted value.

By default, RAW=TRUE.

WOE(WOEADJUST=*number***)**
computes the weight of evidence and information values. In tree-based binning, this option is ignored. You can specify the following suboption:

WOEADJUST=*number*
specifies the adjustment factor for the weight-of-evidence calculation, where *number* is between 0 and 1, inclusive.

By default, WOEADJUST=0.5.

CODE Statement

CODE FILE=*filename* **;**

The CODE statement generates score code and stores it in a file that can be used for scoring purposes. Only one CODE statement is processed. If you specify multiple CODE statements, only the first one is used.

You must specify the following option:

FILE=*filename*
specifies the filename of the file to write the SAS score code to.

FREQ Statement

FREQ *variable* **;**

The *variable* in the FREQ statement identifies a numeric variable in the input data table that contains the frequency of occurrence of each observation. PROC BINNING treats each observation as if it appears f times, where f is the value of the FREQ *variable* for the observation. If f is not an integer, it is truncated to an integer. If f is less than 1 or missing, the observation is not used in the analysis. When you omit the FREQ statement, each observation is assigned a frequency of 1.

INPUT Statement

INPUT *variables* < / *options* > **;**

The INPUT statement names one or more *variables* as input variables for binning. PROC BINNING does not support duplicate variables. If the INPUT statement contains a duplicate variable, PROC BINNING takes only the first variable and provides a warning message.

When the values of the METHOD= option is BUCKET, QUANTILE, WINSOR, or CUTPTS, the specified *variables* must be interval variables. If nominal variables are provided, PROC BINNING stops and returns an error message.

When the values of the METHOD= option is TREE, the specified *variables* can be either interval or nominal variables.

You can specify the following *options* after a slash (/):

NUMBIN=*integer*

specifies the number of binning levels for all binning variables in the current INPUT statement. The value of *integer* can be any integer between 2 and 1,000, inclusive.

The number of binning levels that you specify in an INPUT statement overwrites the global number of binning levels, which is specified in the NUMBIN= option in the PROC BINNING statement (or is 16 by default).

In tree-based binning, this option is ignored.

LEVEL=INTERVAL | NOMINAL

specifies whether to treat the specified variables as interval or nominal. You can specify the following values:

INTERVAL

INT

treats all variables that are specified in this INPUT statement as interval. If the INPUT statement contains any character variables, PROC BINNING stops and returns an error message.

NOMINAL

NOM

treats all variables that are specified in this INPUT statement as nominal. If you specify LEVEL=NOMINAL and the variables in the INPUT statement are interval when the value of the METHOD= option is BUCKET, QUANTILE, WINSOR, or CUTPTS, PROC BINNING prints a warning and continues to treat the variables in the INPUT statement as interval variables.

By default, LEVEL=INTERVAL.

OUTPUT Statement

OUTPUT OUT=*libref.data-table* < *options* > **;**

The OUTPUT statement enables you to write an output table back to the CAS server by creating an output data table that contains the results of PROC BINNING. For tree-based binning of class inputs, the OUTPUT statement also enables you to write an output bin-mapping data table that contains the following three columns: class input variables, their levels, and their associated bin numbers. If you do not specify the OUTPUT statement, the write-back process is skipped. This is useful when you want only the ODS output. By default, the output table contains the new binned variables. If you specify the COPYVARS= option, the output table contains the "copied variables" and the "binned variables". The output bin-mapping data table contains only three columns, and the COPYVARS= option does not apply to it. If you specify multiple OUTPUT statements, PROC BINNING stops and produces an error message.

NOTE: If an input variable value is missing, then the binning output level value is 0.

You must specify one of the following options:

OUT=*libref.data-table*
names the output data table for PROC BINNING to use. *libref.data-table* is a two-level name, where *libref* refers to the library, and *data-table* specifies the name of the output data table. For more information about this two-level name, see the DATA= option and the section "Using CAS Sessions and CAS Engine Librefs" on page 173.

OUTLEVELBINMAP=*libref.data-table*
names the output bin-mapping data table for PROC BINNING to use. *libref.data-table* is a two-level name, where *libref* refers to the library, and *data-table* specifies the name of the output data table. For more information about this two-level name, see the DATA= option and the section "Using CAS Sessions and CAS Engine Librefs" on page 173.

You can also specify the following *option*:

COPYVAR=*variable*
COPYVARS=(*variables***)**
lists one or more *variables* from the input data table to be transferred to the output data table.

TARGET Statement

TARGET *variable* / < *options* > **;**

When the value of the METHOD= option is BUCKET, QUANTILE, WINSOR, or CUTPTS, the TARGET statement names the *variable* that PROC BINNING uses to calculate the weight of evidence and information value. If you specify multiple TARGET statements, only the first one is used.

When the value of the METHOD= option is TREE, the TARGET statement names the *variable* that PROC BINNING uses to create trees.

You can specify the following *options* after a slash (/):

EVENT=*"category"*
specifies the target event category that PROC BINNING uses to calculate the weight of evidence and information value in a quoted string of characters. You must specify this option if the WOE option is specified in the PROC BINNING statement.

LEVEL=INTERVAL | NOMINAL
specifies whether to treat the target variable as interval or nominal. You can specify the following values:

INTERVAL
INT
treats the target variable as interval.

NOMINAL
NOM
treats the target variable as nominal.

By default, LEVEL=INTERVAL.

WEIGHT Statement

WEIGHT *variable* **;**

The *variable* in the WEIGHT statement is used as a weight to perform a weighted analysis of the data. Observations that have nonpositive or missing weights are not included in the analysis. The values of the WEIGHT variable can be nonintegral and are not truncated. When you omit the WEIGHT statement, all observations that are used in the analysis are assigned a weight of 1.

Details: BINNING Procedure

Binning Computation and Formulas

For variable x, assume that the data are represented by $\{x_i\}$, where $i = 1, 2, \ldots, n$. Let $\min(x) = \min_{i \in \{1,\ldots,n\}} \{x_i\}$, and let $\max(x) = \max_{i \in \{1,\ldots,n\}} \{x_i\}$. The range of the variable is $\text{range}(x) = \max(x) - \min(x)$.

The computations for the various binning methods are as follows, where *numbin* is the value of the NUMBIN= option in the PROC BINNING statement:

- For bucket binning, the length of the bucket is

  $$L = \frac{\max(x) - \min(x)}{n}$$

  The split points are

  $$s_k = \min(x) + L \times k$$

  where $k = 1, 2, \ldots, \textit{numbin} - 1$.

  When the data are evenly distributed on the cloud, the time complexity for bucket binning is $\mathcal{O}(n)/(\textit{nodes} \times \textit{nThreads})$, where n is the number of observations, *nodes* is the number of computer nodes in the cloud, and *nThreads* is the number of CPUs on each node.

- For quantile binning, PROC BINNING calculates a quantile table P. Let $P = \{p_k\}$, where $k = 1, 2, \ldots, \textit{numbin}$. Then p_k is described as

  $$p_k = \begin{cases} 1.0/\textit{numbin} + p_{k-1} & \text{if } 0 < k < \textit{numbin} \\ 1.0 & \text{if } k = \textit{numbin} \end{cases}$$

  Quantile binning often requires data to be sorted in a particular way, and the sorting process usually consumes a significant amount of CPU time and memory. When the input data table is larger than the available memory, the sorting algorithm becomes more complicated. In distributed computing, data communications overhead also increases the sorting challenge. To avoid the time-consuming sorting process, the BINNING procedure uses an iterative projection method for quantile binning, which runs much faster than the sorting-based quantile binning method in most cases.

  After calculating the quantile table, PROC BINNING uses an iterative projection method to compute quantiles (percentiles) and uses these quantiles to create bins.

Quantile binning aims to assign the same number of observations to each bin. As a result, each bin should have a similar number of observations. Because PROC BINNING always assigns observations that have the same value to the same bin, quantile binning might create unbalanced bins if any variable has tied values. For example, if an observation whose value is x is assigned to bin k, then every observation whose value is x is assigned to bin k for this variable, and no observation whose value is x is assigned to the next bin, bin $k + 1$. Therefore, bin k might have more observations than bin $k + 1$, because the tied values at the boundaries between bin k and bin $k + 1$ are all assigned to bin k. That is, tied values at the boundaries between two bins are always assigned to the lower-numbered bin.

- Winsorized binning applies bucket binning to the Winsorized data table. Winsorization involves replacing lower and upper outliers (which are defined according to the RATE= suboption in the METHOD=WINSOR option in the PROC BINNING statement) by the lower and upper thresholds. For variable x, PROC BINNING uses a simple bucket sorting method to obtain the basic information. Let N be the number of buckets. For each bucket B_i, $i = 1, 2, \ldots, N$, PROC BINNING keeps following information:

  - c_i: count of x in B_i
  - $\min_i$: minimum value of x in B_i
  - $\max_i$: maximum value of x in B_i
  - $\sum x_i$: sum of x in B_i
  - $\sum x_i^2$: sum of x^2 in B_i

  The Winsorized statistics are computed first. After the minimum and maximum have been found, the bin lower and upper bounds are calculated the same way as in bucket binning.

  Let the tail count, wc, be $\mathrm{ceil}(\mathrm{Rate} \times n)$, and find the smallest I such that $\sum_{i=1}^{I} c_i \geq \mathrm{wc}$. Then the left tail count is $\mathrm{lwc} = \sum_{i=1}^{I} c_i$. Find the next I_l such that $\sum_{i=1}^{I_l} c_i > \mathrm{lwc}$. Therefore, the minimum value is $\mathrm{WinsorMin} = \min_{I_l}$. Similarly, find the largest I such that $\sum_{i=I}^{N} c_i \geq \mathrm{wc}$. The right tail count is $\mathrm{rwc} = \sum_{i=I}^{N} c_i$. Find the next I_r such that $\sum_{i=I_r}^{N} c_i > \mathrm{rwc}$. Then the maximum value is $\mathrm{WinsorMax} = \max_{I_r}$. The mean is calculated by the formula

$$\mathrm{WinsorMean} = \frac{\mathrm{lwc} \times \mathrm{WinsorMin} + \sum_{i=I_l}^{I_r} x_i + \mathrm{rwc} \times \mathrm{WinsorMax}}{n}$$

  The trimmed mean is calculated by the formula

$$\mathrm{TrimmedMean} = \frac{\sum_{i=I_l}^{I_r} x_i}{n - \mathrm{lwc} - \mathrm{rwc}}$$

NOTE: PROC BINNING reserves bin 0 for missing values.

NOTE: Whenever possible, PROC BINNING always tries to generate the specified number of bins. In some cases, some bins might have no observations in them.

Tree-Based Binning

Tree-based binning is different from other binning methods. The basic idea of tree-based binning is to bin (group) input variables by growing a one-level decision tree (or regression tree, when the target variable is not nominal) for each input variable. In the literature, the difference between a decision tree and a regression tree is often ignored (with some exceptions). Therefore, in the rest of this chapter, the term decision tree can be used to represent either a decision tree or a regression tree. To grow a decision tree, PROC BINNING uses a training data set to split the target variable space into nonoverlapping regions. These regions correspond to the terminal nodes of the tree, which are also known as leaves.

The tree growing is done by splitting; the splitting starts with all the observations, which are represented by the node at the top of the tree. The algorithm splits this parent node into child nodes in such a way that the values (levels) of the target variable within each child region are as similar as possible. The split is determined by finding the best split value that optimizes a specified criterion across the child nodes for each input variable. The goal of maximizing similarity is achieved by minimizing node impurity. For an interval target, the default and only available growing criterion is SSE (sum of squared error), which aims to minimize node impurity. For a nominal target, the default growing criterion is GAINRATIO (or ENTROPYRATIO as the alias), which measures the gain ratio in information (decrease in entropy ratio) with the goal of minimizing node impurity. For a nominal target, the other supported growing criteria are GAIN (or ENTROPY as the alias) and GINI, which measure the gain in information (decrease in entropy) and the Gini statistic with the goal to minimize node impurity.

Computing the Weight of Evidence and Information Value

PROC BINNING can compute the weight of evidence and the information value.

Weight of evidence (WOE) is a measure of how much the evidence supports or undermines a hypothesis. WOE measures the relative risk of an attribute of binning level. The value depends on whether the value of the target variable is a nonevent or an event. An attribute's WOE is defined as follows:

$$\mathrm{WOE}_{\mathrm{attribute}} = \ln\frac{p_{\mathrm{attr(nonevent)}}}{p_{\mathrm{attr(event)}}} = \ln\frac{N_{\mathrm{attr(nonevent)}}/N_{\mathrm{tot(nonevent)}}}{N_{\mathrm{attr(event)}}/N_{\mathrm{tot(event)}}}$$

The definitions of the quantities in the preceding formula are as follows:

- $N_{\mathrm{attr(nonevent)}}$: the number of nonevent records that exhibit the attribute
- $N_{\mathrm{tot(nonevent)}}$: the total number of nonevent records
- $N_{\mathrm{attr(event)}}$: the number of event records that exhibit the attribute
- $N_{\mathrm{tot(event)}}$: the total number of event records

To avoid an undefined WOE, an adjustment factor, x, is used:

$$\mathrm{WOE}_{\mathrm{attribute}} = \ln \frac{(N_{\mathrm{attr(nonevent)}} + x)/N_{\mathrm{tot(nonevent)}}}{(N_{\mathrm{attr(event)}} + x)/N_{\mathrm{tot(event)}}}$$

You can use the WOEADJUST= option to specify a value between [0, 1] for x. By default, x is 0.5.

The information value (IV) is a weighted sum of the WOE of the characteristic's attributes. The weight is the difference between the conditional probability of an attribute for an event and the conditional probability of that attribute for a nonevent. In the following formula of IV, m is the number of bins of a variable:

$$\mathrm{IV} = \sum_{i=1}^{m} \left(\frac{N_{\mathrm{attr(nonevent)}}}{N_{\mathrm{tot(nonevent)}}} - \frac{N_{\mathrm{attr(event)}}}{N_{\mathrm{tot(event)}}} \right) \times \mathrm{WOE}_i$$

An information value can be any real number. Generally speaking, the higher the information value, the more predictive an attribute is likely to be.

Displayed Output

The following sections describe the output that PROC BINNING produces. The output is organized into various tables.

Bin Details

The "Bin Details" table displays some parameters and data information, which includes the binning variable, bin ID, bin lower bound, bin upper bound, bin width, number of observations in that bin, and some statistics of that bin (such as mean, standard deviation, minimum, and maximum). If you specify the WOE option in the PROC BINNING statement, this table also includes the target event count, weight of evidence, and information value of that bin.

Trimmed Statistics

The "Trimmed Statistics" table displays the binning variable, trimmed minimum, maximum, mean, standard error mean, left tail, left tail percentage, right tail, and right tail percentage. PROC BINNING generates this table if you specify the METHOD=WINSOR option in the PROC BINNING statement.

Winsorized Statistics

The "Winsorized Statistics" table displays the binning variable, Winsorized minimum, maximum, mean, standard error mean, left tail, left tail percentage, right tail, and right tail percentage. PROC BINNING generates this table if you specify the METHOD=WINSOR option in the PROC BINNING statement.

Variable Information Value

The "Variable Information Value (IV)" table displays the information value for each variable. PROC BINNING generates this table if you specify the WOE option in the PROC BINNING statement.

Variable Transformation Information

The "Variable Transformation Information" table displays the transformation information for each variable, in tree-based binning. PROC BINNING generates this table if you specify the METHOD=TREE option in the PROC BINNING statement.

Variable Mapping Information

The "Variable Mapping Information" table displays how each binning variable name is mapped to each result variable name. This table includes two columns: Variable and Result Variable.

ODS Table Names

Each table created by the BINNING procedure has a name associated with it. You must use this name to refer to the table when you use ODS statements. The names of each table and a short description of the contents are listed in Table 5.2.

Table 5.2 ODS Tables Produced by PROC BINNING

Table Name	Description	Statement	Options
BinDetails	Basic binning information and parameters	PROC BINNING	Default
InfoValue	Information value for each variable	PROC BINNING	WOE
Trim	Trimmed statistics for the given variables	PROC BINNING	METHOD=WINSOR
VarMapping	Variable mapping information	PROC BINNING	Default
VarTransInfo	Transformation information for the specified variables	PROC BINNING	METHOD=TREE
Winsor	Winsor statistics for the given variables	PROC BINNING	METHOD=WINSOR

Examples: BINNING Procedure

The examples in this chapter are available in the GitHub repository located at https://github.com/sascommunities/doc-supplement-casstat.

NOTE: Input data must be in a CAS table that is accessible in your CAS session. You must refer to this table by using a two-level name. The first level must be a CAS engine libref, and the second level must be the table name. For more information, see the sections "Using CAS Sessions and CAS Engine Librefs" on page 7 and "Loading a SAS Data Set onto a CAS Server" on page 7 in Chapter 2, "Shared Concepts."

Example 5.1: Quantile Binning

(View the complete code for this example (binning_ex1.sas) in the example repository.)

The following DATA step generates 1,000,000 observations of an ID variable (id) and two continuous variables (x1–x2). The mylib CAS library reference enables your client machine to communicate with the CAS session. These statements assume that your CAS engine libref is named mylib, but you can substitute any appropriately defined CAS engine libref.

```
data mylib.ex1;
   length id 8;
   call streaminit(12345);
   do id=1 to 1000000;
      x1 = rand("Uniform");
      x2 = rand("Uniform") * 10;
      output;
   end;
run;
```

The following statements demonstrate how to use PROC BINNING to perform the quantile binning:

```
proc binning data=mylib.ex1 numbin=10 method=quantile;
   input x1-x2;
   output out=mylib.out1;
run;
```

The DATA= option specifies the input data table. The NUMBIN= option requests that 10 bins be created for all binning variables. The METHOD= option requests that the quantile binning method be used. The INPUT statement names two continuous variables (x1–x2) as input variables for binning. The OUTPUT statement creates an OUTPUT data table to contain the results of PROC BINNING.

The "Bin Details" table in Output 5.1 shows the binning variable, bin ID, bin lower bound, bin upper bound, bin width, number of observations in that bin, and some statistics of that bin (such as mean, standard deviation, minimum, and maximum). When the binning method is quantile, PROC BINNING assigns the same number of observations to each bin for the input variables if possible.

Output 5.1.1 Bin Details

The BINNING Procedure

Bin Details									
Variable	Bin ID	Lower Bound	Upper Bound	Bin Width	Number of Observations	Mean	Standard Deviation	Minimum	Maximum
x1	Missing				0

Example 5.2: Winsorized Binning

(View the complete code for this example (binning_ex2.sas) in the example repository.)

The following DATA step generates 10,000 observations of an ID variable (id) and three continuous variables (x1–x3). The mylib CAS library reference enables your client machine to communicate with the CAS session.

```
data mylib.ex2;
   length id 8;
   call streaminit(12345);
   do id=1 to 10000;
      x1 = rand("Uniform");
      x2 = rand("Uniform") * 10;
      x3 = rand("Uniform") * 100;
      output;
   end;
run;
```

For Winsorized binning, PROC BINNING provides bucket binning and basic Winsorized statistical information for the input data.

The following statements include the WINSOR(RATE=0.05) option and generate tables for Winsorized and trimmed statistics:

```
proc binning data=mylib.ex2 numbin=10 method=winsor(rate=0.05);
   input x1-x3;
   output out=mylib.out2;
run;
```

The preceding statements generate Output 5.2.1 through Output 5.2.4.

Output 5.2.1 Bin Details

The BINNING Procedure

Bin Details

Example 5.3: Bucket Binning and Weight-of-Evidence Computation

(View the complete code for this example (binning_ex3.sas) in the example repository.)

The following DATA step generates a data table that contains 10 observations of a target variable (y), three continuous variables (x0–x2), and some other variables. The mylib CAS library reference enables your client machine to communicate with the CAS session.

```
data mylib.ex3;
   input cl1 $ x0  x1  x2  y $ freq id;
   datalines;
a  2  .  7  n  2  1
a  2  2  6  .  3  2
a  3  0  1  o  0  3
c  2  3  7  y  .  4
c  2  .  4  n  -5 5
a  3  6  7  n  3  6
b  1  4  4  y  4  7
b  2  5  6  y  3  8
b  1  6  4  o  1  9
b  2  3  2  n  3  10
;
```

The following statements show how you can use the BINNING procedure to perform bucket binning and compute the WOE and the information value (IV):

```
proc binning data=mylib.ex3 numbin=5 woe;
   input x1/numbin=4;
   input x2;
   target y/event="y";
   output out=mylib.out3;
run;
```

The DATA= option specifies the input data table. The WOE option enables computation of the weight of evidence and information values with WOEADJUST=0.5 by default. The first INPUT statement names one continuous variable (x1) as the first input variable for binning with four bins. The second INPUT statement names another continuous variable (x2) as the second input variable for binning with five bins, as specified in the NUMBIN= global option. The TARGET statement names the variable (y) that PROC BINNING uses to calculate the weight of evidence, and the EVENT= option specifies the target event category in a quoted string. The OUTPUT statement creates an OUTPUT data table to contain the results of PROC BINNING.

The preceding statements generate Output 5.3.1 through Output 5.3.2.

Output 5.3.1 Bin Details

The BINNING Procedure

Bin Details

Variable	Bin ID	Lower Bound	Upper Bound	Bin Width	Number of Observations	Mean	Standard Deviation	Minimum	Maximum	Event Count	Weight of Evidence	Information Value

Output 5.3.2 Variable Information Value

Variable Information Value

Variable	Information Value
x1	1.0662
x2	0.5365

Example 5.4: Cutpoint Binning

(View the complete code for this example (binning_ex4.sas) in the example repository.)

The following DATA step generates a data table that contains 10 observations of a target variable (y), two continuous variables (x1, x2), and some other variables:

```
data mylib.ex4;
   input cl1 $ cl2  x1  x2  y  freq id;
   datalines;
a     2    3   7  9   2   1
a     2    2   6  8   3   2
a     3    0   1  5   0   3
c     2    3   7  4   .   4
c     2    .   4  8   -5  5
a     3    6   7  5   3   6
b     1    4   4  8   4   7
b     2    5   6  3   3   8
b     1    6   4  8   1   9
b     2    3   2  6   3   10
;
```

The following statements show how you can use the BINNING procedure to perform cutpoint binning:

```
proc binning data=mylib.ex4 numbin=4 method=cutpts;
   input x2/cutpts(2, 2.3, 4.5);
   input x1/numbin=3 cutpts(3.1, 5);
run;
```

The DATA= option specifies the input data table. The METHOD= option requests that the cutpoint binning method be used. The first INPUT statement names one continuous variable x2 as the first input variable for binning, with four bins specified by the NUMBIN= global option. The second INPUT statement names another continuous variable x1 as the second input variable for binning with three bins. For the first input variable x2, 2, 2.3, 4.5 (and infinity) are used as the upper bounds for its four bins. For the second input variable x1, 3.1, 5 (and infinity) are used as the upper bounds for its three bins.

Output 5.4.1 shows the "Bin Details" table.

Output 5.4.1 Bin Details

The BINNING Procedure

Bin Details

Variable	Bin ID	Lower Bound	Upper Bound	Bin Width	Number of Observations	Mean	Standard Deviation	Minimum	Maximum
x2	Missing				0				
	1	-Infty	2		1	1		1	1
	2	2	2.3000	0.3000	1	2		2	2
	3	2.3000	4.5000	2.2000	3	4	0	4	4
	4	4.5000	Infty		5	6.6000	0.5477	6	7
x1	Missing				1				
	1	-Infty	3.1000		5	2.2000	1.3038	0	3
	2	3.1000	5	1.9000	1	4		4	4
	3	5	Infty		3	5.6667	0.5774	5	6

Example 5.5: Tree-Based Binning

(View the complete code for this example (binning_ex5.sas) in the example repository.)

The following statements show how you can use the BINNING procedure to perform tree-based binning:

```
data mylib.hmeq;
    set sampsio.hmeq;
run;

proc binning data=mylib.hmeq method=tree;
 target bad/level=int;
 input mortdue/level = int;
 input job/ level = nom;
 output outlevelbinmap=mylib.outlevel;
run;

proc print data=mylib.outlevel;
run;
```

The DATA= option specifies the input data table. The METHOD= option requests that tree-based binning method be used. The TARGET statement specifies bad as the target variable and requests that it be treated as an interval variable. The first INPUT statement names one variable, mortdue, and requests that it be treated as interval. The second INPUT statement names one variable, job, and requests that it be treated as nominal.

Output 5.5.1 shows the "Bin Details" table. Compared to the "Bin Details" tables in previous examples, this table has an extra column, "N Levels". The reason is that other binning methods can handle only interval variables, but tree-based binning can handle both interval and nominal variables. The "N Levels" column shows the number of levels of this variable that this bin contains. As a result, for interval variables, this column is empty.

Output 5.5.1 Bin Details

The BINNING Procedure

Overview: CAEFFECT Procedure

The CAEFFECT procedure implements estimation methods that enable you to study the effect of a treatment variable on an outcome variable. When appropriate causal assumptions are satisfied, the estimates that you obtain by using this procedure correspond to potential outcome mean estimates, and the differences between these estimates have a causal interpretation. For more information about the framework that is used to define causal effects and the necessary assumptions, see the section "Potential Outcomes and Effect Definitions" on page 216.

The estimation methods that PROC CAEFFECT implements are designed primarily for use with observational data (that is, data from nonrandomized or imperfectly randomized experiments), in which confounding variables are likely to be present. In the presence of confounding variables, statistical adjustments are necessary to obtain unbiased estimates of the effect of interest. The procedure enables you to adjust for confounding variables by using models for the treatment variable, the outcome variable, or both. By specifying predicted probabilities for the treatment assignment, also referred to as propensity scores, you can use inverse probability weighting to adjust for confounding. By specifying an outcome model or predicted potential outcomes, you can use regression adjustment to adjust for confounding. Finally, you can combine models for the outcome and treatment variables in so-called doubly robust estimation methods. In particular, you can use the procedure to perform doubly robust estimation by using either augmented inverse probability weighting (AIPW) or targeted maximum likelihood estimation (TMLE). For more information about the estimation methods that this procedure supports, see the section "Estimation Methods" on page 219.

PROC CAEFFECT is a model-agnostic tool for effect estimation. Although the procedure itself does not support the modeling of the treatment or outcome variable, it makes statistical adjustments for confounding variables by using precomputed model predictions that you provide as input. For methods that require an outcome model, you can provide a previously fit model for the outcome in the form of an analytic store, which the procedure uses to obtain the appropriate counterfactual outcome predictions. In this way, the procedure enables you to use the modeling technique of your choice for confounding adjustment.

Although the model-agnostic approach that this procedure supports gives you a flexible tool for estimating potential outcome means and effects, the same flexibility does not extend to variance estimation and statistical inference. In general, to obtain valid statistical inference, you must assess model-dependent conditions that are beyond the scope of this procedure. In this way, PROC CAEFFECT's approach differs from other model-specific approaches to causal effect estimation, including those that are implemented for binary treatments by the CAUSALTRT procedure in SAS/STAT software and the DEEPCAUSAL procedure in SAS Econometrics software. In particular, during variance estimation, these model-specific approaches to effect estimation can account for dependencies that are introduced when the data that you use to estimate the potential outcome means are the same data that you use to estimate the treatment and outcome models. In the model-agnostic approach of PROC CAEFFECT, no similar adjustment can be made, and typically some form of data splitting is required in order to obtain valid statistical inference. For more information about the conditions that are required for valid such inference, see the section "Standard Errors and Confidence Limits" on page 227.

PROC CAEFFECT Features

PROC CAEFFECT provides the following features:

- estimation of potential outcome means by using inverse probability weighting, regression adjustment, augmented inverse probability weighting, and targeted maximum likelihood estimation (TMLE)
- estimation of potential outcome means conditional on a treatment level by using inverse probability weighting or regression adjustment
- estimation of effects on the difference scale
- support for categorical treatments
- support for continuous, categorical, and binomial outcomes
- input of previously fit models for the outcome variable in the form of an analytic store

Because PROC CAEFFECT runs on SAS Cloud Analytic Services (CAS), it also does the following:

- enables you to run on a cluster of machines that distribute the data and the computations
- enables you to run in single-machine mode
- exploits available cores and concurrent threads

PROC CAEFFECT Compared with Other SAS Procedures

The CAUSALTRT procedure in SAS/STAT and the DEEPCAUSAL procedure in SAS Econometrics both support the estimation of total causal effects by analyzing observational data. Both procedures are limited to the analysis of binary treatments. PROC CAUSALTRT adjusts for confounding variables by using models for the treatment variable, the outcome variable, or both. It uses generalized linear models when adjusting for confounding and fits these models itself. PROC DEEPCAUSAL adjusts for confounding variables by using models for the treatment and outcome variables that it fits by using deep neural networks.

The CAEFFECT procedure supports the estimation of total effects by analyzing observational data. The procedure supports the analysis of binary or categorical treatments. The estimation methods that the procedure supports adjust for confounding variables by using models for the treatment variable, the outcome variable, or both. Unlike the CAUSALTRT and DEEPCAUSAL procedures, PROC CAEFFECT does not directly fit any statistical models. Instead, it adjusts for confounding by using predictions from precomputed models. In this way, the procedure provides a model-agnostic tool for effect estimation and enables you to use the modeling technique of your choice for confounding adjustment.

The CAUSALTRT and DEEPCAUSAL procedures both support valid statistical inference for total effect estimates. The procedures are able to support valid inference because they fit the models that are used to adjust for confounding. During the variance estimation for the effect, the procedures can make model-specific adjustments that account for dependencies that are introduced when the same data are used to estimate the models, the potential outcome means, and the effect. The model-agnostic approach to effect estimation

that PROC CAEFFECT implements cannot perform any model-specific adjustments during the variance estimation. Typically, some form of data splitting and the assessment of model-dependent conditions are required in order to obtain valid statistical inference by using PROC CAEFFECT. Assessing model-dependent conditions and ensuring the use of proper splitting are beyond the scope of this procedure.

Using CAS Sessions and CAS Engine Librefs

SAS Cloud Analytic Services (CAS) is the analytic server and associated cloud services in SAS Viya. This section describes how to create a CAS session and set up a CAS engine libref that you can use to connect to the CAS session. It assumes that you have a CAS server already available; contact your system administrator if you need help starting and terminating a server. This CAS server is identified by specifying the host on which it runs and the port on which it listens for communications. To simplify your interactions with this CAS server, the host information and port information for the server are stored as SAS option values that are retrieved automatically whenever this CAS server needs to be accessed. You can examine the host and port values for the server at your site by using the following statements:

```
proc options option=(CASHOST CASPORT);
run;
```

In addition to starting a CAS server, your system administrator might also have created a CAS session and a CAS engine libref for your use. You can define your own sessions and CAS engine librefs that connect to the CAS server as shown in the following statements:

```
cas mysess;
libname mylib cas sessref=mysess;
```

The CAS statement creates the CAS session named mysess, and the LIBNAME statement creates the mylib CAS engine libref that you use to connect to this session. It is not necessary to explicitly name the CASHOST and CASPORT of the CAS server in the CAS statement, because these values are retrieved from the corresponding SAS option values.

If you have created the mysess session, you can terminate it by using the TERMINATE option in the CAS statement as follows:

```
cas mysess terminate;
```

For more information about the CAS and LIBNAME statements, see the section “Introduction to Shared Concepts” on page 6 in Chapter 2, “Shared Concepts.”

Getting Started: CAEFFECT Procedure

(View the complete code for this example at https://github.com/sascommunities/doc-supplement-casstat/tree/main/Examples/caeffectgs1.sas.)

NOTE: Input data must be in a CAS table that is accessible in your CAS session. You must refer to this table by using a two-level name. The first level must be a CAS engine libref, and the second level must be the table name. For more information, see the sections "Using CAS Sessions and CAS Engine Librefs" on page 7 and "Loading a SAS Data Set onto a CAS Server" on page 7 in Chapter 2, "Shared Concepts."

This section illustrates some of the basic features of the CAEFFECT procedure. The example uses the School data set available in the examples for the CAUSALTRT procedure in SAS/STAT software. The data for this example are a subset of data from the National Educational Longitudinal Study of 1988 in Murnane and Willett (2011). Demographic information was collected from the students and their families, along with standardized test scores in 1988 and in follow-up years.

As in the PROC CAUSALTRT example, the question of interest in this example is what effect attending a Catholic high school has on a student's performance in mathematics, as measured by the student's score on the mathematics portion of the standardized tests in 1992. The effect of interest is estimated in this example by using the targeted maximum likelihood estimation (TMLE) method, which is doubly robust.

The following DATA step creates the data table School in your CAS session:

```
data mylib.School;
   input
   Income $ FatherEd $ MotherEd $ Math BaseMath  Catholic $;
   datalines;
   Middle HighSchool HighSchool 49.77 50.27 Yes
   Middle Unknown Unknown 59.84 51.52 Yes
   Middle NoHighSchool Postsecondary 50.38 47.56 Yes
   Middle Unknown Unknown 45.03 46.60 Yes
   High HighSchool HighSchool 54.26 60.22 Yes

   ... more lines ...

   High College College 56.60 60.15 Yes
   High College SomeSecondary 56.29 59.53 Yes
   High College Postsecondary 58.16 57.06 Yes
   High College SomeSecondary 63.57 63.51 Yes
;
```

These statements assume that your CAS engine libref is named mylib, but you can substitute any appropriately defined CAS engine libref.

The School data table consists of records for 5,671 high school students whose 1988 total family income was at most $75,000. The variables in the data are as follows:

- BaseMath: student's score on the mathematics portion of a standardized test in 1988
- Catholic: Yes, if a student attended a Catholic high school; No, otherwise
- FatherEd: highest level of education completed by the student's father, with six possible levels

- Income: classification based on total family income, with values of Low, Middle, and High
- Math: student's score on the mathematics portion of a standardized test in 1992
- MotherEd: highest level of education completed by the student's mother, with six possible levels

For this example, it is assumed that the variables BaseMath, FatherEd, MotherEd, and Income make up a valid adjustment set that you can use to obtain an unbiased estimate of the effect of interest. For more information about the causal assumptions that are required for valid effect estimation, see the section "Potential Outcomes and Effect Definitions" on page 216.

The TMLE method adjusts for the confounding variables by using models for both the treatment variable Catholic and the outcome variable Math. PROC CAEFFECT does not fit the required outcome and treatment models. Instead, the procedure performs adjustments that are based on predictions from previously fit models, enabling you to use the modeling technique of your choice to adjust for confounders.

In this example, the model for the treatment variable is fit by using the LOGSELECT procedure, as follows:

```
proc logselect data=mylib.School;
   class FatherEd MotherEd Income;
   model Catholic( event='Yes' ) = FatherEd MotherEd Income;
   output out=mylib.schoolEst pred=pTrt copyvars=(_All_);
run;
```

The PRED= option in the OUTPUT statement is used to name the variable pTrt, which contains the predicted event probability of attending a Catholic high school. The _ALL_ keyword is used in the COPYVARS= option to copy all variables from the input data table to the output data table schoolEst. The following DATA step creates the variable pCnt, which contains the predicted probability of not attending a Catholic high school:

```
data mylib.schoolEst;
   set mylib.schoolEst;
   pCnt = 1 - pTrt;
run;
```

An alternative way to obtain the predicted treatment probabilities is to save the fitted treatment model as an analytic store and use the ASTORE procedure. This approach is demonstrated in "Example 6.1: Estimation by Inverse Probability Weighting" on page 231.

For estimation methods that require modeling of the outcome variable, you can provide a previously fit model for the outcome in the form of an analytic store. PROC CAEFFECT uses this analytic store to obtain the required counterfactual predictions. The saved outcome model that you provide as input must use the confounding variables and the treatment variable as predictors. For this example, PROC BART is used to fit a Bayesian additive regression trees (BART) model for the outcome variable. BART models are nonparametric and use samples of a sum-of-trees ensemble to predict the conditional mean of a response variable. For more information about BART models, see the section "Details: BART Procedure" on page 154 in Chapter 4, "BART Procedure." The following statements use PROC BART to fit an outcome model that is saved in an analytic store named bartOutMod:

```
proc bart data=mylib.schoolEst nMC=200 nTree=100 seed=2455;
   class Income FatherEd MotherEd Catholic;
   model Math = BaseMath Income FatherEd MotherEd Catholic;
   store out=mylib.bartOutMod;
```

```
run;
```

The following statements use PROC CAEFFECT to estimate potential outcome means and their difference by using the TMLE method:

```
proc caeffect data=mylib.schoolEst;
   treatvar Catholic;
   outcomevar Math;
   outcomemodel restore=mylib.bartOutMod predname=P_Math;
   pom treatlev='Yes' treatprob=pTrt;
   pom treatlev='No'  treatprob=pCnt;
   difference evtLev='Yes';
run;
```

When you use PROC CAEFFECT, the TREATVAR statement and at least one POM statement are required. In the TREATVAR statement, you identify the treatment variable for the analysis. You use a POM statement to specify a potential outcome of interest and to specify any variables in the input data table that contain predicted values that the estimation method requires. You specify the outcome variable and any outcome variable options by using the OUTCOMEVAR statement. The TMLE method requires the observed outcome values.

You must use the TREATLEV= option in each POM statement. You use this option to specify the level of treatment that defines the potential outcome of interest. For estimation methods that require predicted treatment probabilities, you specify the variables that contain these values by using the TREATPROB= option.

For this example, you use the OUTCOMEMODEL statement to specify the BART model that has previously been fit to the data. PROC CAEFFECT uses the saved model to compute the predicted counterfactual outcome values for the outcome variable Math that the TMLE method requires. When you use the OUTCOMEMODEL statement, you use the RESTORE= option to specify the model that is saved as an analytic store, and you use the PREDNAME= option to specify the name of the variable that contains the model predictions. If you do not know the name of the variables that are created by the analytic store, you can use the DESCRIBE statement in PROC ASTORE and check the "Output Variables" table that it creates to find the variable names. As an alternative to using the OUTCOMEMODEL statement, you can use the PREDOUT= option in the POM statement to specify variables in the input data table that contain precomputed predictions for the counterfactual outcomes. An example of how you can use the alternative syntax is provided by "Example 6.2: Estimation by Regression Adjustment" on page 235.

The DIFFERENCE statement requests a difference between the potential outcome mean estimates. In this example, a single difference is requested, and the EVTLEV= option specifies that the treatment level 'Yes' is used as the event level. In general, you can specify multiple DIFFERENCE statements, and in each DIFFERENCE statement you can specify reference levels, event levels, or both.

The output from this analysis is presented in Figure 6.1 through Figure 6.4.

The "Model Information" table in Figure 6.1 summarizes important information about the analysis that you perform. It includes the name of the input data source, the treatment variable, the estimation method, and the name of the analytic store that is used to score the predicted counterfactual outcomes.

Figure 6.1 Model Information

The CAEFFECT Procedure

Model Information	
Data Source	SCHOOLEST
Treatment Variable	Catholic
Outcome Variable	Math
Outcome Type	Continuous
Estimation Method	TMLE
Outcome Model Store	BARTOUTMOD

Figure 6.2 displays two tables. The "Number of Observations" table displays the number of observations that are used in the analysis. The "Treatment Profile" table displays information about the levels of the treatment variable that appear in the input data table and the number of observations in each level.

Figure 6.2 Model Information

Number of Observations Read	5671
Number of Observations Used	5671

Treatment Profile	
Catholic	**Total Frequency**
No	5079
Yes	592

Figure 6.3 also displays two tables. The "POM Estimates" table indicates the level of treatment that defines the potential outcome and the estimate of its mean. The "POM Differences" table shows the requested difference in potential outcome mean estimates. The table also includes nonprinting columns that contain the potential outcome mean estimates for the event and reference levels; these columns are accessible if you save the table as an output data set by using the ODS OUTPUT statement or if you modify the table's template. If the necessary causal assumptions are satisfied, then the difference in the potential outcome mean estimates is an unbiased estimate of the average treatment effect (ATE). The ATE estimate of 1.467 indicates that attending a Catholic high school has a small positive effect on math scores. For more information about the assumptions that are required for valid causal effect estimation within a potential outcomes framework, see the section "Potential Outcomes and Effect Definitions" on page 216.

Figure 6.3 Potential Outcome Mean and Difference Estimates

POM Estimates	
Treatment Level	**Estimate**
Yes	52.37357
No	50.90671

POM Differences		
Treatment Levels		
Event	**Reference**	**Difference**
Yes	**No**	1.4669

Finally, PROC CAEFFECT displays the table shown in Figure 6.4, which shows the amount of time (in seconds) that it took to perform the various tasks in the analysis.

Figure 6.4 Procedure Timing

Task Timing

Task	Seconds	Percent
Parsing	0.03	1.79%
Data Preparation	0.03	1.63%
Outcome Prediction	1.53	90.20%
Targeting	0.10	5.66%
Estimation	0.00	0.13%
Miscellaneous	0.00	0.21%
Cleaning Up	0.01	0.36%
Total	1.70	100.00%

Syntax: CAEFFECT Procedure

The following statements are available in the CAEFFECT procedure:

PROC CAEFFECT < *options* > **;**
BY *variables* **;**
DIFFERENCE < **REFLEV=(***reference-list* **)** > < **EVTLEV=(***event-list* **)** > **;**
DISPLAY < *table-list* > < */options* > **;**
DISPLAYOUT *table-spec-list* < */options* > **;**
FREQ *variable* **;**
OUTCOMEMODEL RESTORE=*libref.data-table* **PREDNAME=***prediction-name* **;**
OUTCOMEVAR *outcome-variable* < **(EVENT='***event-level***'**) > < */ outcome-options* > **;**
OUTCOMEVAR *events / trials* < */ outcome-options* > **;**
POM TREATLEV='*treatment-level***'**
< **PREDOUT=***predicted-outcome-value* > < **TREATPROB=***predicted-treatment-probability* > **;**
TREATVAR *treatment-variable* < */treatment-options* > **;**
WEIGHT *variable* **;**

The PROC CAEFFECT statement, TREATVAR statement, and at least one POM statement are required. You can specify multiple POM and DIFFERENCE statements. The following sections describe the PROC CAEFFECT statement and then describe the other statements in alphabetical order.

PROC CAEFFECT Statement

PROC CAEFFECT < *options* > **;**

The PROC CAEFFECT statement invokes the procedure. Table 6.1 summarizes the available options in this statement. The options are described fully after the table.

Table 6.1 PROC CAEFFECT Statement Options

Option	Description
DATA=	Specifies the input data table
INFERENCE	Computes standard errors and confidence limits
METHOD=	Specifies the method to use for estimating potential outcome means
POMCOV	Displays the estimated covariance matrix of the potential outcome means
POMINFO	Displays a table that summarizes the potential outcome specifications
SCALEDIPWFLAG=	Specifies a value to be used to flag large weights

DATA=*libref.data-table*

names the input data table for PROC CAEFFECT to use. The default is the most recently created data table. *libref.data-table* is a two-level name, where

libref refers to a collection of information that is defined in the LIBNAME statement and includes the library, which includes a path to the data, and a session identifier, which defaults to the active session but which can be explicitly defined in the LIBNAME statement. For more information about *libref*, see the section "Using CAS Sessions and CAS Engine Librefs" on page 202.

data-table specifies the name of the input data table.

INFERENCE

computes standard errors and confidence intervals for the potential outcome mean and causal effect estimates. Note that because the CAEFFECT procedure takes a model-agnostic approach to causal effect estimation, the statistical validity of the inference depends on model-specific conditions that you must evaluate and that the procedure cannot verify. For more information about the conditions that are required for valid statistical inference, see the section "Standard Errors and Confidence Limits" on page 227.

METHOD=AIPW | IPW | REGADJ | TMLE

specifies the method to use for estimating potential outcome means (POMs). The required inputs for the procedure depend on the estimation method that you specify.

You can specify one of the following methods:

AIPW
estimates POMs by augmented inverse probability weighting. This method requires the observed values of the outcome, predicted treatment probabilities, and predicted counterfactual outcome values. For more information about the AIPW estimation method, see the section "Augmented Inverse Probability Weighting" on page 223.

IPW
estimates POMs by inverse probability weighting. This method requires the observed values of the outcome and predicted treatment probabilities. For more information about the IPW estimation method, see the section "Inverse Probability Weighting" on page 220.

REGADJ
estimates POMs by regression adjustment. This method requires predicted counterfactual outcome values. For more information about the REGADJ estimation method, see the section "Regression Adjustment" on page 222.

TMLE
estimates POMs by targeted maximum likelihood estimation. This method requires the observed values of the outcome, predicted treatment probabilities, and predicted counterfactual outcome values. For more information about the TMLE method, see the section "Targeted Maximum Likelihood Estimation" on page 225.

A default estimation method is determined by the input that you provide to the procedure. If you provide predicted treatment probabilities and predicted counterfactual outcomes, by using either an OUTCOMEMODEL statement or the PREDOUT= option in a POM statement, the TMLE method is used by default. If you provide predicted treatment probabilities and no predicted counterfactual outcomes, the IPW method is used by default. If you provide predicted counterfactual outcomes and no predicted treatment probabilities, the REGADJ method is used by default.

POMCOV
displays a covariance matrix of the potential outcome mean estimates. Note that because the CAEFFECT procedure takes a model-agnostic approach to causal effect estimation, the statistical validity of the inference depends on model-specific conditions that you must evaluate and that the procedure cannot verify. For more information about the conditions that are required for valid statistical inference, see the section "Standard Errors and Confidence Limits" on page 227.

POMINFO
displays the "Potential Outcome Mean Information" table. This table summarizes the levels of treatment for which potential outcome means are estimated and the names of variables that contain precomputed treatment probabilities or counterfactual outcomes that are used for estimation.

SCALEDIPWFLAG=number
specifies a multiple of the expected inverse probability weight of an observation that is used to flag observations that have large weights.

By default, SCALEDIPWFLAG=10.

BY Statement

BY *variables* **;**

You can specify a BY statement in PROC CAEFFECT to obtain separate analyses of observations in groups that are defined by the values of the BY variables. If you specify more than one BY statement, only the last one specified is used. For more information, see the discussion of BY-group processing in the "Grouping Data" section of *SAS Programmers Guide: Essentials*.

DIFFERENCE Statement

DIFFERENCE < **REFLEV=(***reference-list* **)** > < **EVTLEV=(***event-list* **)** > **;**

The DIFFERENCE statement specifies causal effects to estimate on the difference scale. Causal effects on the difference scale are computed by taking a potential outcome mean that is defined by an event level and subtracting a potential outcome mean that is defined by a reference level.

You can use the following options to specify the treatment levels for causal effect estimates:

EVTLEV= (*event-list* **)**
specifies event levels for causal effect estimates.

REFLEV= (*reference-list* **)**
specifies reference levels for causal effect estimates.

The levels of treatment that you specify in the *reference-list* and *event-list* must also be used to define a potential outcome in a POM statement.

If you specify both a *reference-list* and a *event-list*, causal effects are computed for each unique pair of treatment levels between the two lists. If you specify a *reference-list* but not an *event-list*, a causal effect is computed for each treatment level in the *reference-list* and all other levels of treatment that you specify in a POM statement that do not appear in the *reference-list*. If you specify an *event-list* but not a *reference-list*, a causal effect is computed for each treatment level in the *event-list* and all levels of treatment that you specify in a POM statement that do not appear in the *event-list*. You can specify more than one DIFFERENCE statement.

If the treatment variable is a character variable, each treatment level that you specify in the *reference-list* and *event-list* should be enclosed in quotes.

DISPLAY Statement

DISPLAY < *table-list* > < / *options* > **;**

The DISPLAY statement enables you to specify a list of display tables to display or exclude. This statement is similar to the ODS SELECT, ODS EXCLUDE, and ODS TRACE statements. However, the DISPLAY statement can improve performance when a large number of tables could be generated (such as in BY-group processing). The procedure processes the DISPLAY statement on a CAS server and thus sends only a subset of ODS tables to the SAS client. Because ODS statements are processed on a SAS client, first all the generated display tables are sent to the client, and then the client creates a subset.

If you use both DISPLAY and ODS statements together, the DISPLAY statement takes precedence over the ODS statements. Note that the ODS EXCLUDE statement processes tables that are sent to the client after they have been filtered by the DISPLAY statement. In some cases, it might appear that the ODS EXCLUDE statement is taking precedence because it can further filter the tables. For more information about ODS, see *SAS Output Delivery System: Procedures Guide*.

You can specify the *table-list* as a list of table names, paths, partial pathnames, and regular expressions.

The table names that you can specify are listed in the section "ODS Table Names" on page 230. A path is a table name that is prefixed with dot-separated grouping information. For example, a SelectionSummary table that a procedure produces during a selection routine might have the path *Bygroup1.Summary.SelectionSummary*. A partial pathname does not include all groups; for example, *SelectionSummary* and *Summary.SelectionSummary* are partial pathnames for *Bygroup1.Summary.SelectionSummary*.

When you specify a table name or partial pathname, all display tables whose paths end in the specified name are selected for display or exclusion. For example, both *SelectionSummary* and *Summary.SelectionSummary* select *Bygroup1.Summary.SelectionSummary*.

A regular expression is enclosed in forward slashes (/). For example, specifying "/tions/" selects all pathnames that contain the substring "tions"; in particular, the *Bygroup1.Summary.SelectionSummary* table is selected. Specifying "!/tions/" selects all pathnames that do not contain the substring "tions"; in particular, the *Bygroup1.Summary.SelectionSummary* table is not selected.

You can specify the following *options* after a slash (/):

CASESENSITIVE
performs a case-sensitive comparison of table names in the *table-list* to display table names when tables are subsetted for display. To preserve case, you must enclose table names in the *table-list* in quotation marks.

EXCLUDE
displays all display tables except those that you specify in the *table-list*.

EXCLUDEALL
suppresses display of all tables. This option takes precedence over the other options.

TRACE
displays the display table names, labels, and paths.

DISPLAYOUT Statement

DISPLAYOUT *table-spec-list* < / *options* > **;**

The DISPLAYOUT statement enables you to create output tables from your displayed output. This statement is similar to the ODS OUTPUT statement. For more information about ODS, see *SAS Output Delivery System: Procedures Guide*.

The *table-spec-list* specifies a list of output tables to create. Each entry in the list has either a *key*=*value* format or a *key* format:

key=*value* specifies *key* as the ODS table name, path, or partial pathname, and specifies *value* as the output table name.

key specifies *key* as the ODS table name and also as the output table name.

The ODS table names that you can specify are listed in the section "ODS Table Names" on page 230. You cannot specify the ODS table named OutputCasTables in the *table-spec-list*.

Table names and partial pathnames are discussed under the DISPLAY statement. The DISPLAYOUT statement does not support regular expressions.

You can specify the following *options* after a slash (/):

INCLUDEALL
creates output tables for all display tables. The name of the created output table is the same as the name of the corresponding display table. If you specify this option, the *table-spec-list* specification is ignored.

NOREPLACE
does not replace any existing output table of the same name.

REPEATED
replicates all output tables on all nodes.

FREQ Statement

FREQ *variable* **;**

The *variable* in the FREQ statement identifies a numeric variable in the input data table that contains the frequency of occurrence of each observation. PROC CAEFFECT treats each observation as if it appears f times, where f is the value of the FREQ *variable* for the observation. If f is not an integer, it is truncated to an integer. If f is less than 1 or missing, the observation is not used in the analysis. When you omit the FREQ statement, each observation is assigned a frequency of 1.

OUTCOMEMODEL Statement

OUTCOMEMODEL RESTORE=*libref.data-table* **PREDNAME=***prediction-name* **;**

The OUTCOMEMODEL statement enables you to use a previously fit model for the outcome variable to compute counterfactual outcomes. PROC CAEFFECT uses the model to obtain predicted counterfactual outcomes for each treatment level that you specify in a POM statement.

When you use the OUTCOMEMODEL statement, you must specify the following options:

RESTORE=*libref.data-table*
specifies the saved model in the form of an analytic store.

PREDNAME=*prediction-name*
identifies the variable that contains the outcome of interest when data are scored using the analytic store.

The OUTCOMEMODEL statement is ignored if the method that you use to estimate potential outcome means does not require modeling of the outcome variable. If you specify this statement, any predicted counterfactual outcomes that you specify by using the PREDOUT= option in a POM statement are ignored.

OUTCOMEVAR Statement

OUTCOMEVAR *outcome-variable* < **(EVENT=**'*event-level*'**)** > < */outcome-options* > **;**

OUTCOMEVAR *events* / *trials* < */outcome-options* > **;**

The OUTCOMEVAR statement specifies information about the outcome variable. Information about the outcome variable is required for all estimation methods except the regression adjustment method. You can specify the outcome as a single variable or as a ratio of two variables that are denoted as *events*/*trials*. The first form applies to response variables that are continuous or categorical; the second form applies only to summarized binomial response data.

When you have binomial data, the *events* variable contains the number of positive responses (or events) and the *trials* variable contains the number of trials. The values of both *events* and (*trials* – *events*) must be nonnegative, and the value of *trials* must be positive. For binomial response data, the potential outcomes correspond to the event probability.

When you have categorical data, you must specify the following option:

EVENT='*event-level***'**
specifies the outcome *event-level* of interest.

For categorical response data, the potential outcomes correspond to the probability of the event level occurring.

You can specify the following *outcome-options* after a slash (/):

COUNTMISSING
treats missing values (".", ".A", . . . , ".Z" for numeric variables and blanks for character variables) as valid values of a categorical outcome variable.

LEVELIZERAW
bases the levelization of a categorical outcome variable on raw values.

MAXLEV=*number*
specifies the maximum number of levels for a categorical outcome variable. The *number* 0 means an unlimited number of levels.

TYPE=BINOMIAL | CATEGORICAL | CONTINUOUS
specifies the type of the outcome variable.

You can specify one of the following types:

BINOMIAL
specifies a binomial outcome. For a binomial outcome, the event probability is modeled, and predicted outcome values must be between 0 and 1, inclusive. If the specified estimation method requires the observed outcome values, you must use event/trial syntax. Event variable values must be nonnegative, trial variable values must be positive, and the number of events must be less than or equal to the number of trials.

CATEGORICAL
specifies a categorical outcome. For a categorical outcome, the probability of a designated event level is modeled, and the observed outcome and predicted outcome values must be between 0 and 1, inclusive. If the specified estimation method requires the observed outcome values, you must specify the event level by using the EVENT= option.

CONTINUOUS
specifies a continuous outcome. For a continuous outcome, the observed outcome and predicted outcome values can be any real values.

POM Statement

POM TREATLEV='*treatment-level*' < **PREDOUT=***predicted-outcome-value* > < **TREATPROB=***predicted-treatment-probability* > **;**

The POM statement specifies a potential outcome mean to estimate. You must specify the following option in a POM statement:

TREATLEV='*treatment-level*'

TRTLEV='*treatment-level*'

specifies the level of the treatment variable that defines the potential outcome. If the treatment variable is a character variable, specify the *treatment-level* in quotes.

For more information about the definition of potential outcomes and the counterfactual framework to causal effect estimation, see the section "Potential Outcomes and Effect Definitions" on page 216.

Depending on the estimation method that you use, you can use the following options to specify variables in the input data table that contain precomputed model predictions:

PREDOUT=*predicted-outcome-value*

specifies the input variable that contains the predicted counterfactual outcome values for the specified treatment level. Predicted counterfactual outcomes are not used for the IPW estimation method. If you use the OUTCOMEMODEL statement to specify a previously fit model to use in computing counterfactual outcomes, the PREDOUT= option is ignored.

TREATPROB=*predicted-treatment-probability*

TRTPROB=*predicted-treatment-probability*

specifies the input variable that contains the predicted probability of having the specified level of treatment. Predicted treatment probabilities are not used for the REGADJ estimation method.

TREATVAR Statement

TREATVAR *treatment-variable* < */treatment-options* > **;**

The TREATVAR statement specifies information about the treatment variable. For all the estimation methods, you must specify the name of the *treatment-variable*.

You can specify the following *treatment-options* after a slash (/):

CONDEVENT='*treatment-level*'

EVENT='*treatment-level*'

specifies the estimation of conditional potential outcome means and the observed *treatment-level* to condition on. This *treatment-level* must appear in a potential outcome specification. Conditional potential outcome mean estimation is supported only for the IPW and REGADJ estimation methods. For more information about the definition of causal effects, see the section "Potential Outcomes and Effect Definitions" on page 216.

COUNTMISSING
treats missing values (“.”, “.A”, . . . , “.Z” for numeric variables and blanks for character variables) as valid values of the treatment variable.

LEVELIZERAW
bases the levelization of the treatment variable on raw values.

MAXLEV=*number*
specifies the maximum number of levels for the treatment variable. The *number* 0 means an unlimited number of levels.

WEIGHT Statement

WEIGHT *variable* **;**

The *variable* that you specify in the WEIGHT statement is used as a weight to perform a weighted analysis of the data. Observations that have nonpositive weights or missing weights are excluded from the analysis. The values of the WEIGHT variable can be nonintegral and are not truncated. When you omit this statement, all observations that are used in the analysis are assigned a weight of 1.

Details: CAEFFECT Procedure

Missing Values

Any observation that has missing values for a predicted counterfactual outcome, predicted treatment probability, treatment variable, frequency variable, or weight variable is excluded from the analysis; however, missing values are valid for the treatment variable if you specify the COUNTMISSING option in the TREATVAR statement. If the estimation method requires the observed outcome values, any observation that has a missing value for the outcome is excluded from the analysis; however, missing values are valid for the categorical outcome variable if you specify the COUNTMISSING option in the OUTCOMEVAR statement.

Potential Outcomes and Effect Definitions

This section describes the Neyman-Rubin potential outcomes framework (Rubin 1980, 1990), which the CAEFFECT procedure uses to define causal effects. This framework provides an approach that you can use to clearly articulate causal assumptions and to define causal effects of a treatment T on an outcome Y. Note that although the effects are referred to as treatment effects, this is done only for ease of exposition, because the variable T could also represent an intervention or exposure. For example, T could indicate enrollment in a job training program, and Y could indicate subsequent employment.

Potential outcomes, which are also referred to as counterfactual outcomes, are used to describe an idealized source of data where you can observe a subject’s response to all possible treatment assignments. The potential outcome $Y(t)$ is defined to be the value of the outcome variable that would occur if the subject were to receive

treatment level t (possibly contrary to the observed assignment). For example, if you consider a categorical treatment T with p levels, there are p potential outcomes $Y(t_i)$, for $i = 1, \ldots, p$. With the potential outcomes, it is natural to define a unit-level treatment effect between treatment levels t_1 and t_0 as the difference between $Y(t_1)$ and $Y(t_0)$.

Although the individual-level treatment effects that are defined using potential outcomes are intuitive, a number of assumptions must be satisfied for them to be well-defined quantities. The stable unit treatment value assumption (SUTVA), which is described by Rubin (1980), is one assumption that you typically make when using potential outcomes to define causal effects. This assumption ensures that the potential outcomes that you hypothesize are well-defined intrinsic values associated with a subject. SUTVA has two components:

- a no-interference condition, which assumes that a subject's potential outcomes are not affected by the treatment assignment of the other subjects
- an assumption of no hidden levels of treatment, meaning that the potential outcomes capture all relevant variability in the treatment

In a more refined statement, VanderWeele (2009) proposed a less restrictive version of the second component of SUTVA. Essentially, VanderWeele's version requires that the potential outcomes remain unchanged within a certain degree of treatment variation for each treatment level. This version is also known as the treatment variation irrelevance assumption. (See also Cole and Frangakis 2009.)

To connect the potential outcomes to observed data, you make a consistency assumption that states that the observed outcome Y is equal to the potential outcome that is defined by the observed level of the treatment T. To express this assumption mathematically, let $\mathbb{1}(T = t)$ denote the indicator function for the event in which $T = t$. You can then write the consistency assumption as

$$Y = \sum_{i=1}^{p} \mathbb{1}(T = t_i) Y(t_i)$$

The consistency assumption makes clear that you can observe at most one potential outcome for each subject. Therefore, you are typically unable to reliably estimate all potential outcomes and the unit-level treatment effects that they define for a subject. Instead, you typically consider the estimation of the potential outcome means, $E\left[Y(t)\right]$. You can also consider average treatment effects for the entire population. For example, for the designated event level t_1 and reference level t_0, the average treatment effect (ATE) on the difference scale is given by

$$E\left[Y(t_1)\right] - E\left[Y(t_0)\right]$$

The ATE is interpreted as the mean difference between the outcomes when everyone in the population receives treatment level t_1 and when everyone receives treatment level t_0.

In addition to estimating potential outcome means and average treatment effects for the entire population, you can consider estimating potential outcome means and treatment effects conditional on subjects receiving a particular level of treatment. That is, for a designated level of treatment t_{trt}, you can estimate $E\left[Y(t) \mid T = t_{\text{trt}}\right]$. For a binary treatment variable T, these conditional potential outcome mean estimates define the average treatment effect for the treated (ATT). Assuming that $T = t_1$ is the designated treatment level and $T = t_0$ is the reference level, the ATT is given by

$$E\left[Y(1) \mid T = t_1\right] - E\left[Y(0) \mid T = t_1\right]$$

Here, the ATT is interpreted as the average effect of treatment on those subjects who receive it.

Identification of Causal Effects

As described by Rubin (1990), it is implied in this potential outcomes approach to defining causal effects that if the SUTVA assumption holds, the potential outcomes are not affected by the treatment assignment mechanism that is used to generate the observed data. That is, whether you conduct a fully randomized experiment or an observational study, if you can assume SUTVA and you have a well-defined causal problem, you can define the same potential outcomes and average treatment effects.

Data that are generated from a fully randomized experiment and from an observational study differ in what you can assume about the relationship between the potential outcomes and the observed treatment assignment. This difference determines whether it is feasible to obtain unbiased estimates of the effects of interest and what estimation methods you can use to do so.

When the data are generated from a fully randomized experiment, external randomization enables you to safely assume that the potential outcomes and treatment assignment are independent. The observed outcome Y still depends on the treatment assignment through the consistency assumption. Assuming independent potential outcomes and treatment assignment, you can obtain an unbiased estimate of $E[Y(t)]$ by taking the average of the observed outcome Y for those subjects in which treatment $T = t$.

When the data are generated from a nonrandomized or observational study, there can be a number of pretreatment characteristics that are associated with both the potential outcomes and the treatment assignment. These pretreatment variables are often referred to as confounding variables or confounding covariates. To enable the unbiased estimation of potential outcome means in the presence of confounding, you must assume that there is a set of measured confounders $\boldsymbol{X}$ such that the potential outcomes and treatment are conditionally independent given $\boldsymbol{X}$. This condition is often articulated as an ignorability or conditional exchangeability assumption. A set of confounders $\boldsymbol{X}$ that satisfies this conditional independence property is often referred to as a valid adjustment set, because a statistical adjustment of these confounders can produce an unbiased estimate of the potential outcome means.

The assumption that a set of confounders $\boldsymbol{X}$ is a valid adjustment set typically is not empirically verifiable, because the assumption involves the unobserved potential outcomes. Moreover, the potential outcome definitions do not naturally lend themselves to representing assumptions of why a particular set of confounders $\boldsymbol{X}$ might provide a valid adjustment set. Graphical causal models (Spirtes, Glymour, and Scheines 2001; Pearl 2009a, b; Elwert 2013) are one approach that you can use to depict assumptions about the data-generating process and the association between variables. As described by Shpitser, VanderWeele, and Robins (2010), graphical causal models and potential outcomes can be related through an equivalence between a set of confounders $\boldsymbol{X}$, which satisfy the conditional exchangeability assumption, and a certain graphical identification criterion. You can therefore use graphical causal models as a way to represent the causal assumptions about a data-generating process that would justify the use of a particular adjustment set. For more information about graphical causal models and how you can use them to assess the identifiability of treatment effects, see Chapter 37, "The CAUSALGRAPH Procedure" (*SAS/STAT User's Guide*).

An additional assumption that you typically make when estimating a causal effect is the positivity assumption: that is, each subject should have a nonzero probability of receiving any treatment level. This assumption can be expressed as

$$0 < \Pr(T = t \mid \boldsymbol{X} = \mathbf{x}) < 1 \quad \text{for all } t = 1, \ldots, p$$

The positivity assumption ensures that the causal effects are practically well defined for the population of interest.

Adjustment for Confounding

You can adjust for a set of confounding variables $\boldsymbol{X}$ by modeling the treatment variable T, the outcome variable Y, or both. PROC CAEFFECT enables you to use a model for the treatment variable T to estimate potential outcome means through inverse probability of treatment weighting. When you use a model for the outcome variable Y, the procedure can estimate potential outcome means by using regression adjustment (also called a response surface approach). Finally, you can combine predicted treatment probabilities and an outcome model in so-called doubly robust approaches. An estimation method is considered doubly robust if it provides unbiased estimates of the potential outcome means even if one of the models is misspecified. PROC CAEFFECT can perform doubly robust estimation by using either augmented inverse probability weighting or targeted maximum likelihood estimation. For more information about the estimation methods that this procedure implements, see the section "Estimation Methods" on page 219.

For more information about defining and estimating causal effects by using a potential outcomes framework, see Rubin (1980), Rubin (1990), Neyman, Dabrowska, and Speed (1990), Imbens and Rubin (2015), Hernán and Robins (2020), and references therein.

Estimation Methods

PROC CAEFFECT implements several methods of estimating potential outcome means and their differences. The causal interpretation of these estimates depends on the plausibility of the causal assumptions that are described in the section "Potential Outcomes and Effect Definitions" on page 216.

These estimation methods differ primarily in how they make statistical adjustments for confounding variables. In general, you can adjust for confounding variables by modeling the treatment variable, the outcome variable, or both. PROC CAEFFECT is a model-agnostic tool for effect estimation. That is, the procedure itself does not support modeling of the treatment and outcome variables. Instead, as input to the procedure, you provide the quantities necessary for your chosen estimation method. Thus, you can adjust for the effects of confounding variables by using predictions from a previously fit model for the treatment variable, a previously fit model for the outcome variable, or models for both the treatment and outcome variables. The required inputs for each method that PROC CAEFFECT supports are summarized in Table 6.2.

Table 6.2 Required Inputs of Different Estimation Methods

Method	Treatment Model	Outcome Model	Observed Outcome
Inverse probability weighting	X		X
Regression adjustment		X	
Augmented inverse probability weighting	X	X	X
Targeted maximum likelihood estimation	X	X	X

The inverse probability weighting (IPW) method requires a model for the treatment variable. To use this method, you must specify variables in the input data table that contain the precomputed treatment assignment probabilities. For an example of how you can perform IPW estimation, see "Example 6.1: Estimation by Inverse Probability Weighting" on page 231. For more information about estimation by inverse probability weighting, see the section "Inverse Probability Weighting" on page 220.

The regression adjustment method requires a model for the outcome variable. To use this method, you have two choices for the input that you must provide: you can specify variables in the input data table that contain the predicted potential outcomes for each specified level of treatment, or you can provide a previously fit model in the form of an analytic store by using the OUTCOMEMODEL statement. In the second case, the procedure uses the analytic store to compute the relevant predicted outcome values. When you provide an analytic store as input, the model must include the specified treatment variables as a predictor, and all the required predictor variables must appear in the input data table. For an example that shows how you can perform estimation by regression adjustment by providing the procedure with either an analytic store or precomputed predicted values, see "Example 6.2: Estimation by Regression Adjustment" on page 235. For more information about estimation by regression adjustment, see the section "Regression Adjustment" on page 222.

The remaining two methods, augmented inverse probability weighting (AIPW) and targeted maximum likelihood estimation (TMLE), are so-called doubly robust estimation methods. An estimation method is considered doubly robust if it provides unbiased estimates whenever at least one of the models is correctly specified. For these methods, you must specify a model for both the treatment variable and the outcome variable. For an example of how you can use PROC CAEFFECT to perform doubly robust estimation, see "Example 6.3: Estimation by Doubly Robust Methods" on page 239. For more information about estimation by augmented inverse probability weighting, see the section "Augmented Inverse Probability Weighting" on page 223. For more information about targeted maximum likelihood estimation, see the section "Targeted Maximum Likelihood Estimation" on page 225.

Supported Variable Types

PROC CAEFFECT supports the estimation of treatment effects for categorical treatment variables and for continuous, categorical, or binomial outcomes. In the case of categorical outcomes, you must specify a designated event level by using the EVENT= option in the OUTCOMEVAR statement, and the outcome model (specified as either predicted potential outcomes or an analytic store) must represent the probability of that event level. Similarly, for binomial data, the outcome model must represent the event probability. If you are modeling binomial data and the estimation method that you use requires observed outcome values, you must use the event/trial syntax in the OUTCOMEVAR statement. This syntax requires that you specify two variables that contain the counts from a binomial experiment. The event variable contains the number of positive responses, or events, and the trial variable contains the number of trials that are conducted.

Inverse Probability Weighting

When you estimate potential outcome means by inverse probability weighting (IPW), the observed outcomes for each subject are assigned weights inversely proportional to the probability of having received the observed level of treatment. Incorporating the IPW weights creates a pseudopopulation that corrects for the bias that the confounding variables introduce. You can obtain unbiased estimates of the potential outcome means from the weighted pseudopopulation. For more information about IPW estimation, see Lunceford and Davidian (2004), Hernán and Robins (2020), and references therein.

When estimating ℓ potential outcome means by IPW, you must provide as input ℓ variables that contain the predicted treatment probabilities of a subject being assigned to the specified treatment levels. You specify the variables that contain these precomputed probabilities by using the TREATPROB= option in each potential outcome specification. For an example of using PROC CAEFFECT to implement the IPW estimation method, see "Example 6.1: Estimation by Inverse Probability Weighting" on page 231.

The following list defines components of the estimating equations that you solve to obtain the IPW estimates of the potential outcome means:

- T denotes the treatment variable.
- y_i denotes the observed outcome for subject i.
- $\mathbb{1}(T_i = t)$ denotes the indicator function for subject i being assigned to treatment level t.
- e_{ti} denotes the conditional probability of subject i being assigned to treatment level t; that is, $\Pr(T_i = t \mid \boldsymbol{X} = \boldsymbol{x}_i)$.

The IPW estimates of the potential outcome means solve the equations

$$\mathbf{S}_{\text{ipw}}(\boldsymbol{\mu}) = \sum_{i=1}^{n} \mathbf{S}_{\text{ipw},i}(\boldsymbol{\mu}) = 0$$

where

$$\mathbf{S}_{\text{ipw},i}(\boldsymbol{\mu}) = \begin{bmatrix} \mathbb{1}(T_i = t_1)\left(\frac{y_i - \mu_1}{e_{1i}}\right) \\ \vdots \\ \mathbb{1}(T_i = t_\ell)\left(\frac{y_i - \mu_\ell}{e_{\ell i}}\right) \end{bmatrix}$$

The solution to these equations has a closed-form expression given by

$$\hat{\mu}_{t_j} = \left(\sum_{i=1}^{n} \frac{\mathbb{1}(T_i = t_j)}{e_{t_j i}}\right)\left(\sum_{i=1}^{n} \frac{\mathbb{1}(T_i = t_j) y_i}{e_{t_j i}}\right) \quad \text{for } j = 1, \ldots, \ell$$

You can also use the IPW estimation method to estimate potential outcome means conditional on subjects receiving a particular treatment assignment. You specify the level of treatment to condition on by using the CONDEVENT= option in the TREATVAR statement. The level of treatment that you specify for the conditioning event must also be used in a potential outcome specification in a POM statement.

Let t_{trt} denote the level of treatment that you specify to condition on for computing conditional potential outcome mean estimates. The IPW estimates of the potential outcome means conditional on $T = t_{\text{trt}}$ solve a similar set of estimating equations, where the weights that are used to estimate the unconditional means (one over the observed treatment assignment probability) are multiplied by $e_{t_{\text{trt}}}$, the probability of being assigned to the treatment level t_{trt}. The score equation for each subject is then given by

$$\mathbf{S}_{\text{ipw},i}(\boldsymbol{\mu}) = \begin{bmatrix} \mathbb{1}(T_i = t_1) e_{t_{\text{trt}} i}\left(\frac{y_i - \mu_1}{e_{1i}}\right) \\ \vdots \\ \mathbb{1}(T_i = t_\ell) e_{t_{\text{trt}} i}\left(\frac{y_i - \mu_\ell}{e_{\ell i}}\right) \end{bmatrix}$$

The solution to the estimating equations for the conditional potential outcome means is then given by

$$\hat{\mu}_{t_j | T = t_{\text{trt}}} = \left(\sum_{i=1}^{n} \frac{\mathbb{1}(T_i = t_j) e_{t_{\text{trt}} i}}{e_{t_j i}}\right)\left(\sum_{i=1}^{n} \frac{\mathbb{1}(T_i = t_j) e_{t_{\text{trt}} i} y_i}{e_{t_j i}}\right) \quad \text{for } j = 1, \ldots, \ell$$

If you specify a weight variable by using the WEIGHT statement, the score equation for each subject is multiplied by the value of this variable, and the solutions to the estimating equations are updated accordingly. When you use the IPW estimation method, an observation from the input data table is not used if any of the following conditions occur:

- A predicted treatment assignment probability is missing.
- The value of the outcome variable is missing.
- The observed treatment level is not used in a potential outcome specification.
- The value of a frequency or weight variable, if specified, is missing or nonpositive.

Regression Adjustment

When you estimate potential outcome means by regression adjustment, you use predicted potential outcome values that are obtained from a model of the outcome variable. The predicted potential outcome values for each subject are obtained by replacing the observed treatment assignment with the treatment assignments that define the potential outcomes of interest and then by evaluating the outcome model for each treatment assignment in turn. The averages of the predicted values are used to estimate the average of the potential outcomes. For more information about estimation by regression adjustment, see Hernán and Robins (2020) and references therein.

To estimate ℓ potential outcome means by regression adjustment, you must provide as input either ℓ variables that contain the predicted potential outcome values or a previously fit model for the outcome in the form of an analytic store. If the input that you provide consists of predicted potential outcome values, you must use the PREDOUT= option for each potential outcome specification to specify the variable that represents the predicted potential outcomes. If the input that you provide consists of a previously fit model, you use the OUTCOMEMODEL statement, specify the name of the analytic store by using the RESTORE= option, and specify the name of the variable that contains the model predictions by using the PREDNAME= option. When you specify a previously fit model, PROC CAEFFECT uses the model to compute the potential outcome predictions. For an example of using this procedure to implement the regression adjustment estimation method, see "Example 6.2: Estimation by Regression Adjustment" on page 235.

To describe the estimating equations, you solve to obtain the regression adjustment estimates of the potential outcome means. Let $\hat{y}_{ti}$ denote the predicted counterfactual outcome value that you obtain by replacing the observed treatment assignment with $T = t$. The regression adjustment estimates of the potential outcome means solve the equations

$$\mathbf{S}_{\text{regadj}}(\boldsymbol{\mu}) = \sum_{i=1}^{n} \mathbf{S}_{\text{regadj},i}(\boldsymbol{\mu}) = 0$$

where

$$\mathbf{S}_{\text{regadj},i}(\boldsymbol{\mu}) = \begin{bmatrix} \hat{y}_{1i} - \mu_1 \\ \vdots \\ \hat{y}_{\ell i} - \mu_\ell \end{bmatrix}$$

The solution to these equations has a closed-form expression given by

$$\hat{\mu}_{t_j} = \frac{1}{n} \sum_{i=1}^{n} \hat{y}_{t_j i} \quad \text{for } j = 1, \ldots, \ell$$

You can also use the regression adjustment estimation method to estimate potential outcome means conditional on subjects receiving a particular treatment assignment. You specify the level of treatment to condition on by using the CONDEVENT= option in the TREATVAR statement. The level of treatment that you specify for the conditioning event must also be used in a potential outcome specification in a POM statement.

The regression adjustment estimates of the potential outcome means conditional on $T = t_{\text{trt}}$ solve a similar set of estimating equations, where predicted counterfactual values are averaged only for subjects that have the treatment assignment that you are conditioning on. The following list defines components of the estimating equations that you solve to obtain the regression adjustment estimates of the potential outcome means conditional on a treatment level:

- t_{trt} denotes the level of treatment that you specify to define the conditioning event $T = t_{\text{trt}}$.
- $\mathbb{1}(T_i = t_{\text{trt}})$ denotes the indicator function for subject i being assigned to treatment level t_{trt}.
- $n_{t_{\text{trt}}}$ denotes the number of subjects that have the observed treatment assignment $T_i =_{\text{trt}}$.

The score equation for each subject is then given by

$$\mathbf{S}_{\text{regadj},i}(\boldsymbol{\mu}) = \begin{bmatrix} \mathbb{1}(T_i = t_{\text{trt}})(\hat{y}_{1i} - \mu_1) \\ \vdots \\ \mathbb{1}(T_i = t_{\text{trt}})(\hat{y}_{\ell i} - \mu_\ell) \end{bmatrix}$$

The solution to these equations has a closed-form expression given by

$$\hat{\mu}_{t_j|T=t_{\text{trt}}} = \frac{1}{n_{t_{\text{trt}}}} \sum_{i=1}^{n} \mathbb{1}(T_i = t_{\text{trt}}) \hat{y}_{t_j i} \quad \text{for } j = 1, \ldots, \ell$$

If you specify a weight variable by using the WEIGHT statement, the score equation for each subject is multiplied by the value of this variable, and the solutions to the estimating equations are updated accordingly. When you use the regression adjustment estimation method, an observation from the input data table is not used if either of the following conditions occurs:

- A predicted potential outcome value is missing.
- The value of a frequency or weight variable, if specified, is missing or nonpositive.

In addition to these conditions, if you are estimating potential outcome means conditional on a particular treatment assignment, only observations that have the specified treatment assignment are used.

Augmented Inverse Probability Weighting

When you estimate potential outcome means by augmented inverse probability weighting (AIPW), predictions from a model for the outcome variable and predictions from a model for the treatment variable are combined to form a doubly robust estimation method. An estimation method is said to be doubly robust if it provides unbiased estimates whenever at least one of the models that you use is correctly specified. The model for the outcome variable is used in the AIPW estimation method to predict potential outcome values for each subject by replacing the observed treatment assignment with the treatment assignments that define the potential outcomes of interest. The model for the treatment variable is used to compute weights that are inversely

proportional to the probability that a subject has the observed treatment assignment. For more information about the AIPW estimation method, see Lunceford and Davidian (2004), Hernán and Robins (2020), and references therein.

To estimate ℓ potential outcome means by AIPW, you must provide as input ℓ variables that contain the predicted probability of a subject being assigned to the specified treatment levels. You specify the variables that contain the precomputed treatment assignment probabilities by using the TREATPROB= option in each potential outcome specification. Also, you must specify either ℓ variables that contain the predicted potential outcome values or a previously fit model for the outcome in the form of an analytic store. If the input that you provide consists of predicted potential outcome values, you must use the PREDOUT= option for each potential outcome specification to specify the variable that represents the predicted potential outcomes. If the input that you provide consists of a previously fit model, you use the OUTCOMEMODEL statement, specify the name of the analytic store by using the RESTORE= option, and specify the name of the variable that contains the model predictions by using the PREDNAME= option. When you specify a previously fit model, PROC CAEFFECT uses the model to compute the potential outcome predictions. For an example of using this procedure to implement the AIPW estimation method, see "Example 6.3: Estimation by Doubly Robust Methods" on page 239.

The following list defines components of the estimating equations that you solve to obtain the AIPW estimates of the potential outcome means:

- T denotes the treatment variable.
- y_i denotes the observed outcome for subject i.
- $\hat{y}_{ti}$ denotes the predicted potential outcome value that you obtain by replacing the observed treatment assignment with $T = t$.
- $\mathbb{1}(T_i = t)$ denotes the indicator function for subject i being assigned to treatment level t.
- e_{ti} denotes the conditional probability of subject i being assigned to treatment level t; that is, $\Pr(T_i = t \mid \boldsymbol{X} = \boldsymbol{x}_i)$.

The AIPW estimates of the potential outcome means solve the equations

$$\mathbf{S}_{\text{aipw}}(\boldsymbol{\mu}) = \sum_{i=1}^{n} \mathbf{S}_{\text{aipw},i}(\boldsymbol{\mu}) = 0$$

where

$$\mathbf{S}_{\text{aipw},i}(\boldsymbol{\mu}) = \begin{bmatrix} \frac{\mathbb{1}(T_i=t_1)y_i}{e_{1i}} - \hat{y}_{1i}\left(\frac{\mathbb{1}(T_i=t_1)-e_{1i}}{e_{1i}}\right) - \mu_1 \\ \vdots \\ \frac{\mathbb{1}(T_i=t_\ell)y_i}{e_{\ell i}} - \hat{y}_{\ell i}\left(\frac{\mathbb{1}(T_i=t_\ell)-e_{\ell i}}{e_{\ell i}}\right) - \mu_\ell \end{bmatrix}$$

The solution to these equations has a closed-form expression given by

$$\hat{\mu}_{t_j} = \frac{1}{n}\sum_{i=1}^{n} \frac{\mathbb{1}(T_i = t_j)y_i}{e_{t_j i}} - \hat{y}_{t_j i}\left(\frac{\mathbb{1}(T_i = t_j) - e_{t_j i}}{e_{t_j i}}\right) \quad \text{for } j = 1, \ldots, \ell$$

If you specify a weight variable by using the WEIGHT statement, the score equation for each subject is multiplied by the value of this variable, and the solutions to the estimating equations are updated accordingly. When you use the AIPW estimation method, an observation from the input data table is not used if any of the following conditions occur:

- A predicted treatment assignment probability is missing.
- The value of the outcome variable is missing.
- A predicted counterfactual value is missing.
- The value of a frequency or weight variable, if specified, is missing or nonpositive.

Targeted Maximum Likelihood Estimation

When you estimate potential outcome means by targeted maximum likelihood estimation (TMLE), predictions from a model for the outcome variable and predictions from a model for the treatment variable are combined to form a doubly robust estimation method. An estimation method is said to be doubly robust if it provides unbiased estimates whenever one of the models that you use is correctly specified. The model for the outcome variable is used in the TMLE method to predict potential outcome values for each subject by replacing the observed treatment assignment with the treatment assignments that define the potential outcomes of interest. The model for the treatment variable is used to compute covariates that a targeting step uses to reduce finite sample bias and model misspecification bias in the outcome model. For more information about the TMLE method, see Gruber and Van der Laan (2009), Van der Laan (2010a), Van der Laan (2010b), and Van der Laan and Rose (2011).

To estimate ℓ potential outcome means by TMLE, you must provide as input ℓ variables that contain the predicted probability of a subject being assigned to the specified treatment levels. You specify the variables that contain the precomputed treatment assignment probabilities by using the TREATPROB= option in each potential outcome specification. Also, you must specify either ℓ variables that contain the predicted potential outcome values or a previously fit model for the outcome in the form of an analytic store. If the input that you provide consists of predicted potential outcome values, you must use the PREDOUT= option for each potential outcome specification to specify the variable that represents the predicted potential outcomes. If the input that you provide consists of a previously fit model, you use the OUTCOMEMODEL statement, specify the name of the analytic store by using the RESTORE= option, and specify the name of the variable that contains the model predictions by using the PREDNAME= option. When you specify a previously fit model, PROC CAEFFECT uses the model to compute the potential outcome predictions. For an example of using this procedure to implement the TMLE method, see "Example 6.3: Estimation by Doubly Robust Methods" on page 239.

The following list defines components of the equations that you use to obtain the TMLE estimates of the potential outcome means:

- T denotes the treatment variable.
- y_i denotes the observed outcome for subject i.
- $\hat{y}_{ti}$ denotes the predicted potential outcome value that you obtain by replacing the observed treatment assignment with $T = t$.

- $\tilde{y}_i$ denotes the predicted potential outcome value that corresponds to the observed treatment value.
- y^*_{ti} denotes the predicted potential outcome value that you obtain by applying the targeting step to the initial predicted potential outcome value that corresponds to treatment level $T = t$.
- $\mathbb{1}(T_i = t)$ denotes the indicator function for subject i being assigned to treatment level t.
- e_{ti} denotes the conditional probability of subject i being assigned to treatment level t; that is, $\Pr(T_i = t \mid \boldsymbol{X} = \boldsymbol{x}_i)$.

The TMLE algorithm starts with the predicted potential outcomes that are obtained from the outcome model that you provide as input. The algorithm then uses a targeting step to refine those predictions. The targeting step is performed by regressing the observed outcome variable against a carefully chosen set of covariates; the initial predicted potential outcomes are specified as a regression offset.

There is one covariate, H_{t_j}, for each potential outcome mean that you want to estimate ($j = 1, \ldots, \ell$). When you estimate the potential outcome means in the population, the values of the clever covariates are computed for each observation by the equation

$$\hat{h}_{t_j i} = \frac{\mathbb{1}(T_i = t_j)}{e_{t_j i}} \quad \text{for } j = 1, \ldots, \ell$$

Note that for each individual, only one of the ℓ covariates is nonzero. The covariates are used in the regression equation

$$\operatorname{logit}(y) = \operatorname{logit}(\tilde{y}) + \sum_{j=1}^{\ell} \epsilon_j \hat{h}_{t_j}$$

In the targeting step, the TMLE algorithm computes estimates $\hat{\epsilon}_j$ of the regression parameters ϵ_j and then uses these estimates to update the predicted potential outcomes. These updated predictions are computed by the formula

$$\operatorname{logit}(y^*_{t_j i}) = \operatorname{logit}(\hat{y}_{t_j i}) + \frac{\hat{\epsilon}_j}{e_{t_j i}}$$

When the outcome variable is binary, the estimated regression parameters $\hat{\epsilon}_j$ are computed by logistic regression. When the outcome variable is continuous or binomial, the regression parameters are computed by a generalized linear model that has a binomial distribution and a logit link. In the latter case, you must rescale the observed outcomes and the predicted potential outcomes so that all values are contained in the open interval (0,1). In both cases, the regression is computed with no intercept and with $\operatorname{logit}(\tilde{y})$ as the offset.

After the targeting step, the potential outcome means are given by

$$\hat{\mu}_{t_j} = \frac{1}{n} \sum_{i=1}^{n} y^*_{t_j i} \quad \text{for } j = 1, \ldots, \ell$$

If you specify a weight variable by using the WEIGHT statement, this weight variable is applied to the regression model that defines the targeting step, and final computation of the potential outcome means is updated accordingly. When you use the TMLE estimation method, an observation from the input data table is not used if any of the following conditions occur:

- A predicted treatment assignment probability is missing.
- The value of the outcome variable is missing.
- A predicted potential outcome value is missing.
- The value of a frequency or weight variable, if specified, is missing or nonpositive.

Standard Errors and Confidence Limits

You can specify the INFERENCE option in the PROC CAEFFECT statement to request standard errors and confidence limits for the potential outcome mean estimates.

Note that the statistical validity of the standard error estimates and confidence limits that the CAEFFECT procedure computes depends on how the treatment and outcome models are estimated. Because the procedure takes a model-agnostic approach to estimating potential outcome means, it cannot assess these model-dependent conditions, and you must determine whether the modeling techniques that you are using will result in valid inference.

The following sections discuss how the CAEFFECT procedure performs variance estimation for the different estimation methods and what conditions are required for these estimates to produce statistically valid inference. These conditions are specific to the statistical validity of the variance and interval estimation only. The statistical validity of the point estimation of potential outcome means and their differences is not affected by these conditions.

Estimating Equation Methods

For the inverse probability weighting (IPW), regression adjustment, and augmented inverse probability weighting (AIPW) estimation methods, standard errors and confidence limits for the potential outcome mean estimates are computed by using the sandwich covariance formula that is based on asymptotic theory. This approach considers the estimating equations as an M-estimation problem (Stefanski and Boos 2002) that is given by

$$S(\boldsymbol{\mu}) = \sum_{i=1}^{n} S_i(\boldsymbol{\mu}) = 0$$

The robust, or sandwich, covariance matrix $\hat{\boldsymbol{V}}(\hat{\boldsymbol{\mu}})$ for the estimates $\hat{\boldsymbol{\mu}}$ is given by

$$\hat{\boldsymbol{V}}(\hat{\boldsymbol{\mu}}) = n^{-1}\boldsymbol{A}_n(\hat{\boldsymbol{\mu}})^{-1}\boldsymbol{B}_n(\hat{\boldsymbol{\mu}})\boldsymbol{A}_n(\hat{\boldsymbol{\mu}})^{-T}$$

where n is the sample size, $\boldsymbol{A}^{-T}$ denotes $\left(\boldsymbol{A}^{-1}\right)^{T}$, and

$$\boldsymbol{A}_n(\hat{\boldsymbol{\mu}}) = n^{-1}\sum_{i=1}^{n} -\frac{\partial S_i(\hat{\boldsymbol{\mu}})}{\partial \boldsymbol{\mu}}$$

$$\boldsymbol{B}_n(\hat{\boldsymbol{\mu}}) = n^{-1}\sum_{i=1}^{n} S_i(\hat{\boldsymbol{\mu}})S_i(\hat{\boldsymbol{\mu}})^{T}$$

Note that the validity of this estimate for the covariance matrix and the rate of convergence that it assumes depend on a number of factors that relate to the modeling of the treatment and outcome variables. In particular, because PROC CAEFFECT takes a model-agnostic approach to estimating potential outcome means, these expressions treat all predicted treatment probabilities and predicted counterfactual outcome values as fixed quantities. If you use the same data (that is, you do not use data splitting) to estimate the potential outcome means and to estimate the underlying treatment and outcome models, you can introduce dependencies that are unaccounted for in the covariance matrix estimate. Moreover, if the modeling technique that you use for the treatment or outcome variable converges at a rate slower than the square root of n, variability in the predicted quantities might lead to a rate of convergence for the potential outcome mean estimates that is slower than the rate that this approach to inference assumes. Because PROC CAEFFECT considers only the estimation of potential outcome means and does not directly model the treatment or outcome variable, you must assess whether the modeling techniques that you are using will result in valid inference when you use this expression.

A special case when the expression for $\hat{\boldsymbol{V}}(\hat{\boldsymbol{\mu}})$ can provide valid inference, even if data splitting is not used, is IPW estimation with predicted treatment probabilities estimated by using maximum likelihood estimation. In that case, the expression for $\hat{\boldsymbol{V}}(\hat{\boldsymbol{\mu}})$ that treats the predicted treatment assignment probabilities as fixed is known to be conservative and to produce standard errors larger than the errors that you would obtain if you were to adjust for the estimation of the treatment model (Lunceford and Davidian 2004). Note that the same is not true of estimation by regression adjustment when you use maximum likelihood estimation for the outcome model and no data splitting.

Targeted Maximum Likelihood Estimation

For the targeted maximum likelihood estimation (TMLE) method, standard errors and confidence limits are computed by using the influence function for the estimator that is based on semiparametric efficiency theory.

The TMLE estimator is asymptotically linear, so

$$\hat{\boldsymbol{\mu}} - \boldsymbol{\mu} = \frac{1}{n}\sum_{i=1}^{n}\boldsymbol{\phi}_i + o\left(\frac{1}{\sqrt{n}}\right)$$

where $\boldsymbol{\phi}_i$ is the influence function of the estimator for the ith observation. By definition, the mean of the influence function is the zero vector (Tsiatis 2006). Thus the covariance matrix $\hat{\boldsymbol{V}}(\hat{\boldsymbol{\mu}})$ for the estimates $\hat{\boldsymbol{\mu}}$ is given by

$$\hat{\boldsymbol{V}}(\hat{\boldsymbol{\mu}}) = \frac{1}{n^2}\sum_{i=1}^{n}\hat{\boldsymbol{\phi}}_i\hat{\boldsymbol{\phi}}_i^T$$

where n is the sample size and

$$\hat{\boldsymbol{\phi}}_i = \begin{bmatrix} \hat{h}_{t_1 i}\left(y_i - y^*_{1i}\right) + y^*_{1i} - \hat{\mu}_{t_1} \\ \vdots \\ \hat{h}_{t_\ell i}\left(y_i - y^*_{\ell i}\right) + y^*_{\ell i} - \hat{\mu}_{t_\ell} \end{bmatrix}$$

is an estimate of the influence function for each observation.

As with the methods based on estimating equations, the validity of this estimate for the covariance matrix and the rate of convergence that it assumes depend on a number of factors related to the modeling of the treatment and outcome variables. In particular, if you use the same data (that is, you do not use data splitting)

to compute the predicted treatment probabilities or predicted potential outcome means as well as to perform the targeting step and compute the influence functions, this can introduce dependencies that are unaccounted for in the covariance matrix estimate. Moreover, if the modeling technique that you use for the treatment or outcome variable converges at a rate slower than the square root of n, variability in the predicted quantities might lead to a rate of convergence for the potential outcome mean estimates that is slower than the rate that this approach to inference assumes. Because PROC CAEFFECT considers only the estimation of potential outcome means and does not directly model the treatment or outcome variable, you must assess whether the modeling techniques that you are using will result in valid inference when you use this expression.

As an alternative to sample splitting, ensemble modeling strategies based on cross validation, such as superlearning (Van der Laan and Rose 2011), have proved very effective when combined with TMLE for effect estimation.

Displayed Output

The following sections describe the output that PROC CAEFFECT produces. The output is organized into various tables, which are discussed in order of their appearance.

Model Information

The "Model Information" table displays basic information about the model, such as the input data, the treatment variable, and the estimation method.

Potential Outcome Mean Information

The "Potential Outcome Mean Information" table displays information about the potential outcome means that are estimated, such as the level of treatment that defines the potential outcomes and the source of predicted values that are used for their estimation.

Number of Observations

The "Number of Observations" table displays the number of observations that are read from the input data table and the number of observations that are used in the analysis. If you specify a FREQ statement, the table displays the sum of the frequencies that are read and used. If you specify a WEIGHT statement, the table displays the sum of the weighted frequencies that are read and used.

Treatment Profile

The "Treatment Profile" table displays the levels of the treatment variable that appear in the input data table and the number of observations in each level.

Response Profile

The "Response Profile" table displays the levels of the outcome variable that appear in the input data table and the number of observations in each level.

Potential Outcome Mean Covariance Matrix

The "Potential Outcome Mean Covariance Matrix" displays the estimated covariance matrix for the potential outcome means. Because of the model-agnostic approach that PROC CAEFFECT uses to perform estimation, the statistical validity of this estimate depends on model-specific conditions that you must evaluate and that the procedure cannot verify. For more information about how the procedure estimates the potential outcome mean covariance matrix and the conditions that are required for valid statistical inference, see the section "Standard Errors and Confidence Limits" on page 227.

Potential Outcome Mean Estimates

The "Potential Outcome Mean Estimates" table displays the estimated potential outcome means.

Potential Outcome Mean Differences

The "Potential Outcome Mean Differences" table displays the requested differences in potential outcome mean estimates.

Timing

The "Timing" table displays the amount of time (in seconds) that it took PROC CAEFFECT to perform different tasks in the analysis.

OutputCasTables Table

The OutputCasTables table is a special table that has information about each CAS table that is created during a CAS action execution. The information for each CAS table consists of the CAS table name, the caslib in which the table resides, and the number of columns and rows in the CAS table. Because this table is not a typical ODS table that contains analytical results, you cannot include it in the *table-spec-list* in the DISPLAYOUT statement.

ODS Table Names

Each table that the CAEFFECT procedure creates has a name that is associated with it. You must use this name to refer to the table when you use ODS statements. Table 6.3 lists the name of each table and a short description of its contents.

Table 6.3 ODS Tables Produced by PROC CAEFFECT

Table Name	Description	Statement	Option
ModelInfo	Information about the modeling environment	Default output	
NObs	Number of observations read and used	Default output	
OutputCasTables	See the section "OutputCasTables Table" on page 230	DISPLAYOUT	
POMCov	Potential outcome mean covariance matrix	PROC CAEFFECT	POMCOV

Table 6.3 *continued*

Table Name	Description	Statement	Option
POMDiffs	Potential outcome mean differences	DIFFERENCE	
POMEstimates	Potential outcome mean estimates	Default output	
POMInfo	Potential outcome mean information	PROC CAEFFECT	POMINFO
ResponseProfile	Response levels for categorical outcomes	Default output	
Timing	Absolute and relative times for tasks performed by the procedure	Default output	
TreatmentProfile	Treatment levels	Default output	

Examples: CAEFFECT Procedure

The examples in this chapter are available in the GitHub repository located at `https://github.com/sascommunities/doc-supplement-casstat`.

Example 6.1: Estimation by Inverse Probability Weighting

(View the complete code for this example (caeffectIPWEx1.sas) in the example repository.)

This example uses the SmokingWeight data set available in the examples for the CAUSALTRT procedure in SAS/STAT software. These data are a subset of data from the NHANES I Epidemiologic Follow-Up Study (NHEFS) in Hernán and Robins (2020). For the study, medical and behavioral information were collected during an initial physical examination and again at follow-up interviews about 10 years later. As in the PROC CAUSALTRT examples, the question of interest here is what effect does quitting smoking, as recorded in the variable Quit, have on an individual's change in weight (measured in kilograms), as recorded in the variable Change.

To create the data table SmokingWeight in your CAS session, you can modify the DATA step that is used to create the data set in PROC CAUSALTRT to create the data table in your CAS engine libref. For this example, it is assumed that your CAS engine libref is named mylib, but you can substitute any appropriately defined CAS engine libref.

In addition to the treatment variable Quit and outcome variable Change, the data include the following variables:

- Activity: level of daily activity, with values 0, 1, and 2
- Age: age in 1971
- BaseWeight: weight in kilograms in 1971
- Education: level of education, with values 0, 1, 2, 3, and 4
- Exercise: amount of regular recreational exercise, with values 0, 1, and 2

- PerDay: number of cigarettes smoked per day in 1971
- Race: 0 for white; 1 otherwise
- Sex: 0 for male; 1 for female
- Weight: weight in kilograms at the follow-up interview
- YearsSmoke: number of years an individual has smoked

For this example, it is assumed that the variables Activity, Age, BaseWeight, Education, Exercise, PerDay, Race, Sex, and YearsSmoke make up a valid adjustment set that you can use to obtain unbiased estimates of the potential outcome means.

The following statements use the LOGSELECT procedure to fit a logistic model for the treatment variable Quit:

```
proc logselect data=mylib.SmokingWeight;
   class Sex Race Education Exercise Activity;
   model Quit = Sex Race Education Exercise
                Activity Age YearsSmoke PerDay;
   store out=mylib.logTrtModel;
run;
```

The model for the treatment variable is specified in the MODEL statement. The STORE statement creates an analytic store that contains the fitted model in the logTrtModel data table.

The following statements use the SCORE statement in the ASTORE procedure to obtain the predicted probabilities of a subject being assigned to each treatment level:

```
proc astore;
   score data=mylib.SmokingWeight out=mylib.logScored
         rstore=mylib.logTrtModel copyvars=(Quit Change);
run;
```

You use the DATA= option to specify the data table to score, and you use the RSTORE= to specify the stored model to use for scoring. To avoid data duplication for large data tables, the variables in the input data table are not included in the output data table unless you specify them in the COPYVARS= option. To estimate the potential outcome means by inverse probability weighting, you need the treatment variable and observed outcome values, so the variables Quit and Change are specified in the COPYVARS= option.

The following statements use the CAEFFECT procedure to estimate potential outcome means by using inverse probability weighting (IPW):

```
proc caeffect data=mylib.logScored inference;
   treatvar Quit;
   outcomevar Change;
   pom treatlev = 1 treatProb = P_Quit1;
   pom treatlev = 0 treatProb = P_Quit0;
   difference reflev=0;
run;
```

When you use the CAEFFECT procedure, you must specify the TREATVAR statement and at least one POM statement. You specify the input data table to use for the potential outcome means estimation in the DATA=

option. The TREATVAR statement specifies information about the treatment variable. Each POM statement specifies a potential outcome of interest for your analysis.

For each potential outcome specification, you must use the TREATLEV= option to identify the level of treatment that defines the potential outcome. In this example, two potential outcomes are specified. One outcome is defined by the level 1, which corresponds to a subject quitting smoking, and the second outcome is defined by the level 0, which corresponds to a subject not quitting. For each potential outcome specification, you must also identify any variables in the input data table that are needed for the estimation. For IPW estimation, you must specify variables in the input data table that contain the previously computed treatment assignment probabilities; you do this by using the TREATPROB= option. In this example, the names of those variables are created by PROC ASTORE. If you do not know the names of the variables created by PROC ASTORE that contain the predicted values, you can use the DESCRIBE statement in PROC ASTORE and check the "Output Variables" table that it creates to find the variable names.

For IPW estimation, the observed outcome values are required, and therefore you must also specify the OUTCOMEVAR statement. Finally, in this example, you specify a DIFFERENCE statement to request a difference between the potential outcome mean estimates. A single difference is requested, and the REFLEV= option specifies that the treatment level 0 is used as the reference level. In general, you can specify multiple DIFFERENCE statements, and in each DIFFERENCE statement you can specify reference levels, event levels, or both.

The output from this analysis is displayed by default. It is presented in Output 6.1.1 through Output 6.1.4.

The "Model Information" table in Output 6.1.1 summarizes important information, including the data source, treatment variable name, estimation method, and type of outcome variable.

Output 6.1.1 Model Information

The CAEFFECT Procedure

Model Information	
Data Source	LOGSCORED
Treatment Variable	Quit
Outcome Variable	Change
Outcome Type	Continuous
Estimation Method	Inverse Probability Weighting

Output 6.1.2 displays the "Number of Observations" table. In this analysis, a number of observations are not used, because there are missing predicted treatment assignment probabilities. These probabilities are missing because there are missing values in the predictor variables.

Output 6.1.2 Number of Observations

Number of Observations Read	1746
Number of Observations Used	1566

Output 6.1.3 displays the "Treatment Profile" table. This table includes information about the levels of the treatment variable that appear in the input data table and the number of observations in each level that are used to estimate the potential outcome means.

Output 6.1.3 Treatment Profile

Treatment Profile	
Quit	Total Frequency
0	1163
1	403

Output 6.1.4 displays the potential outcome mean estimates and their difference. The "POM Estimates" table indicates the level of treatment that defines the potential outcome and the estimate of its mean. The "POM Differences" table shows the requested difference in potential outcome mean estimates. The table also includes nonprinting columns that contain the potential outcome mean estimates for the event and reference levels; these columns are accessible if you save the table as an output data set by using the ODS OUTPUT statement or if you modify the table's template. If the relevant causal assumptions hold true for the data-generating process that produced these data, then the difference in potential outcome mean estimates corresponds to an estimate of the average treatment effect (ATE) of a weight change that is approximately 3.25 kilograms greater because the subjects quit smoking.

Output 6.1.4 Potential Outcome Mean and Difference Estimates

POM Estimates

Treatment Level	Estimate	Standard Error	95% Confidence Limits		Z	Pr > |Z|
1	5.05146	0.47254	4.12530	5.97762	10.69	<.0001
0	1.80099	0.21938	1.37100	2.23097	8.21	<.0001

POM Differences

Treatment Levels							
Event	Reference	Difference	Standard Error	95% Confidence Limits		Z	Pr > |Z|
1	0	3.2505	0.52098	2.22936	4.27158	6.24	<.0001

By default, PROC CAEFFECT does not produce standard errors or confidence limits, because the validity of the covariance matrix estimate for the potential outcome mean estimates depends on factors outside the procedure invocation. In this example, where maximum likelihood estimation is used to estimate the treatment model and inverse probability weighting is used to estimate the potential outcome means, the variance estimation method that the procedure uses is known to produce valid but conservative statistical inference even without the use of data splitting. For this reason, standard errors and confidence limits are produced by using the INFERENCE option. For more information about the factors that determine the validity of the inferential statistics that the procedure produces, see the section "Standard Errors and Confidence Limits" on page 227.

You can also use the IPW estimation method in PROC CAEFFECT to produce estimates of the potential outcome means that are conditional on subjects receiving a particular level of treatment. To specify the level of treatment to condition on, you can use the CONDEVENT= option in the TREATVAR statement. The following statements request an analysis that uses the same data, but in this case for potential outcome mean estimates conditional on subjects quitting smoking:

```
proc caeffect data=mylib.logScored;
   treatvar Quit / condevent=1;
   outcomevar Change;
   pom treatlev = 1 treatProb = P_Quit1;
   pom treatlev = 0 treatProb = P_Quit0;
   difference reflev=0;
run;
```

The potential outcome mean estimates conditional on subjects quitting smoking and their difference are displayed in Output 6.1.5. The "POM Estimates" and "POM Differences" tables now include a column for the level of treatment that defines the conditioning event; this column is not displayed but is accessible if you save the table as an output data set by specifying the ODS OUTPUT statement. In this case, because the potential outcome that defines the event level in the difference comparison is the same as the level that defines the conditioning event, the estimated difference would correspond to an estimate of the average treatment effect for the treated (ATT).

Output 6.1.5 Conditional Potential Outcome Mean and Difference Estimates

The CAEFFECT Procedure

Example 6.2: Estimation by Regression Adjustment

(View the complete code for this example (caeffectRegAdjEx1.sas) in the example repository.)

This example uses the birthwgt data set available in the Sashelp library. The data are information about infant mortality in 2003 and were obtained from the US National Center for Health Statistics. A random sample of 100,000 observations is used in this example. The analysis of these data is purely illustrative, and definitive conclusions should not be drawn from it.

The following DATA step creates the data table mylib.birthwgt in your CAS session. For this example, it is assumed that your CAS engine libref is named mylib, but you can substitute any appropriately defined CAS engine libref.

```
data mylib.birthwgt;
   set sashelp.birthwgt;
run;
```

For this example, the treatment variable Smoking is an indicator of maternal smoking behavior, with values of 'Yes' and 'No'. The outcome variable of interest, Death, is an indicator of infant death within one year of

birth, with values of 'Yes' and 'No'. The following variables are assumed to be confounding variables that you can use in the model for the outcome variable, Death:

- AgeGroup represents maternal ages of less than 20, between 20 and 35, and greater than 35, with values 1, 2, and 3, respectively.
- Drinking is an indicator of maternal drinking during pregnancy, with values 'Yes' and 'No'.
- Married is an indicator of marital status, with values 'Yes' and 'No'.
- SomeCollege is an indicator of whether the mother has 12 or more years of education, with values 'Yes' and 'No'.

The following statements use the GRADBOOST procedure, which is part of SAS Viya machine learning software, to fit a model for the outcome variable, Death:

```
proc gradboost data=mylib.birthwgt ntrees=100 seed=8959;
   target Death / level=nominal;
   input  Smoking AgeGroup Married Drinking
          SomeCollege /level=nominal;
   savestate rstore=mylib.gbOutMod;
run;
```

The fitted gradient boosting model is saved in the data table gbOutMod, which you can provide as input to PROC CAEFFECT. The following statements use the saved outcome model to estimate two potential outcome means by regression adjustment:

```
proc caeffect data=mylib.birthwgt;
   treatvar Smoking;
   outcomevar Death( event='Yes') / type=Categorical;
   outcomemodel restore=mylib.gbOutMod predname=P_DeathYes;
   pom treatlev='Yes';
   pom treatlev='No';
run;
```

You use the POM statement to specify the potential outcomes of interest for your analysis. For each potential outcome specification, you must use the TREATLEV= option to identify the level of treatment that defines the potential outcome.

In this example, you use the TYPE= option in the OUTVAR statement to indicate that the outcome variable of interest is categorical. For categorical outcomes, PROC CAEFFECT estimates the probability of a designated outcome event level. The potential outcome means that you estimate therefore correspond to the counterfactual probability of that outcome occurring, and all predicted outcome values must be between 0 and 1, inclusive. You specify the designated event level for the outcome variable by using the EVENT= option.

When you provide a previously fit outcome model as input to PROC CAEFFECT, you use the OUTCOMEMODEL statement. You specify the name of the analytic store that contains the saved model by using the RESTORE= option. You must also use the PREDNAME= option to provide the name of the variable that contains the outcome of interest when you score data by using the analytic store. If you do not know the names of the variables that the analytic store creates, you can use the DESCRIBE statement in PROC ASTORE and check the "Output Variables" table that it produces to find the variable names.

The output from this analysis is displayed by default and is presented in Output 6.2.1 through Output 6.2.3.

The "Model Information" table in Output 6.2.1 summarizes important information, including the data source, treatment variable name, estimation method, and type of outcome variable.

Output 6.2.1 Model Information

The CAEFFECT Procedure

Model Information	
Data Source	BIRTHWGT
Treatment Variable	Smoking
Outcome Type	Categorical
Estimation Method	Regression Adjustment
Outcome Model Store	GBOUTMOD

Output 6.2.2 displays the "Number of Observations" table. In this analysis, a number of observations are not used, because the treatment variable Smoking has missing values. To indicate that a missing value is a valid value of the treatment variable, you can specify the COUNTMISSING option in the TREATVAR statement.

Output 6.2.2 Number of Observations

Number of Observations Read	100000
Number of Observations Used	94388

Output 6.2.3 displays the potential outcome mean estimates that are obtained by using the gradient boosting model for the outcome variable.

Output 6.2.3 Estimates Using a Stored Model

POM Estimates	
Treatment Level	**Estimate**
Yes	0.00829
No	0.00640

As an alternative to providing a previously fit outcome model as input to PROC CAEFFECT, you can also specify variables in the input data table that contain predicted counterfactual outcome values for each treatment level of interest. You specify the names of these variables by using the PREDOUT= option for each potential outcome specification in a POM statement. To obtain these predicted values, you can use a fitted model for the outcome and score the data with the treatment set to the counterfactual level of interest.

The following statements demonstrate one way to obtain predicted counterfactual outcome values that you can provide as input to PROC CAEFFECT. This example uses PROC ASTORE to score the data by using the previously fit model that is saved in the gbOutMod data table.

The first step is to create a table that renames the observed treatment variable tempSmoking and sets the value of the treatment variable Smoking to the counterfactual level 'Yes' for scoring the data. The following DATA step performs these tasks and creates the gbPredData data table:

```
data mylib.gbPredData;
   set mylib.birthwgt;
   tempSmoking = Smoking;
   Smoking = 'Yes';
run;
```

After creating the gbPredData data table, you can score the counterfactual outcomes by using PROC ASTORE, as in the following statements. To avoid data duplication for large data tables, the variables in the input data table are not included in the output data table that PROC ASTORE creates unless you specify them in the COPYVARS= option. To score the counterfactual outcomes for the treatment level 'No', you must include all the predictors that are used in the outcome model in the COPYVARS= option along with the observed treatment values that are stored in the variable tempSmoking.

```
proc astore;
   score data=mylib.gbPredData out=mylib.gbPredData
         rstore=mylib.gbOutMod
         copyvars=(tempSmoking AgeGroup Married
                   Drinking SomeCollege Death);
run;
```

Because PROC ASTORE uses the same variable names for the predicted values to score the next counterfactual values, you must first rename the variable that contains the predicted outcome probability of interest. You must also set the value of the treatment variable Smoking to the level 'No' to score the remaining counterfactual outcomes. These steps are performed using the following statements:

```
data mylib.gbPredData;
   set mylib.gbPredData;
   rename P_DeathYes = SmokingPred;
   Smoking = 'No';
run;
```

Next, the data are scored again for the counterfactual treatment level 'No':

```
proc astore;
   score data=mylib.gbPredData out=mylib.gbPredData
         rstore=mylib.gbOutMod
         copyvars=(tempSmoking SmokingPred Death);
run;
```

Because there are no additional counterfactual values to score, you can limit the list of variables in the COPYVARS= option to only those that you need for the effect estimation. Although it is not necessary to do this before using PROC CAEFFECT, you can use the following statements to rename the variable that contains the newly predicted counterfactual outcome values, and you can also replace the temporary name that was applied to the observed treatment variable with the original variable name, Smoking:

```
data mylib.gbPredData;
   set mylib.gbPredData;
   rename P_DeathYes = NoSmokingPred tempSmoking=Smoking;
run;
```

The following statements use the previously computed predicted counterfactual outcome values as input to estimate the potential outcome means:

```
proc caeffect data=mylib.gbPredData;
   treatvar Smoking;
   outcomevar Death( event='Yes') / type=Categorical;
   pom treatlev='Yes' predOut=SmokingPred;
   pom treatlev='No'  predOut=NoSmokingPred;
run;
```

Output 6.2.4 displays the potential outcome mean estimates that are obtained by using the previously estimated counterfactual outcome values. These estimates of the potential outcome means are the same as the estimates shown in Output 6.2.3, because the same model for the outcome variable is used to obtain the predictions.

Output 6.2.4 Estimates Using Previously Predicted Values

The CAEFFECT Procedure

Example 6.3: Estimation by Doubly Robust Methods

(View the complete code for this example (caeffectDREx1.sas) in the example repository.)

This example uses the mylib.SmokingWeight data table from "Example 6.1: Estimation by Inverse Probability Weighting" on page 231. The same causal question is examined, but this example uses the augmented inverse probability weighting (AIPW) and targeted maximum likelihood estimation (TMLE) methods.

The AIPW and TMLE methods are doubly robust methods, and they combine modeling of both the treatment and outcome variables. The following statements use the LOGSELECT procedure to fit a logistic model for the treatment variable Quit and create an output data table that contains the predictions from the fitted model:

```
proc logselect data=mylib.SmokingWeight;
   class Sex Race Education Exercise Activity;
   model Quit(Event='1') = Sex Race Education
         Exercise Activity Age YearsSmoke PerDay;
   output out=mylib.swDREstData pred=pTrt copyvars=(_ALL_);
run;
```

The EVENT= response variable option in the MODEL statement ensures that the LOGSELECT procedure models the probability that the variable Quit takes the value 1. In the OUTPUT statement, the PRED= option names the variable in the output data table that contains the predicted event probability, and the COPYVARS= option copies all variables from the input data table to the output data table.

The following DATA step creates the variable pCnt, which contains the predicted probability of being assigned to the control condition, Quit=0:

```
data mylib.swDREstData;
   set mylib.swDREstData;
   pCnt = 1 - pTrt;
run;
```

An alternative way to obtain the predicted treatment probabilities is to save the fitted treatment model as an analytic store and use the ASTORE procedure. This approach is demonstrated in "Example 6.1: Estimation by Inverse Probability Weighting" on page 231.

The following statements use the BART procedure to fit a model for the outcome variable by using Bayesian additive regression trees (BART). The model for this example is fit by using an ensemble of 100 trees; 200 samples of the ensemble are saved for prediction, and the fitted model is saved in the analytic store bartOutMod.

```
proc bart data=mylib.swDREstData nTree=100 nMC=200 seed=2156;
   class Sex Race Education Exercise Activity Quit;
   model Change = Sex Race Education Exercise Quit Activity
         Age YearsSmoke PerDay;
   store out=mylib.bartOutMod;
run;
```

The following statements use the CAEFFECT procedure to estimate potential outcome means by using the AIPW estimation method and to compute the difference between the two potential outcomes:

```
proc caeffect data=mylib.swDREstData method=aipw;
   treatvar Quit;
   outcomevar Change;
   outcomemodel restore=mylib.bartOutMod predName=P_Change;
   pom treatLev=1 treatProb=pTrt;
   pom treatLev=0 treatProb=pCnt;
   difference evtLev=1;
run;
```

When you use PROC CAEFFECT, at least one POM statement is required in order to specify the potential outcomes of interest, and the TREATVAR statement is required in order to specify the treatment variable of interest. For the AIPW estimation method, you must also specify the outcome variable by using the OUTCOMEVAR statement. For each potential outcome specification, you use the TREATLEV= option to identify the level of treatment that defines the potential outcome, and you use the TREATPROB= option to specify the variable in the input data table that contains the predicted probability of being assigned to that level.

The AIPW estimation method also requires predicted counterfactual values for each observation. For each potential outcome of interest, the counterfactual predictions are obtained by replacing the observed treatment level with the level that defines the potential outcome. In this example, the previously fit BART model is specified by using the OUTCOMEMODEL statement, and the procedure uses the previously fit model to predict counterfactual outcome values. When you provide as input to PROC CAEFFECT an analytic store that contains a model for the outcome variable, the input data table must contain the predictor variables that the model requires, and you must specify the names of the variables created by the analytic store that contains the predicted values. If you do not know these variable names, you can use the DESCRIBE statement in PROC ASTORE to describe the store.

As an alternative to providing a previously fit outcome model as input to PROC CAEFFECT, you can specify variables in the input data table that contain predicted counterfactual outcome values for each treatment level

of interest. You specify the names of these variables by using the PREDOUT= option for each potential outcome specification in a POM statement. An example of how you can use this alternative syntax and how you can obtain the necessary counterfactual predictions is provided by "Example 6.2: Estimation by Regression Adjustment" on page 235.

The output from this analysis is displayed by default and is presented in Output 6.3.1 through Output 6.3.3.

The "Model Information" table in Output 6.3.1 summarizes important information, including the data source, treatment variable name, estimation method, type of outcome variable, and name of the analytic store used for outcome modeling.

Output 6.3.1 Model Information

The CAEFFECT Procedure

Model Information	
Data Source	SWDRESTDATA
Treatment Variable	Quit
Outcome Variable	Change
Outcome Type	Continuous
Estimation Method	AIPW
Outcome Model Store	BARTOUTMOD

Output 6.3.2 displays the "Number of Observations" table. In this analysis, a number of observations are not used, because there are missing predicted treatment assignment probabilities. These probabilities are missing because there are missing values in the predictor variables and because a generalized linear model, in particular logistic regression, is used to model the treatment variable. The BART model that is used for the outcome variable can predict counterfactual outcome values even for observations that have missing predictor values.

Output 6.3.2 Number of Observations

Number of Observations Read	1746
Number of Observations Used	1566

Output 6.3.3 displays the potential outcome mean estimates and their difference. The "POM Estimates" table indicates the level of treatment that defines the potential outcome and the estimate of its mean. The "POM Differences" table shows the requested difference in potential outcome mean estimates. With the proper causal assumptions, the difference in potential outcome mean estimates corresponds to an estimate of the average treatment effect (ATE) of a weight change that is approximately 3.27 kilograms greater because the subjects quit smoking. This value is comparable to the estimate that is obtained in "Example 6.1: Estimation by Inverse Probability Weighting" on page 231.

Output 6.3.3 Potential Outcome Mean and Difference Estimates

POM Estimates	
Treatment Level	**Estimate**
1	5.12356
0	1.78772

Output 6.3.3 *continued*

POM Differences		
Treatment Levels		
Event	Reference	Difference
1	0	3.3358

The TMLE method is a doubly robust method that you can use as an alternative to the AIPW method. The required inputs are the same for both methods. The following statements use PROC CAEFFECT to estimate potential outcome means by using the TMLE method and to compute the difference between the two potential outcomes:

```
proc caeffect data=mylib.swDREstData method=tmle;
   treatvar Quit;
   outcomevar Change;
   outcomemodel restore=mylib.bartOutMod predName=P_Change;
   pom treatLev=1 treatProb=pTrt;
   pom treatLev=0 treatProb=pCnt;
   difference evtLev=1;
run;
```

The syntax is identical to the syntax that is used to invoke the AIPW method, except that the METHOD= option now specifies the TMLE method.

As in the analysis that uses the AIPW method, the output from the analysis that uses the TMLE method is displayed by default.

The "Model Information" table in Output 6.3.4 summarizes important information, including the data source, treatment variable name, estimation method, type of outcome variable, and name of the analytic store used for outcome modeling.

Output 6.3.4 Model Information

The CAEFFECT Procedure

Model Information	
Data Source	SWDRESTDATA
Treatment Variable	Quit
Outcome Variable	Change
Outcome Type	Continuous
Estimation Method	TMLE
Outcome Model Store	BARTOUTMOD

Output 6.3.5 displays the "Number of Observations" table. It is identical to the table that is produced by the analysis that uses the AIPW method.

Output 6.3.5 Number of Observations

Number of Observations Read	1746
Number of Observations Used	1566

Output 6.3.6 displays the potential outcome mean estimates and their difference. The values in these tables are almost the same as the values in the corresponding tables that are produced by the AIPW method.

Output 6.3.6 Potential Outcome Mean and Difference Estimates

POM Estimates

Treatment Level	Estimate
1	5.12564
0	1.78811

POM Differences

Treatment Levels		
Event	Reference	Difference
1	0	3.3375

Overview: CARDINALITY Procedure

The CARDINALITY procedure determines a variable's cardinality or limited cardinality in SAS Viya. The cardinality of a variable is the number of its distinct values, and the limited cardinality of a variable is the number of its distinct values that do not exceed a specified threshold.

In order to decide whether to include a variable in a subsequent SAS analysis as a classification or interval variable, it is sufficient to compute only the limited cardinality (and not the full cardinality) because both tend to yield the same decision. The limited cardinality is computationally less expensive than the full cardinality, especially for big data.

The CARDINALITY procedure creates the following:

- a cardinality data table, which contains summary information for each variable and some additional statistics about numeric variables
- a details data table, which contains the levels of each variable

PROC CARDINALITY Features

The CARDINALITY procedure has the following features:

- treats all variables as classification variables and attempts to determine the highest levels of each variable not to exceed a specified limit
- performs a single pass to determine the limited cardinality of each variable
- runs with all the input variables in the data table or with a specified list of variables
- can be run multiple times with a WHERE clause to reveal more levels. The results are not affected by the number of units doing the work (distributed or threaded or both) because PROC CARDINALITY produces the highest levels of each variable without exceeding the specified limit.
- recommends a level (CLASS, INTERVAL, or ID) for each variable. You can override these recommended levels in subsequent steps.
- can be run multiple times to extract subsequent segments of the full histogram of any variable
- builds the levelization in an ascending or descending order with or without formats

PROC CARDINALITY Compared to Other SAS Procedures

Other SAS procedures, such as the SUMMARY procedure, can calculate the cardinality of variables, but some are expensive to compute and result in a huge data set, and others yield nondeterministic results (that is, the results depend on the number of working units).

Using CAS Sessions and CAS Engine Librefs

SAS Cloud Analytic Services (CAS) is the analytic server and associated cloud services in SAS Viya. This section describes how to create a CAS session and set up a CAS engine libref that you can use to connect to the CAS session. It assumes that you have a CAS server already available; contact your system administrator if you need help starting and terminating a server. This CAS server is identified by specifying the host on which it runs and the port on which it listens for communications. To simplify your interactions with this CAS server, the host information and port information for the server are stored as SAS option values that are retrieved automatically whenever this CAS server needs to be accessed. You can examine the host and port values for the server at your site by using the following statements:

```
proc options option=(CASHOST CASPORT);
run;
```

In addition to starting a CAS server, your system administrator might also have created a CAS session and a CAS engine libref for your use. You can define your own sessions and CAS engine librefs that connect to the CAS server as shown in the following statements:

```
cas mysess;
libname mylib cas sessref=mysess;
```

The CAS statement creates the CAS session named mysess, and the LIBNAME statement creates the mylib CAS engine libref that you use to connect to this session. It is not necessary to explicitly name the CASHOST and CASPORT of the CAS server in the CAS statement, because these values are retrieved from the corresponding SAS option values.

If you have created the mysess session, you can terminate it by using the TERMINATE option in the CAS statement as follows:

```
cas mysess terminate;
```

For more information about the CAS and LIBNAME statements, see the section “Introduction to Shared Concepts” on page 6 in Chapter 2, “Shared Concepts.”

Getting Started: CARDINALITY Procedure

(View the complete code for this example at https://github.com/sascommunities/doc-supplement-casstat/tree/main/Examples/cardinality_gs.sas.)

NOTE: Input data must be in a CAS table that is accessible in your CAS session. You must refer to this table by using a two-level name. The first level must be a CAS engine libref, and the second level must be the table name. For more information, see the sections "Using CAS Sessions and CAS Engine Librefs" on page 7 and "Loading a SAS Data Set onto a CAS Server" on page 7 in Chapter 2, "Shared Concepts."

This example uses the Iris data set as input to demonstrate how to use PROC CARDINALITY. The Iris data published by Fisher (1936) include the species of iris and the sepal length, sepal width, petal length, and petal width (which are measured in millimeters) on 50 iris specimens from each of three species: *Iris setosa, I. versicolor, and I. virginica*.

You can load the sashelp.iris data set into your CAS session by naming your CAS engine libref in the first statement of the following DATA step:

```
data mylib.iris;
   set sashelp.iris;
run;
```

These statements assume that your CAS engine libref is named mylib, but you can substitute any appropriately defined CAS engine libref.

The following statements show the basic usage:

```
proc cardinality data=mylib.iris outcard=mylib.card
                outdetails=mylib.details maxlevels=10;
run;
```

The DATA= option names mylib.iris as the input data table. Two output data tables are requested: the required OUTCARD= option requests that cardinality and summary information be stored in the mylib.card data table, and the OUTDETAILS= option requests that the levels found for each variable be stored in the mylib.details data table. The MAXLEVELS= option specifies 10 as the maximum number of levels to report.

The following statements produce the "Cardinality Output Data" table, shown in Figure 7.1. This table contains one row for each variable in the input data table. If you do not want to display all the variables in the input data table, you can use the VAR statement to specify which variables you want to display.

```
proc print data=mylib.card;
   var _varname_ _type_ _cardinality_ _more_;
run;
```

Figure 7.1 Cardinality Output Data Table

Obs	_VARNAME_	_TYPE_	_CARDINALITY_	_MORE_
1	Species	C	3	N
2	SepalLength	N	10	Y
3	SepalWidth	N	10	Y
4	PetalLength	N	10	Y
5	PetalWidth	N	10	Y

Table 7.1 explains the columns in the "Cardinality Output Data Table." This example works with a simple subset of the variables in both the cardinality and details data tables.

Table 7.1 Variables from the Cardinality Data

Name	Description
VARNAME	Variable name
TYPE	Variable type (N for numeric or C for character)
CARDINALITY	Number of levels extracted (less than or equal to the value of the MAXLEVELS= option)
MORE	Indication of more unreported levels (Y to indicate more levels or N to indicate no more levels)

Figure 7.1 shows that the Species variable has _TYPE_ = C, indicating that it is a character variable; its _CARDINALITY_ value is 3, indicating that three levels (values) are reported in the details data; and _MORE_ = N, indicating that there are no unreported levels.

Figure 7.1 shows that the SepalLength variable is a numeric variable (_TYPE_ = N); its _CARDINALITY_ value is 10, indicating that 10 different values are reported; and _MORE_ = Y, indicating that there are still more levels that can be explored.

The following statements produce the details output data table, as shown in Figure 7.2:

```
data details;
   set mylib.details;
   where _varname_ in ('Species', 'SepalLength');
run;

proc print data=details;
   var _VARNAME_ _INDEX_ _FREQ_ _RAWNUM_ _RAWCHAR_;
run;
```

Figure 7.2 Details Output Data Table

Obs	_VARNAME_	_INDEX_	_FREQ_	_RAWNUM_	_RAWCHAR_
1	Species	1	50	.	Setosa
2	Species	2	50	.	Versicolor
3	Species	3	50	.	Virginica
4	SepalLength	1	1	43	
5	SepalLength	2	3	44	
6	SepalLength	3	1	45	
7	SepalLength	4	4	46	
8	SepalLength	5	2	47	
9	SepalLength	6	5	48	
10	SepalLength	7	6	49	
11	SepalLength	8	10	50	
12	SepalLength	9	9	51	
13	SepalLength	10	4	52	
14	SepalLength	.	105	52	

Table 7.2 explains the columns in the details output data table.

Table 7.2 Variables from the Details Output Data Table

Name	Description
VARNAME	Variable name
INDEX	Index of the level
FREQ	Frequency of the level
RAWNUM	Raw level of the variable if numeric
RAWCHAR	Raw level of the variable if character

The Species variable has three rows in the details data table, one row for each of the reported levels (the _CARDINALITY_ variable in the "Cardinality Output Data Table" has the value 3). Each of these rows has _FREQ_ = 50, and the _RAWCHAR_ values are reported for each level. There are no more unreported levels for the variable Species (_MORE_ = N); thus, no row has a missing value (.) in the _INDEX_ column for the Species variable.

The "Details Output Data Table" reports the top 10 levels of the SepalLength variable and shows that there are still as many as 105 unreported levels that are greater than 52. (For the SepalLength variable, _CARDINALITY_ = 10 and _MORE_ = Y in the "Cardinality Output Data Table.") Therefore, SepalLength occupies 11 rows in the details data table (10 reported levels and one additional level that describes the group of all unreported levels.) The _INDEX_ of the unreported group of levels for the SepalLength variable is missing, reminding you that many levels make up this group. Essentially, the last row lumps all the other SepalLength rows into one level that has a missing _INDEX_ value. So you see 10 levels in addition to the levels greater than 52, a total of 11 rows for the SepalLength variable. The last row, which includes a missing _INDEX_ value, contains enough information to run the procedure again with a WHERE clause to obtain the next set of details.

Syntax: CARDINALITY Procedure

The following statements are available in the CARDINALITY procedure:

```
PROC CARDINALITY OUTCARD=libref.data-table < options > ;
    FREQ variable ;
    VAR variables < / options > ;
    WEIGHT variable ;
```

The PROC CARDINALITY statement is required.

PROC CARDINALITY Statement

PROC CARDINALITY OUTCARD=*libref.data-table* < *options* > **;**

The PROC CARDINALITY statement invokes the procedure. Table 7.3 summarizes the options available in the PROC CARDINALITY statement.

Table 7.3 PROC CARDINALITY Statement Options

Option	Description
Input and Output Data Sets	
DATA=	Specifies the input data table
OUTCARD=	Names the cardinality data table to contain the summary information for each variable
OUTDETAILS=	Names an optional data table to contain the detailed levels of all the variables
Cardinality Options	
MAXLEVELS=	Specifies the maximum number of levels to consider
ORDER=	Specifies the order to be applied to all variables that have an unspecified order

You must specify the following option:

OUTCARD=*libref.data-table*

specifies the output data table to contain the cardinality and summary information for each variable. *libref.data-table* is a two-level name, where *libref* refers to the library, and *data-table* specifies the name of the output data table. For more information about this two-level name, see the DATA= option and the section "Using CAS Sessions and CAS Engine Librefs" on page 247.

You can also specify the following *options*:

DATA=*libref.data-table*

names the input data table for PROC CARDINALITY to use. *libref.data-table* is a two-level name, where

libref refers to a collection of information that is defined in the LIBNAME statement and includes the library, which includes a path to the data, and a session identifier, which defaults to the active session but which can be explicitly defined in the LIBNAME statement. For more information about *libref*, see the section "Using CAS Sessions and CAS Engine Librefs" on page 247.

data-table specifies the name of the input data table.

MAXLEVELS=*number*

specifies the maximum *number* of levels of the variables in the input data to consider. The *number* should be between 5 and 254.

By default, MAXLEVELS=20.

ORDER=ASC | DESC | ASCFMT | DESFMT
specifies the order to be applied to all variables whose order is not specified in a VAR statement.

You can specify the following values:

ASC	orders variables in unformatted ascending order.
DESC	orders variables in unformatted descending order.
ASCFMT	orders variables in formatted ascending order.
DESFMT	orders variables in formatted descending order.

By default, ORDER=ASC.

OUTDETAILS=*libref.data-table*
specifies the output data table to contain the levels that are found for each variable. *libref.data-table* is a two-level name, where *libref* refers to the library, and *data-table* specifies the name of the input data table. For more information about this two-level name, see the DATA= option and the section "Using CAS Sessions and CAS Engine Librefs" on page 247.

All the levels that are higher than the value of the MAXLEVELS= option are grouped together into one level that has a missing value (.) in the _INDEX_ column in the output data table. For this level, the corresponding raw and formatted levels contain the last values visible in the histogram. This is useful when you need the next segment of the histogram past the visible levels of a variable.

FREQ Statement

FREQ *variable* **;**

The *variable* in the FREQ statement identifies a numeric variable in the input data table that contains the frequency of occurrence of each observation. PROC CARDINALITY treats each observation as if it appears f times, where f is the value of the FREQ *variable* for the observation. If f is not an integer, it is truncated to an integer. If f is less than 1 or missing, the observation is not used in the analysis. When you omit the FREQ statement, each observation is assigned a frequency of 1.

Missing and nonpositive values do not contribute to the other statistics.

VAR Statement

VAR *variables* < / *options* > **;**

The VAR statement enables you to specify a subset of *variables* in the input data table (which is specified in the DATA= option in the PROC CARDINALITY statement) and specify how to order them.

You can specify one or more VAR statements for each type of ordering that you want. You cannot specify a variable more than once in all the VAR statements.

ORDER=ASC | DESC | ASCFMT | DESFMT
requests a specific method of levelization. You can specify the following values:

ASC	orders the specified *variables* in unformatted ascending order.
DESC	orders the specified *variables* in unformatted descending order.
ASCFMT	orders the specified *variables* in formatted ascending order.
DESFMT	orders the specified *variables* in formatted descending order.

By default, the value of the ORDER= option in the PROC CARDINALITY statement is used. If the ORDER= option is not specified in the PROC CARDINALITY statement, ORDER=ASC by default if the variable is unformatted or ORDER=ASCFMT by default if the variable is formatted.

WEIGHT Statement

WEIGHT *variable* **;**

The *variable* in the WEIGHT statement is used as a weight to perform a weighted analysis of the data. Observations that have nonpositive or missing weights are not included in the analysis. When you omit the WEIGHT statement, all observations that are used in the analysis are assigned a weight of 1.

Details: CARDINALITY Procedure

The CARDINALITY procedure extracts from a specified data table the distinct values of its variables up to a specified maximum number of levels. The maximum number of levels that you specify cannot exceed 254. The number of distinct levels of a variable is called its cardinality.

You need this information in a data exploration phase in order to understand the contents of big data and the possible role that a variable can play in subsequent analyses.

A limited cardinality study is sufficient to determine the variable roles—class, interval, or ID (a record identifier)—on the basis of the distinct values that are observed from the data. A full cardinality study might be computationally prohibitive, because it requires a lot of memory and resources. You can arrive at the same conclusion by running a limited cardinality analysis on the data.

The limited cardinality study reads and processes data until the number of levels reaches the value that you specify in the MAXLEVELS= option. All the levels that are higher than the value of this option are grouped together into one level that has a missing value (.) in the _INDEX_ column in the output details data table. All variables whose visibility is 100 are identified as having a class role. Any nonnumeric variable whose number of levels is greater than the MAXLEVELS= option value is identified as having an ID role. A numeric variable whose number of levels is greater than the MAXLEVELS= option value is identified as having either an interval or ID role, depending on whether all the processed data of the variable are unique or not. If all the processed data of the variable are unique, then the variable is identified as having an ID role; otherwise it is identified as having an interval role.

Displayed Output

The output data tables have fixed variable names and labels. Each variable occupies one row in the cardinality data table; the number of rows that it can occupy in the details data table is less than or equal to the value of the MAXLEVELS= option plus 1. The following statements run PROC CARDINALITY and then PROC CONTENTS to examine contents of the CARD table:

```
proc cardinality data=mylib.iris outcard=mylib.card
                 outdetails=mylib.details maxlevels=10;
run;

data card;
   set mylib.card;
run;

proc contents data=card order=varnum;
run;
```

Figure 7.3 Contents of the Cardinality Output Data Table

The CONTENTS Procedure

Variables in Creation Order

#	Variable	Type	Len	Format	Label
1	_VARNAME_	Char	32	$.	Variable name
2	_FMTWIDTH_	Num	8	BEST.	Width of the variable formatted value
3	_TYPE_	Char	1	$.	Type of the raw values
4	_RLEVEL_	Char	10	$.	Recommended level for analytics
5	_ORDER_	Char	8	$.	Variable sort order
6	_MORE_	Char	1	$.	Have more unreported levels
7	_CARDINALITY_	Num	8	BEST.	Number of levels
8	_NOBS_	Num	8	BEST.	Number of observations
9	_SUMFREQS_	Num	8	BEST.	Total summation of frequencies
10	_NMISS_	Num	8	BEST.	Number of missing values
11	_MISSFMT_	Char	32	$.	Format of the missing value
12	_VISIBLE_	Num	8	BEST.	Percentage of the visible part of the report
13	_MIN_	Num	8	BEST.	Minimum numeric value
14	_MAX_	Num	8	BEST.	Maximum numeric value
15	_MEAN_	Num	8	BEST.	Mean
16	_STDDEV_	Num	8	BEST.	Standard deviation
17	_SKEWNESS_	Num	8	BEST.	Skewness
18	_KURTOSIS_	Num	8	BEST.	Kurtosis
19	_MFREQ_	Num	8	BEST.	Maximum frequency
20	_MFREQFOUNDLEVEL_	Char	1	$.	Found maximum frequency in the visible part of the report
21	_MFREQNUM_	Num	8	BEST.	Numeric level with the maximum frequency
22	_MFREQCHR_	Char	32	$.	Character level with the maximum frequency
23	_MFREQCFMT_	Char	32	$.	Formatted level with the maximum frequency
24	_LASTNUM_	Num	8	BEST.	Last raw numeric value (cutoff)
25	_LASTCHR_	Char	32	$.	Last raw character value (cutoff)
26	_LASTCFMT_	Char	32	$.	Last formatted value (cutoff)

Note that even though the numbers of columns is fixed, the width of some of the columns in both data tables (for example, _RAWCHAR_ and _CFMT_) is related to the raw and formatted data values of each input variable. The width of these two variables is set to the maximum width over all the variables in the reports.

#	Variable	Type	Len	Format	Label
1	_VARNAME_	Char	32	$.	Variable name
2	_INDEX_	Num	8	BEST.	Level index
3	_FREQ_	Num	8	BEST.	Level frequency
4	FREQPERCENT	Num	8	BEST.	Percentage of the frequency of current level
5	NMISSPERCENT	Num	8	BEST.	Percentage of non missing values
6	_RAWNUM_	Num	8	BEST.	Raw numeric value
7	_RAWCHAR_	Char	32	$.	Raw character value
8	_FMTWIDTH_	Num	8	BEST.	Width of the variable formatted value
9	_CFMT_	Char	32	$.	Formatted value of a variable

Examples: CARDINALITY Procedure

The examples in this chapter are available in the GitHub repository located at https://github.com/sascommunities/doc-supplement-casstat.

NOTE: Input data must be in a CAS table that is accessible in your CAS session. You must refer to this table by using a two-level name. The first level must be a CAS engine libref, and the second level must be the table name. For more information, see the sections "Using CAS Sessions and CAS Engine Librefs" on page 7 and "Loading a SAS Data Set onto a CAS Server" on page 7 in Chapter 2, "Shared Concepts."

Example 7.1: Limited Cardinality of the Species Variable

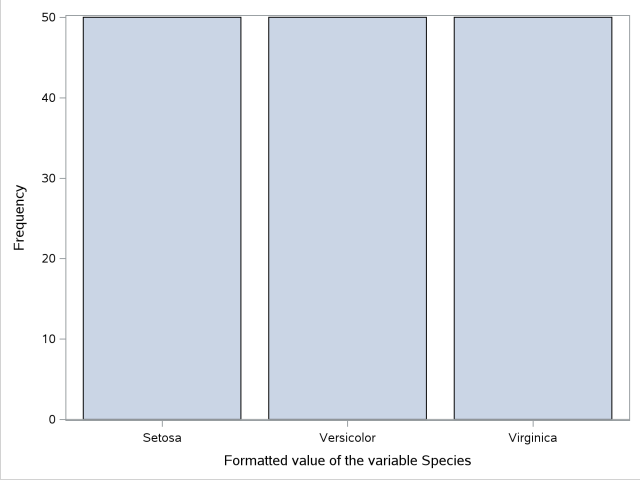
(View the complete code for this example (cardinality_ex1.sas) in the example repository.)

This example illustrates how you can use PROC CARDINALITY to determine the limited cardinality of a variable. It uses the same input data table as is used in the section "Getting Started: CARDINALITY Procedure" on page 248.

You can load the sashelp.iris data set into your CAS session by naming your CAS engine libref in the first statement of the following DATA step:

```
data mylib.iris;
   set sashelp.iris;
run;
```

The following statements run PROC CARDINALITY and plot the levels from the details data set for the variable Species:



```
proc cardinality data=mylib.iris outcard=mylib.card
                outdetails=mylib.details maxlevels=5;
run;

data sp;
   set mylib.details( where=(_varname_='Species'));
   label _cfmt_='Formatted value of the variable Species';
   if _index_ = . then do;
      _cfmt_=cats(">",left(_cfmt_));
   end;
  _cfmt_=left(_cfmt_);
run;

proc sgplot data=sp;
  vbar _cfmt_ / freq=_freq_;
run;
```

Output 7.1.1 shows that the variable Species has only three levels in the details data.

Output 7.1.1 Histogram of Species

Whether MAXLEVELS=100 or 5, the Species variable remains fully visible with a _CARDINALITY_ value of 3.

Example 7.2: Limited Cardinality of the Sepal Length Variable

(View the complete code for this example (cardinality_ex2.sas) in the example repository.)

This example demonstrates how to use PROC CARDINALITY with more levels; it uses the same data table as is used in the section "Getting Started: CARDINALITY Procedure" on page 248.

You can load the sashelp.iris data set into your CAS session by naming your CAS engine libref in the first statement of the following DATA step:

```
data mylib.iris;
   set sashelp.iris;
run;
```

The following statements run PROC CARDINALITY and display some of the contents of the cardinality data set:

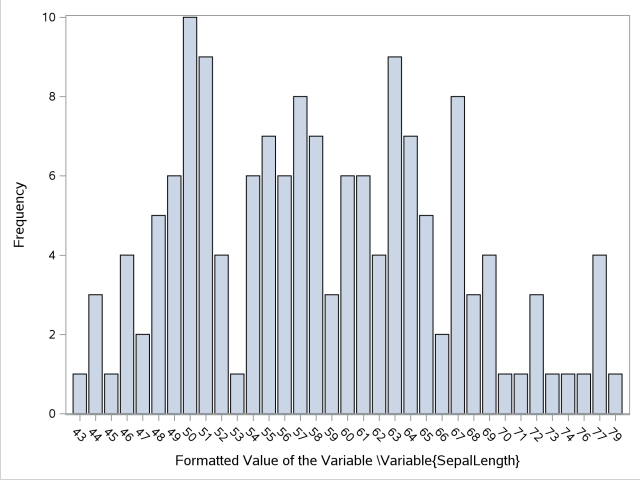
```
proc cardinality data=mylib.iris outcard=mylib.card
                 outdetails=mylib.details maxlevels=100;
run;

proc print data=mylib.card;
   var _varname_ _type_ _cardinality_ _more_ _visible_ _min_ _max_;
run;
```

Output 7.2.1 shows that all the variables have a _VISIBILITY_ value of 100%.

Output 7.2.1 Visibility of the Variables

Obs	_VARNAME_	_TYPE_	_CARDINALITY_	_MORE_	_VISIBLE_	_MIN_	_MAX_
1	Species	C	3	N	100	.	.
2	SepalLength	N	35	N	100	43	79
3	SepalWidth	N	23	N	100	20	44
4	PetalLength	N	43	N	100	10	69
5	PetalWidth	N	22	N	100	1	25



The following statements extract and display the levels of the variable SepalLength:

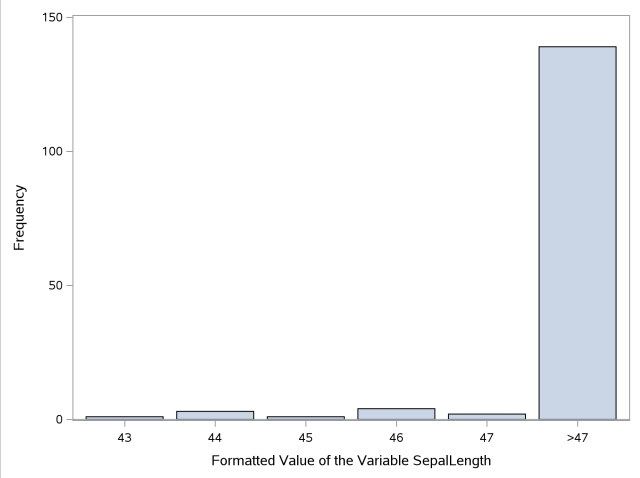
```
data sp;
   label _cfmt_='Formatted Value of the Variable \Variable{SepalLength}';
   set mylib.details( where=(_varname_='SepalLength'));
   if _index_ = . then do;
      _cfmt_=cats(">",left(_cfmt_));
   end;
   _cfmt_=left(_cfmt_);
run;

proc sgplot data=sp;
   vbar _cfmt_ / freq=_freq_;
run;
```

Output 7.2.2 shows the histogram.

Output 7.2.2 Full Histogram of the SepalLength Variable

The following statements specify MAXLEVELS=5, so only the leftmost five levels of the full histogram are displayed. All the other levels are combined into one level, which is reported in the details data table with a missing value in the _INDEX_ column.



```
proc cardinality data=mylib.iris outcard=mylib.card
                 outdetails=mylib.details maxlevels=5;
run;

data sp;
   label _cfmt_='Formatted Value of the Variable SepalLength';
   set mylib.details( where=(_varname_='SepalLength'));
   if _index_ = . then do;
      _cfmt_=cats(">",left(_cfmt_));
   end;
   _cfmt_=left(_cfmt_);
run;

proc sgplot data=sp;
   vbar _cfmt_ / freq=_freq_;
run;
```

Output 7.2.3 shows the full histogram of the variable SepalLength. It shows all 35 levels of the variable.

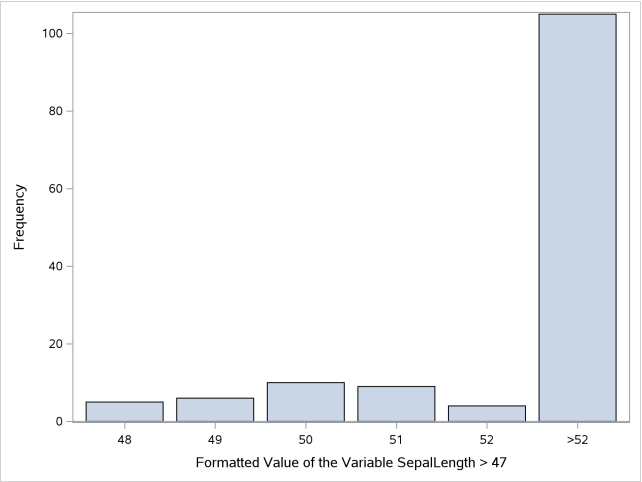
Output 7.2.3 Limited Histogram of the SepalLength Variable

Example 7.3: More Levels of the Sepal Length Variable

(View the complete code for this example (cardinality_ex3.sas) in the example repository.)

You can load the sashelp.iris data set into your CAS session by naming your CAS engine libref in the first statement of the following DATA step:

```
data mylib.iris;
   set sashelp.iris;
run;
```



You can dig deeper by requesting a subsequent segment of the histogram of any variable. This example further examines the SepalLength variable. The cutoff reported from Example 7.2 was 47, which means that all levels less than or equal to 47 have been reported. So you might want to run PROC CARDINALITY again in order to report levels greater than 47, as shown in the following statements:

```
proc cardinality data=mylib.iris (where=(SepalLength > 47))
                 outcard=mylib.card outdetails=mylib.details maxlevels=5;
   var SepalLength;
run;

data sp;
   set mylib.details;
   label _cfmt_='Formatted Value of the Variable SepalLength > 47';
   if _index_ = . then do;
      _cfmt_=cats(">",left(_cfmt_));
   end;
  _cfmt_=left(_cfmt_);
run;

proc sgplot data=sp;
   vbar _cfmt_ / freq=_freq_;
run;
```

Output 7.3.1 Histogram for SepalLength Levels Greater Than 47

The union of the detailed levels from Example 7.2 and this example cover 10 levels of the SepalLength variable.

Table 7.4 lists the variables that are related to the maximum frequency in the histogram.

Table 7.4 More Variables from the Cardinality Data

Name	Description
MFREQ	Maximum frequency
MFREQFOUNDLEVEL	Maximum frequency found in the visible part of the report
MFREQNUM	Numeric level that has the maximum frequency
MFREQCHR	Character level that has the maximum frequency
MFREQFMT	Formatted level that has the maximum frequency

The maximum frequency can be attained in the visible part of the histogram, or it can be hidden with the others. If the level that has the maximum frequency is in the visible part, the _MFREQFOUNDLEVEL_ variable is set to Y (Yes); otherwise it is set to N (No). This information is reported here because it is useful for subsequent analysis.

The following statements illustrate the variables that pertain to the maximum frequency of each variable.

```
proc cardinality data=mylib.iris outcard=mylib.card
                outdetails=mylib.details maxlevels=5;
run;

proc print data=mylib.card;
   var _varname_ _mf:;
run;
```

Output 7.3.2 Maximum Frequency Information

Obs	_VARNAME_	_MFREQ_	_MFREQFOUNDLEVEL_	_MFREQNUM_	_MFREQCHR_	_MFREQCFMT_
1	Species	50	Y	.	Setosa	Setosa
2	SepalLength	139	N	.		
3	SepalWidth	131	N	.		
4	PetalLength	126	N	.		
5	PetalWidth	101	N	.		

For the Species variable, the value of _MFREQ_ is 50. Because the Species variable has a limited cardinality of 3, _MFREQFOUNDLEVEL_ = Y. Also note that both _MFREQCHR_ and its formatted value in _MFREQCFMT_ are Setosa.

For the SepalLength variable, _MFREQ_ is 139 (which occurs for the value _MFREQNUM_= .), and _MFREQFOUNDLEVEL_ = N (which means that the visible part of the histogram does not contain the level that has the maximum frequency).

Example 7.4: A Variable with a User-Defined Format

(View the complete code for this example (cardinality_ex4.sas) in the example repository.)

This example demonstrates how PROC CARDINALITY determines how to order variables that have user-defined formats. User-defined formats are considered to be prior knowledge about the variable and are used by default. (You can override this behavior by requesting a specific order in the ORDER= option.)

You can load the sashelp.cars data set into your CAS session by naming your CAS engine libref in the first statement of the following DATA step:

```
data mylib.cars;
   set sashelp.cars;
run;
```

The following statements create the format on the variable engineSize, run the procedure, and examine some of the variables in the cardinality data set:

```
proc format casfmtlib='myfmtlib';
   value engsize
       low - <3 ='toys'
       3   - <6 ='granny'
       6   -high='usable';
run;

data mylib.cars;
   format engineSize engsize.;
   set mylib.cars;
run;

proc cardinality data=mylib.cars outcard=mylib.card
                 outdetails=mylib.details maxlevels=5;
   var engineSize;
run;
```

```
title 'Cars data with a user-defined format';
proc print data=mylib.card;
   var _varname_ _order_ _more_ _cardinality_;
run;
```

Output 7.4.1 Summary of the Variable engineSize

Cars data with a user-defined format

Obs	_VARNAME_	_ORDER_	_MORE_	_CARDINALITY_
1	engineSize	ASCFMT	N	3

The order that is used for the engineSize variable is ascending formatted (ASCFMT), because engineSize has a user-defined format (engsize7). Three levels were found (_CARDINALITY_ = 3). There are no more levels to report (_MORE_ = N). The full histogram is displayed. The following statements produce Output 7.4.2:

```
proc print data=mylib.details;
   var _varname_ _index_ _freq_ _cfmt_;
run;
```

Output 7.4.2 Details Data with a User-Defined Format for the Variable engineSize

Cars data with a user-defined format

Obs	_VARNAME_	_INDEX_	_FREQ_	_CFMT_
1	engineSize	1	242	granny
2	engineSize	2	178	toys
3	engineSize	3	8	usable

The order that is used for the engineSize variable is ascending formatted (ASCFMT), because engineSize has a user-defined format engsize7. All the levels are reported. There is no missing values in the _INDEX_ column for the engineSize variable.

Example 7.5: Forcing Another Order on the engineSize Variable

(View the complete code for this example (cardinality_ex5.sas) in the example repository.)

You can load the sashelp.cars data set into your CAS session by naming your CAS engine libref in the first statement of the following DATA step:

```
data mylib.cars;
   set sashelp.cars;
run;
```

The following statements specify the ORDER= option in the VAR statement in order to use a different levelization order:

```
title 'Cars data with a user-defined format with an ASC order';
proc cardinality data=mylib.cars outcard=mylib.card
                outdetails=mylib.details maxlevels=5;
   var engineSize /order=asc;
run;

proc print data=mylib.card ;
   var _varname_ _order_ _more_ _cardinality_;
run;
```

Output 7.5.1 Summary of the engineSize Variable without a Format

Cars data with a user-defined format with an ASC order

Obs	_VARNAME_	_ORDER_	_MORE_	_CARDINALITY_
1	EngineSize	ASC	Y	5

The order that is used in the engineSize variable is ascending unformatted, as requested by the ORDER=ASC option in the VAR statement. The reported levels are based on the numeric raw values of the engineSize variable. The format engsize7. is ignored. The raw values are more than 5 (the value of the MAXLEVEL= option). The details data table contains six rows: five for reported known levels and one for all the remaining unreported levels). The cardinality data table reports _MORE_ = Y (Yes) and _CARDINALITY_ = 5 for the engineSize variable. The details of the variable engineSize are discussed next, starting with the details data set produced in the previous step:

```
data details(drop=_rawchar_);
   set mylib.details;
   if _index_ = . then do;
      _cfmt_ = cats(">",  put(_rawnum_,best12.));
      _rawnum_ = .;
   end;
     _cfmt_=left(_cfmt_);
run;

proc print data=details;
run;
```

Output 7.5.2 Details of the engineSize Variable without a Format

Cars data with a user-defined format with an ASC order

Obs	_VARNAME_	_INDEX_	_FREQ_	FREQPERCENT	NMISSPERCENT	_RAWNUM_	_FMTWIDTH_	_CFMT_
1	EngineSize	1	2	0.4672897196	0.4672897196	1.3	12	1.3
2	EngineSize	2	1	0.2336448598	0.2336448598	1.4	12	1.4
3	EngineSize	3	6	1.4018691589	1.4018691589	1.5	12	1.5
4	EngineSize	4	10	2.3364485981	2.3364485981	1.6	12	1.6
5	EngineSize	5	4	0.9345794393	0.9345794393	1.7	12	1.7
6	EngineSize	.	405	94.626168224	94.626168224	.	12	>1.7

The order that is used in the engineSize variable is ascending unformatted, as requested by the ORDER= ASC option in the VAR statement. The reported levels are based on the numeric raw value of the engineSize

variable in ascending order. The format engsize7. is ignored. Five raw values are displayed with one additional level, indicating that the histogram of the variable is partial and not full. The observation for which _INDEX_ = . indicates that there are still unreported levels in the raw values. A second pass with a WHERE clause can reveal the details of the levels.

Overview: CATTRANSFORM Procedure

The CATTRANSFORM procedure transforms categorical variables in SAS Viya. It supports binning and encoding methods that are commonly performed as part of the data preprocessing step in creating machine learning models.

Categorical variables that have high cardinality can slow the computing performance of machine learning algorithms and increase the risk of model overfitting. PROC CATTRANSFORM supports several binning methods, both supervised and unsupervised, that enable you to reduce cardinality. These methods include grouping rare levels, classification tree binning, regression tree binning, and weight-of-evidence binning. The procedure also supports one-hot encoding by transforming the values of categorical variables to numeric values that start with the number 1.

PROC CATTRANSFORM facilitates transformation scoring of new data by using either an analytic store or scoring code in a SAS DATA step.

PROC CATTRANSFORM Features

The CATTRANSFORM procedure has the following features:

- supports supervised and unsupervised binning methods
- labels data by using one-hot encoding
- places missing values into a separate bin
- computes evaluation statistics for comparing the predictive performance of transformed variables
- scores transformations by using an analytic store
- generates scoring code for a SAS DATA step

Using CAS Sessions and CAS Engine Librefs

SAS Cloud Analytic Services (CAS) is the analytic server and associated cloud services in SAS Viya. This section describes how to create a CAS session and set up a CAS engine libref that you can use to connect to the CAS session. It assumes that you have a CAS server already available; contact your system administrator if you need help starting and terminating a server. This CAS server is identified by specifying the host on which it runs and the port on which it listens for communications. To simplify your interactions with this CAS server, the host information and port information for the server are stored as SAS option values that are retrieved automatically whenever this CAS server needs to be accessed. You can examine the host and port values for the server at your site by using the following statements:

```
proc options option=(CASHOST CASPORT);
run;
```

In addition to starting a CAS server, your system administrator might also have created a CAS session and a CAS engine libref for your use. You can define your own sessions and CAS engine librefs that connect to the CAS server as shown in the following statements:

```
cas mysess;
libname mylib cas sessref=mysess;
```

The CAS statement creates the CAS session named mysess, and the LIBNAME statement creates the mylib CAS engine libref that you use to connect to this session. It is not necessary to explicitly name the CASHOST and CASPORT of the CAS server in the CAS statement, because these values are retrieved from the corresponding SAS option values.

If you have created the mysess session, you can terminate it by using the TERMINATE option in the CAS statement as follows:

```
cas mysess terminate;
```

For more information about the CAS and LIBNAME statements, see the section "Introduction to Shared Concepts" on page 6 in Chapter 2, "Shared Concepts."

Getting Started: CATTRANSFORM Procedure

NOTE: Input data must be in a CAS table that is accessible in your CAS session. You must refer to this table by using a two-level name. The first level must be a CAS engine libref, and the second level must be the table name. For more information, see the sections "Using CAS Sessions and CAS Engine Librefs" on page 7 and "Loading a SAS Data Set onto a CAS Server" on page 7 in Chapter 2, "Shared Concepts."

This example demonstrates the basic features of the CATTRANSFORM procedure.

The following DATA step creates the data table mylib.catdata, which consists of 1,000 observations and includes two nominal variables:

```
data mylib.catdata;
    call streaminit(12345);
    do myid=1 to 1000;
        y=rand('table',.1,.9);
        c1=rand('table',.35,.25,.2,.1,.04,.03,.02,.01);
        c2=rand('table',.01,.02,.03,.04,.1,.2,.25,.35);
        output;
    end;
run;
```

These statements assume that your CAS engine libref is named mylib, as in the section "Using CAS Sessions and CAS Engine Librefs" on page 266, but you can substitute any appropriately defined CAS engine libref.

The following statements execute PROC CATTRANSFORM and use the default transformation method to group rare levels:

```
proc cattransform data=mylib.catdata;
    input c1 c2;
    output out=mylib.out;
run;
```

The INPUT statement defines the categorical input variables c1 and c2, and the OUTPUT statement puts the transformed variables into the output data table mylib.out.

The results are shown in Figure 8.1 through Figure 8.4, which display the following tables: "Transformation Requests," "Variable Transformation Information," "Nominal Variable Information," and "Bin Details." The "Bin Details" table shows that four levels of both variables were combined into a bin to meet the default rare threshold percentage of 5%.

Figure 8.1 Transformation Requests

The CATTRANSFORM Procedure

Transformation Requests

Transformation Name	Transformation Variables	N Nominal Transform Method
CAT	2	Group Rare

Figure 8.2 Variable Transformation Information

c1	CAT_c1	1000	0	5
c2	CAT_c2	1000	0	5

Figure 8.3 Nominal Variable Information

Nominal Variable Information

Variable	N	N Miss	N Levels
c1	1000	0	8
c2	1000	0	8

Figure 8.4 Bin Details

Bin Details

Variable	Bin ID	N Levels	N
c1	1	1	363
c1	2	1	212
c1	3	1	211
c1	4	1	110
c1	5	4	104
c2	1	1	369
c2	2	1	248
c2	3	1	189
c2	4	1	96
c2	5	4	98

Syntax: CATTRANSFORM Procedure

The following statements are available in the CATTRANSFORM procedure:

PROC CATTRANSFORM < *options* > **;**
CODE FILE=*filename* **;**
FREQ *variable* **;**
INPUT *variables* **;**
METHOD *method*(< *options* >) **;**
OUTPUT OUT=*libref.data-table* < *option* > **;**
SAVESTATE RSTORE=*libref.data-table* **;**
TARGET *variable* / **LEVEL=INTERVAL** | **NOMINAL** < *option* > **;**
WEIGHT *variable* **;**

The PROC CATTRANSFORM and INPUT statements are required. The TARGET statement is required for the supervised binning methods and optional for the unsupervised binning methods.

The following sections describe the PROC CATTRANSFORM statement and then describe the other statements in alphabetical order.

PROC CATTRANSFORM Statement

PROC CATTRANSFORM < *options* > **;**

The PROC CATTRANSFORM statement invokes the procedure.

You can specify the following *options*:

BINMISSING
places missing values into a separate bin whose bin ID value is 0.

DATA=*libref.data-table*
names the input data table for PROC CATTRANSFORM to use. The default is the most recently created data table. *libref.data-table* is a two-level name, where

libref refers to a collection of information that is defined in the LIBNAME statement and includes the library, which includes a path to the data, and a session identifier, which defaults to the active session but which can be explicitly defined in the LIBNAME statement. For more information about *libref*, see the section "Using CAS Sessions and CAS Engine Librefs" on page 266.

data-table specifies the name of the input data table.

DISTINCTCOUNTLIMIT=*integer*
specifies the maximum level limit.

By default, DISTINCTCOUNTLIMIT=5000.

EVALUATIONSTATS(*options***)**
requests evaluation statistics about the transformed variables. You can specify the following *options*:

WOEADJUST=*number*
specifies the weight-of-evidence adjustment value. The *number* can range from 0 to 1, inclusive.

By default, WOEADJUST=0.5.

WOEDEFINITION=EVENT | NONEVENT
specifies the weight-of-evidence definition. If WOEDEFINITION=EVENT, the weight of evidence is defined as event/nonevent. If WOEDEFINITION=NONEVENT, the weight of evidence is defined as nonevent/event.

By default, WOEDEFINITION=NONEVENT.

MISSINGEVALNONEVENT
treats missing targets as nonevents.

NBINS=*integer*
specifies the number of bins for all input variables.

OUTLEVELBINMAP=*libref.data-table*
saves the bin mapping information to a data table. The bin mapping table contains three columns: Variable, Level, and BinID. *libref.data-table* is a two-level name, where *libref* refers to the library, and *data-table* specifies the name of the output data table. For more information about this two-level name, see the DATA= option and the section "Using CAS Sessions and CAS Engine Librefs" on page 266.

PREFIX="*string***"**
specifies the prefix for the transformed variables.

By default, PREFIX="CAT".

PREPROCESSRARE
groups levels whose frequency percentages are 5% or less with the next least frequent level until all percentages are greater than 5% before implementing the specified method.

CODE Statement

CODE FILE=*filename* **;**

The CODE statement generates scoring code and saves it in a file that you can include in a SAS DATA step.

You must specify the following option:

FILE=*filename*
specifies the name of the file to write the SAS scoring code to.

FREQ Statement

FREQ *variable* **;**

The *variable* in the FREQ statement identifies a numeric variable in the input data table that contains the frequency of occurrence of each observation. PROC CATTRANSFORM treats each observation as if it appears f times, where f is the value of the FREQ *variable* for the observation. If f is not an integer, it is truncated to an integer. If f is less than 1 or missing, the observation is not used in the analysis. When you omit the FREQ statement, each observation is assigned a frequency of 1.

INPUT Statement

INPUT *variables* **;**

The INPUT statement specifies one or more *variables* as input for binning or encoding. All input variables are assumed to be nominal.

METHOD Statement

METHOD *method(< options >)* **;**

The METHOD statement specifies the binning or encoding method and any associated options.

You must specify one of the following *methods*:

GROUPRARE(*options***)**
groups levels that have a rare frequency or percentage with the next least frequent level until a threshold has been satisfied for all levels. By default, the *method* is GROUPRARE.

You can specify the following *options*:

RARETHRESHOLD=*integer*
specifies the rare frequency threshold where levels whose frequencies are less than or equal to the threshold are grouped with the next least-frequent level. The *integer* must be greater than 0.

RARETHRESHOLDPERCENT=*number*
specifies the rare threshold percentage where levels whose percentages are less than or equal to the threshold are grouped with the next least-frequent level. The *number* can range between 0 and 100.

By default, RARETHRESHOLDPERCENT=5.0.

ONEHOT
uses one-hot encoding of the input variables.

TREE(*options***)**
uses the supervised tree-based binning method. You can specify the following *options*:

CRITERIA=GAIN | GAINRATIO | GINI | SSE
specifies the tree criteria. You can specify the following criteria:

GAIN	uses the information gain as the tree-growing criterion for a nominal target.
GAINRATIO	uses the gain ratio as the tree-growing criterion for a nominal target.
GINI	uses the Gini statistic as the tree-growing criterion for a nominal target.
SSE	uses the residual sum of squares as the tree-growing criterion for an interval target.

MAXNBINS=*integer*
specifies the maximum number of bins. The *integer* must be greater than or equal to 2. The default for each *integer* is computed as the binary logarithm (log base 2) of the number of distinct values.

MINNBINS=*integer*
specifies the minimum number of bins. The *integer* must be greater than or equal to 1.

MINNOBSINBIN=*integer*
specifies the minimum number of observations to include in a bin.

MINPERNOBSINBIN=*number*
specifies the minimum percentage of observations to include in a bin. The *number* can be between 0 and 50.

By default, MINPERNOBSINBIN=5.0.

NOTE: For the tree-based method, a valid target is required.

WOE(*options***)**
uses the supervised weight-of-evidence (WOE) binning method.

You can specify the following *options*:

MAXNBINS=*integer*
specifies the maximum number of bins. The *integer* must be greater than or equal to 2. The default for each *integer* is computed as the binary logarithm (log base 2) of the number of distinct values.

MINNBINS=*integer*
specifies the minimum number of bins. The *integer* can be greater than or equal to 1.

MINNOBSINBIN=*integer*
specifies the minimum number of observations to include in a bin.

MINPERNOBSINBIN=*number*
specifies the minimum percentage of observations to include in a bin. The *number* can be between 0 and 50.

By default, MINPERNOBSINBIN=5.0.

NOTE: For the WOE method, a nominal target and a target event are required.

OUTPUT Statement

OUTPUT OUT=*libref.data-table* < *option*> **;**

The OUTPUT statement creates an output data table that contains the transformed variables.

You must specify the following option:

OUT=*libref.data-table*
names the output data table for PROC CATTRANSFORM to use. You must specify this option before any other options. *libref.data-table* is a two-level name, where

libref refers to a collection of information that is defined in the LIBNAME statement and includes the library, which includes a path to where the data table is to be stored, and a session identifier, which defaults to the active session but which can be explicitly defined in the LIBNAME statement. For more information about *libref*, see the section "Using CAS Sessions and CAS Engine Librefs" on page 266.

data-table specifies the name of the output data table.

You can also specify the following *option*:

COPYVAR=*variable*
COPYVARS=(*variables***)**
copies one or more *variables* from the input data table to the output data table.

SAVESTATE Statement

SAVESTATE RSTORE=*libref.data-table* **;**

The SAVESTATE statement creates an analytic store for the model and saves it as a binary object in a data table. You can use the analytic store in the ASTORE procedure to score new data. For more information, see Chapter 4, "ASTORE Procedure" (*SAS Viya: Machine Learning Procedures*).

You must specify the following option:

RSTORE=*libref.data-table*
specifies a data table in which to save the analytic store for the model. *libref.data-table* is a two-level name, where *libref* refers to the library, and *data-table* specifies the name of the output data table. For more information about this two-level name, see the DATA= option and the section "Using CAS Sessions and CAS Engine Librefs" on page 266.

TARGET Statement

TARGET *variable* / **LEVEL=INTERVAL | NOMINAL** < *option* > **;**

The TARGET statement names the target *variable* to use in the supervised tree-based and weight-of-evidence binning methods. You can also use the target *variable* to compute evaluation statistics. The target *variable* can be nominal or interval, and it cannot be listed in the INPUT statement.

If you specify LEVEL=NOMINAL, you can also specify the following *option*:

EVENT="*string***"**
specifies the event of a nominal target for calculating binary target statistics, which are Gini, weight of evidence, and information value. This option is required for the weight-of-evidence binning method and is optional for other methods. If you specify an event along with a multinomial target, PROC CATTRANSFORM computes the binary target statistics by combining the nonevent levels.

WEIGHT Statement

WEIGHT *variable* **;**

The *variable* in the WEIGHT statement is used as a weight to perform a weighted analysis of the data. Observations that have nonpositive or missing weights are not included in the analysis. The values of the WEIGHT variable can be nonintegral and are not truncated. When you omit the WEIGHT statement, all observations that are used in the analysis are assigned a weight of 1.

Details: CATTRANSFORM Procedure

PROC CATTRANSFORM transforms categorical variables in SAS Viya. It supports supervised and unsupervised binning methods for categorical input variables. The supervised methods include tree-based and weight-of-evidence-based binning. For the tree-based method, the target can be nominal or interval. For the weight-of-evidence-based method, the target must be nominal. For unsupervised binning, PROC CATTRANSFORM supports the grouping of rare levels. It can also encode categorical input variables with one-hot encoding.

For each input variable, if the target is specified, the evaluation statistics of transformed variable can be computed. The statistics include chi-square, G2, Gini, weight of evidence, information value, *F* test, residual sum of squares, and relative variable importance.

Unsupervised Grouping

PROC CATTRANSFORM provides one unsupervised binning method that you specify by using the GROUPRARE option in the METHOD statement. It groups levels that have a rare frequency or percentage with the next least-frequent level until a threshold has been satisfied for all levels. You can specify the threshold as a frequency or a percentage. By default, the threshold is 5.0%.

Supervised Grouping

The supervised binning methods in PROC CATTRANSFORM, the tree-based and weight-of-evidence-based methods, are specified by the TREE and WOE options, respectively, in the METHOD statement. For the tree-based method, the target can be nominal or interval. If the target is nominal, the classification tree algorithm is used. If the target is interval, the regression tree algorithm is used. For the weight-of-evidence method, the target must be nominal, and the target event must be specified.

One-Hot Encoding

The one-hot encoding method in PROC CATTRANSFORM, which is specified by the ONEHOT option in the METHOD statement, transforms the values of a categorical variables to numeric values that start with the number 1. The order of the values in the transformed variable corresponds to the sorted order of the original values. The transformation is useful for machine learning because it converts nominal variables to variables that have only numeric values. The encoded variables are also sequentially numbered like binned variables.

One-hot encoding is known for transforming each value of a categorical variable to a zero-one variable, and the resulting set of zero-one variables is used as input to machine learning algorithms. Although the transformed variable from the one-hot method could be further processed into zero-one variables, the zero-one variables are not necessary in SAS modeling procedures. Because the CLASS statement internally creates the zero-one variables from any nominal variable, you can choose to specify either the original variable or the transformed variable when you use SAS procedures for modeling.

Scoring

PROC CATTRANSFORM facilitates transformation scoring of new data by using either an analytic store or scoring code in a SAS DATA step.

When you specify the SAVESTATE statement with the RSTORE= option, an analytic store is created for the scoring model. You can then score new data from the model by using the ASTORE procedure. For more information, see Chapter 4, “ASTORE Procedure” (*SAS Viya: Machine Learning Procedures*).

Alternatively, you can specify the CODE statement with the FILE= option to save scoring code in a file. In this case, you score new data by using the SAS DATA step.

Displayed Output

PROC CATTRANSFORM produces output that is organized into various tables, which the following sections describe in the order of their appearance.

Transformation Requests

The "Transformation Requests" table displays the transformation name, number of transformation variables, and transformation method.

If you specify the EVALUATIONSTATS option in the PROC CATTRANSFORM statement and the EVENT= option in the TARGET statement, the table also displays the weight-of-evidence definition, weight-of-evidence adjustment value, and information value factor.

Variable Transformation Information

The "Variable Transformation Information" table displays the variable name, target variable, result variable, number of observations, number of missing observations, and number of bins.

If you specify the EVALUATIONSTATS option in the PROC CATTRANSFORM statement with an interval target, the table also displays the *F*-test statistic.

If you specify the EVALUATIONSTATS option with a nominal target, the table also displays the chi-square and G2 statistics.

If you specify the EVALUATIONSTATS option together with the TREE option in the METHOD statement, the table also displays the residual sum of squares and relative variable importance.

If you specify the EVALUATIONSTATS option and the EVENT= option in the TARGET statement with a nominal target, the table also displays the information value and weight-of-evidence statistics.

Nominal Variable Information

The "Nominal Variable Information" table displays the variable name, number of observations, number of missing observations, and number of levels for the inputs and nominal target.

Bin Details

For each bin, the "Bin Details" table displays the variable name, bin ID, number of levels, and number of observations.

If you specify the EVALUATIONSTATS option in the PROC CATTRANSFORM statement with an interval target, the table also displays the mean, standard deviation, and number of missing values of the target for each bin.

If you specify the EVALUATIONSTATS option and the EVENT= option in the TARGET statement with a nominal target, the table also displays the event count, nonevent count, weight of evidence, and information value for each bin.

OutputCasTables Table

The OutputCasTables table is a special table that has information about each CAS table that is created during a CAS action execution. The information for each CAS table consists of the CAS table name, the caslib in which the table resides, and the number of columns and rows in the CAS table.

ODS Table Names

Every table that PROC CATTRANSFORM creates has a name associated with it. You must use this name to refer to the table when you use ODS statements. The name of each table and a short description of the contents are listed in Table 8.1.

Table 8.1 ODS Tables Produced by PROC CATTRANSFORM

Table Name	Description	Statement	Option
BinDetails	Bin details	PROC CATTRANSFORM	Default
NomVarInfo	Nominal variable information	PROC CATTRANSFORM	Default
OutputCasTables	See the section "OutputCasTables Table" on page 278	PROC CATTRANSFORM, OUTPUT, or SAVESTATE	OUTLEVELBINMAP=
TransInfo	Transformation requests	PROC CATTRANSFORM	Default
VarTransInfo	Variable transformation information	PROC CATTRANSFORM	Default

Examples: CATTRANSFORM Procedure

NOTE: Input data must be in a CAS table that is accessible in your CAS session. You must refer to this table by using a two-level name. The first level must be a CAS engine libref, and the second level must be the table name. For more information, see the sections "Using CAS Sessions and CAS Engine Librefs" on page 7 and "Loading a SAS Data Set onto a CAS Server" on page 7 in Chapter 2, "Shared Concepts."

Example 8.1: Binning by Grouping Rare Levels

This example shows how to use the CATTRANSFORM procedure to reduce the number of levels of nominal variables by using the binning method of grouping rare levels. The input data come from the Hmeq data set, which is in the Sampsio library that SAS provides. It contains 5,960 mortgage applicants. A target variable named Bad indicates whether the customer has paid on the loan or defaulted on it. Table 8.2 describes the variables in Hmeq.

Table 8.2 Variables in the Home Equity (Hmeq) Data Set

Variable	Role	Level	Description
Bad	Response	Binary	1 = customer defaulted on the loan or is seriously delinquent 0 = customer is current on loan payments
CLAge	Predictor	Num	Age of oldest credit line in months
CLNo	Predictor	Num	Number of credit lines
DebtInc	Predictor	Num	Debt-to-income ratio
Delinq	Predictor	Num	Number of delinquent credit lines
Derog	Predictor	Num	Number of major derogatory reports
Job	Predictor	Char	Occupational category
Loan	Predictor	Num	Requested loan amount
MortDue	Predictor	Num	Amount due on existing mortgage
nInq	Predictor	Num	Number of recent credit inquiries
Reason	Predictor	Binary	`'DebtCon'` = debt consolidation `'HomeImp'` = home improvement
Value	Predictor	Num	Value of current property
YoJ	Predictor	Num	Years at present job

You can load the Hmeq data set into your CAS session by specifying your CAS engine libref in the first statement in the following DATA step. These statements assume that your CAS engine libref is named mylib, but you can substitute any appropriately defined CAS engine libref.

```
data mylib.hmeq;
   set sampsio.hmeq;
run;
```

The following statements call PROC CATTRANSFORM to bin the selected variables by using the default GROUPRARE option in the METHOD statement. Also, the BINMISSING option places the missing values into a separate bin.

```
proc cattransform data=mylib.hmeq binmissing;
    input reason job derog delinq ninq;
    output out=mylib.score;
run;
```

PROC CATTRANSFORM generates the results tables shown in Output 8.1.1 through Output 8.1.4.

The "Transformation Requests" table in Output 8.1.1 shows that the number of transformation variables is five and the transformation method is "Group Rare."

Output 8.1.1 Transformation Requests

The CATTRANSFORM Procedure

Transformation Requests

Transformation Name	N Transformation Variables	Nominal Transform Method
CAT	5	Group Rare

The "Variable Transformation Information" table in Output 8.1.2 shows the variable name, result variable, number of observations, number of missing observations, and number of bins for each variable.

Output 8.1.2 Variable Transformation Information

Variable Transformation Information

Variable	Result Variable	N	N Miss	N Bins
DELINQ	CAT_DELINQ	5380	580	4
DEROG	CAT_DEROG	5252	708	3
NINQ	CAT_NINQ	5450	510	6
JOB	CAT_JOB	5681	279	6
REASON	CAT_REASON	5708	252	3

The "Nominal Variable Information" table in Output 8.1.3 shows the number of levels of each input variable.

Output 8.1.3 Nominal Variable Information

Nominal Variable Information

Variable	N	N Miss	N Levels
DELINQ	5380	580	14
DEROG	5252	708	11
JOB	5681	279	6
NINQ	5450	510	16
REASON	5708	252	2

The "Bin Details" table in Output 8.1.4 displays the binning details for each input variable. The first step of the method of grouping rare levels encodes the values to ordered numerical values from most frequent to least frequent. The second step groups levels that have a rare frequency with the next least-frequent level until the threshold has been met. In this case, the default threshold is 5%. In addition, the BINMISSING option places the missing values into a bin and assigns a value of 0 to them.

Output 8.1.4 Bin Details

Bin Details

Variable	Bin ID	N Levels	N
DELINQ	0	1	580
DELINQ	1	1	4179
DELINQ	2	1	654
DELINQ	3	12	547
DEROG	0	1	708
DEROG	1	1	4527
DEROG	2	10	725
NINQ	0	1	510
NINQ	1	1	2531
NINQ	2	1	1339
NINQ	3	1	780
NINQ	4	1	392
NINQ	5	12	408
JOB	0	1	279
JOB	1	1	2388
JOB	2	1	1276
JOB	3	1	948
JOB	4	1	767
JOB	5	2	302
REASON	0	1	252
REASON	1	1	3928
REASON	2	1	1780

The OUTPUT statement generates the "OutputCasTables" table, which is not shown. It displays the scored table that contains the transformed variables.

Example 8.2: Classification Tree Binning

This example shows how to use the CATTRANSFORM procedure to reduce the number of levels of nominal variables by using the classification tree binning method.

The following DATA step creates the data table mylib.catdata, which consists of 1,000 observations that contain two nominal predictor variables and a nominal target:

```
data mylib.catdata;
    call streaminit(12345);
    do myid=1 to 1000;
        y=rand('table',.1,.9);
        c1=rand('table',.35,.25,.2,.1,.04,.03,.02,.01);
        c2=rand('table',.01,.02,.03,.04,.1,.2,.25,.35);
        output;
    end;
run;
```

These statements assume that your CAS engine libref is named mylib, but you can substitute any defined CAS engine libref.

The following statements use PROC CATTRANSFORM to perform supervised binning by using the classification tree algorithm:

```
proc cattransform data=mylib.catdata evaluationstats;
    input c1 c2;
    target y / level=nominal event='1';
    method tree;
    output out=mylib.score;
    savestate rstore=mylib.classmodel;
run;
```

The statements generate the results shown in Output 8.2.1 through Output 8.2.4, which display the following tables: "Transformation Requests," "Variable Transformation Information," "Nominal Variable Information," and "Bin Details."

Specifying the TREE binning method option with the EVENT and EVALUATIONSTATS options adds columns to the tables. The "Transformation Requests" table displays the WOE definition, WOE adjustment, and information value (IV) factor. The "Variable Transformation Information" table displays evaluation statistics for comparing the predictive performance of the transformed variables. The "Nominal Variable Information" table displays the number of observations, number of missing observations, and number of nominal variable levels. The "Bin Details" table has event counts, weight-of-evidence, and information value for each bin.

The OUTPUT and SAVESTATE statements also generate the "OutputCasTables" results table, which is not shown. It displays the scored table from the OUTPUT statement and the scoring model from the SAVESTATE statement.

Output 8.2.1 Transformation Requests

The CATTRANSFORM Procedure

Transformation Requests

Transformation Name	Transformation Variables	Nominal Transform Method	WOE Definition	WOE Adjustment	IV Factor

Variable	Bin ID	N Levels	N	Event Count	Non-Event Count	Weight of Evidence	Information Value
c1	1	3	343	44	299	-0.31476	0.038555
c1	2	2	404	37	367	0.063432	0.001585
c1	3	3	253	16	237	0.46446	0.045289
c2	1	3	575	60	515	-0.08119	0.003916
c2	2	2	344	31	313	0.081204	0.002195
c2	3	3	81	6	75	0.294717	0.006248

Example 8.3: Regression Tree Binning

This example shows how to use the CATTRANSFORM procedure to reduce the number of levels of nominal variables by using the regression tree binning method.

The following DATA step creates the data table mylib.regdata, which consists of 1,000 observations that contain two nominal predictor variables and an interval target:

```
data mylib.regdata;
    call streaminit(12345);
    do myid=1 to 1000;
        y=round(rand('normal',50,10),.1);
        c1=rand('table',.35,.25,.2,.1,.04,.03,.02,.01);
        c2=rand('table',.01,.02,.03,.04,.1,.2,.25,.35);
        output;
    end;
run;
```

These statements assume that your CAS engine libref is named mylib, but you can substitute any defined CAS engine libref.

The following statements use PROC CATTRANSFORM to perform supervised binning by using the regression tree algorithm:

```
proc cattransform data=mylib.regdata evaluationstats;
    input c1 c2;
    target y / level=interval;
    method tree;
    output out=mylib.score;
```

```
    savestate rstore=mylib.regmodel;
run;
```

The statements generate the results shown in Output 8.3.1 through Output 8.3.4, which display the following tables: "Transformation Requests," "Variable Transformation Information," "Nominal Variable Information," and "Bin Details."

Specifying the TREE method option with an interval target and the EVALUATIONSTATS option adds columns to the tables. The "Transformation Requests" table shows that the target is interval by denoting the regression tree binning method. The "Variable Transformation Information" table displays evaluation statistics for comparing the predictive performance of the transformed variables. The "Nominal Variable Information" table displays the number of observations, number of missing observations, and number of input variable levels. The "Bin Details" table displays descriptive statistics of the target variable for each bin.

The OUTPUT and SAVESTATE statements also generate the "OutputCasTables" results table, which is not shown. It displays the scored table from the OUTPUT statement and the scoring model from the SAVESTATE statement.

Output 8.3.1 Transformation Requests

Overview: CORRELATION Procedure

The CORRELATION procedure computes Pearson correlation coefficients and the probabilities that are associated with these statistics in SAS Viya.

The Pearson product-moment correlation is a parametric measure of a linear relationship between two variables. When only one set of analysis variables is specified, the default correlation analysis includes descriptive statistics for each analysis variable and pairwise Pearson correlation statistics for these variables. When two sets of analysis variables are specified, the default correlation analysis includes descriptive statistics for each analysis variable and pairwise Pearson correlation statistics between the two sets of variables. When the relationship between two variables is nonlinear or when outliers are present, the correlation coefficient might incorrectly estimate the strength of the relationship.

PROC CORRELATION Features

The CORRELATION procedure offers the following functionality:

- provides a WITH statement for analysis of pairwise Pearson correlation statistics between two sets of variables
- provides a FREQ statement for grouped analysis
- provides a WEIGHT statement for weighted analysis
- produces output data tables that contain descriptive statistics for analysis variables, Pearson correlation statistics, covariances, sums of squares, and corrected sums of squares
- computes Cronbach's coefficient alpha for estimating reliability

Because the CORRELATION procedure runs on CAS, it also does the following:

- enables you to run on a cluster of machines that distribute the data and the computations
- enables you to run in single-machine mode
- exploits all the available cores and concurrent threads (for information about how PROC CORRELATION uses threads, see the section "Multithreading" on page 102 in Chapter 2, "Shared Concepts")

PROC CORRELATION Compared with Other SAS Procedures

The CORRELATION procedure provides functionality that is comparable to that of the HPCORR and CORR procedures in Base SAS software.

The functionality of the CORRELATION procedure closely resembles that of the HPCORR procedure, which is a high-performance procedure. The CORRELATION procedure is the next generation of the HPCORR procedure, and it was developed specifically for SAS Viya. Both procedures are designed to run on a cluster of machines that distribute the data and the computations.

The CORRELATION procedure, the HPCORR procedure, and the CORR procedure have the similarities and differences shown in Table 9.1.

Table 9.1 Comparison of PROC CORRELATION, PROC HPCORR, and PROC CORR

Feature	PROC CORRELATION	PROC HPCORR	PROC CORR
Supports the computation of Pearson correlation coefficients and the probabilities associated with these statistics	Yes	Yes	Yes
Supports BY statement	Yes	No	Yes
Supports DISPLAY and DISPLAYOUT statements	Yes	No	No
Supports the computation of nonparametric measure of association	No	No	Yes
Supports OUTP statements	Yes	Yes	Yes
Supports Cronbach's alpha coefficient alpha for estimating reliability	Yes	No	Yes
Threading	Executes on multiple threads	Executes on multiple threads	Executes on a single thread

Using CAS Sessions and CAS Engine Librefs

SAS Cloud Analytic Services (CAS) is the analytic server and associated cloud services in SAS Viya. This section describes how to create a CAS session and set up a CAS engine libref that you can use to connect to the CAS session. It assumes that you have a CAS server already available; contact your system administrator if you need help starting and terminating a server. This CAS server is identified by specifying the host on which it runs and the port on which it listens for communications. To simplify your interactions with this CAS server, the host information and port information for the server are stored as SAS option values that are retrieved automatically whenever this CAS server needs to be accessed. You can examine the host and port values for the server at your site by using the following statements:

```
proc options option=(CASHOST CASPORT);
run;
```

In addition to starting a CAS server, your system administrator might also have created a CAS session and a CAS engine libref for your use. You can define your own sessions and CAS engine librefs that connect to the CAS server as shown in the following statements:

```
cas mysess;
libname mylib cas sessref=mysess;
```

The CAS statement creates the CAS session named mysess, and the LIBNAME statement creates the mylib CAS engine libref that you use to connect to this session. It is not necessary to explicitly name the CASHOST and CASPORT of the CAS server in the CAS statement, because these values are retrieved from the corresponding SAS option values.

If you have created the mysess session, you can terminate it by using the TERMINATE option in the CAS statement as follows:

```
cas mysess terminate;
```

For more information about the CAS and LIBNAME statements, see the section “Introduction to Shared Concepts” on page 6 in Chapter 2, “Shared Concepts.”

Getting Started: CORRELATION Procedure

(View the complete code for this example at https://github.com/sascommunities/doc-supplement-casstat/tree/main/Examples/cascorrgs.sas.)

This example creates a data table and then uses PROC CORRELATION to produce Pearson correlations.

The following statements create the mylib.Fitness data table. These data have been altered to contain some missing values:

```
*----------------- Data on Physical Fitness -----------------*
| These measurements were made on men involved in a physical |
| fitness course at N.C. State University.                   |
| The variables are Age (years), Weight (kg),                |
| Runtime (time to run 1.5 miles in minutes), and            |
| Oxygen (oxygen intake, ml per kg body weight per minute)   |
| Certain values were changed to missing for the analysis.   |
*------------------------------------------------------------*;
data mylib.Fitness;

;
```

These statements assume that your CAS engine libref is named mylib, but you can substitute any appropriately defined CAS engine libref.

The following statements invoke the CORRELATION procedure and request a correlation analysis:

```
proc correlation data=mylib.Fitness;
run;
```

The "Simple Statistics" table in Figure 9.1 displays univariate statistics for the analysis variables.

Figure 9.1 Univariate Statistics

The CORRELATION Procedure

4 Variables	Age	Weight	Oxygen	RunTime

Figure 9.1 *continued*

Simple Statistics						
Variable	N	Mean	Std Dev	Sum	Minimum	Maximum
Age	31	47.67742	5.21144	1478	38.00000	57.00000
Weight	31	77.44452	8.32857	2401	59.08000	91.63000
Oxygen	29	47.22721	5.47718	1370	37.38800	60.05500
RunTime	29	10.67414	1.39194	309.55000	8.17000	14.03000

By default, all numeric variables not listed in other statements are used in the analysis. Observations that have nonmissing values for each variable are used to derive the univariate statistics for that variable.

The "Pearson Correlation Coefficients" table in Figure 9.2 displays the Pearson correlation, the *p*-value under the null hypothesis of zero correlation, and the number of nonmissing observations for each pair of variables.

Figure 9.2 Pearson Correlation Coefficients

Pearson Correlation Coefficients Prob > |r| under H0: Rho=0 Number of Observations				
	Age	Weight	Oxygen	RunTime
Age	1.0000	-0.2335	-0.3147	0.1448
		0.2061	0.0963	0.4536
	31	31	29	29
Weight	-0.2335	1.0000	-0.1536	0.2007
	0.2061		0.4264	0.2965
	31	31	29	29
Oxygen	-0.3147	-0.1536	1.0000	-0.8684
	0.0963	0.4264		<.0001
	29	29	29	28
RunTime	0.1448	0.2007	-0.8684	1.0000
	0.4536	0.2965	<.0001	
	29	29	28	29

By default, Pearson correlation statistics are computed from observations that have nonmissing values for each pair of analysis variables. Figure 9.2 displays a correlation of –0.86843 between Runtime and Oxygen, which is significant with a *p*-value less than 0.0001. That is, an inverse linear relationship exists between these two variables. As Runtime (time in minutes to run 1.5 miles) increases, Oxygen (oxygen intake in milliliters per kilogram body weight per minute) decreases.

Syntax: CORRELATION Procedure

The following statements are available in PROC CORRELATION:

PROC CORRELATION < *options* > ;
  BY *variables* ;
  DISPLAY < *table-list* > < / *options* > ;
  DISPLAYOUT *table-spec-list* < / *options* > ;
  FREQ *variable* ;
  VAR *variables* ;
  WEIGHT *variable* ;
  WITH *variables* ;

The PROC CORRELATION statement is the only required statement for the CORRELATION procedure. The following sections describe the PROC CORRELATION statement and then describe the other statements in alphabetical order.

PROC CORRELATION Statement

PROC CORRELATION < *options* > ;

The PROC CORRELATION statement invokes the procedure. Table 9.2 summarizes the options available in the PROC CORRELATION statement.

Table 9.2 PROC CORRELATION Statement Options

Option	Description
Data Tables	
DATA=	Specifies the input data table
OUTP=	Specifies the output data table to contain the Pearson correlation statistics
Statistical Analysis	
EXCLNPWGT	Excludes observations that have nonpositive weight values from the analysis
NOMISS	Excludes observations that have missing analysis values from the analysis
Statistics	
ALPHA	Computes Cronbach's coefficient alpha
COV	Computes covariances
CSSCP	Computes corrected sums of squares and crossproducts
SSCP	Computes sums of squares and crossproducts
VARDEF=	Specifies the divisor for variance calculations
Printed Output	
BEST=	Displays the specified number of ordered correlation coefficients
NOCORR	Suppresses Pearson correlations
NOPROB	Suppresses *p*-values
NOSIMPLE	Suppresses descriptive statistics
RANK	Displays ordered correlation coefficients

ALPHA

calculates and prints Cronbach's coefficient alpha. PROC CORRELATION computes separate coefficients by using raw and standardized values (scaling the variables to a unit variance of 1). For each analysis variable, PROC CORRELATION computes the correlation between that variable and all the remaining variables. It also computes Cronbach's coefficient alpha by using only the remaining variables.

When you specify this option, the Pearson correlations are also displayed. If you also specify the OUTP= option, the output data table also contains observations that have Cronbach's coefficient alpha. For more information about Cronbach's coefficient alpha, see the section "Cronbach's Coefficient Alpha" on page 300.

This option is not valid if a WITH statement is specified.

BEST=*n*

prints the *n* highest correlation coefficients for each variable, where $n \geq 1$. Correlations are ordered from highest to lowest in absolute value. (If you do not specify this option, PROC CORRELATION prints correlations in a rectangular table, using the variable names as row and column labels.)

COV

displays the variance and covariance matrix. When you specify this option, the Pearson correlations are also displayed. If you also specify the OUTP= option, the output data table also contains the covariance matrix with the corresponding _TYPE_ variable value 'COV.'

CSSCP

displays a table of the corrected sums of squares and crossproducts. When you specify this option, the Pearson correlations are also displayed. If you also specify the OUTP= option, the output data table also contains a CSSCP matrix with the corresponding _TYPE_ variable value 'CSSCP.'

DATA=*libref.data-table*

names the input data table for PROC CORRELATION to use. The default is the most recently created data table. *libref.data-table* is a two-level name, where

libref refers to a collection of information that is defined in the LIBNAME statement and includes the library, which includes a path to the data, and a session identifier, which defaults to the active session but which can be explicitly defined in the LIBNAME statement. For more information about *libref*, see the section "Using CAS Sessions and CAS Engine Librefs" on page 290.

data-table specifies the name of the input data table.

EXCLNPWGT

EXCLNPWGTS

excludes observations that have nonpositive weight values from the analysis. (By default, PROC CORRELATION treats observations that have negative weights like those observations that have zero weights and counts them in the total number of observations.)

NOCORR
suppresses display of Pearson correlations.

NOMISS
excludes observations that have missing values from the analysis. (If you do not specify this option, PROC CORRELATION computes correlation statistics by using all the nonmissing pairs of variables.)

NOPROB
suppresses display of the probabilities that are associated with each correlation coefficient.

NOSIMPLE
suppresses printing of simple descriptive statistics for each variable. However, if you request an output data table, the output data table still contains simple descriptive statistics for the variables.

OUTP=*libref.data-table*
creates an output data table that contains Pearson correlation statistics.

libref.data-table is a two-level name, where

libref refers to a collection of information that is defined in the LIBNAME statement and includes the library, which includes a path to the data, and a session identifier, which defaults to the active session but which can be explicitly defined in the LIBNAME statement. For more information about *libref*, see the section "Using CAS Sessions and CAS Engine Librefs" on page 290.

data-table specifies the name of the output data table.

This data table also includes means, standard deviations, and the number of observations. If you also specify the ALPHA option, the output data table also contains six observations that have Cronbach's coefficient alpha.

RANK
displays the ordered correlation coefficients for each variable. Correlations are ordered from highest to lowest in absolute value.

SSCP
displays a table of the sums of squares and crossproducts. When you specify this option, the Pearson correlations are also displayed. If you also specify the OUTP= option, the output data table contains an SSCP matrix and the corresponding _TYPE_ variable value is 'SSCP.'

VARDEF=DF | N | WDF | WEIGHT | WGT
specifies the variance divisor in the calculation of variances and covariances. The default is VARDEF=DF.

Table 9.3 displays available values and associated divisors for the VARDEF= option, where n is the number of nonmissing observations and w_j is the weight associated with the jth nonmissing observation.

Table 9.3 Possible Values for the VARDEF= Option

Value	Description	Divisor
DF	Degrees of freedom	$n - 1$
N	Number of observations	n
WDF	Sum of weights minus one	$\sum_j^n w_j - 1$
WEIGHT | WGT	Sum of weights	$\sum_j^n w_j$

BY Statement

BY *variables* **;**

You can specify a BY statement in PROC CORRELATION to obtain separate analyses of observations in groups that are defined by the values of the BY variables. If you specify more than one BY statement, only the last one specified is used. For more information, see the discussion of BY-group processing in the "Grouping Data" section of *SAS Programmers Guide: Essentials*.

DISPLAY Statement

DISPLAY < *table-list* > < / *options* > **;**

The DISPLAY statement enables you to specify a list of display tables to display or exclude. This statement is similar to the ODS SELECT, ODS EXCLUDE, and ODS TRACE statements. However, the DISPLAY statement can improve performance when a large number of tables could be generated (such as in BY-group processing). The procedure processes the DISPLAY statement on a CAS server and thus sends only a subset of ODS tables to the SAS client. Because ODS statements are processed on a SAS client, first all the generated display tables are sent to the client, and then the client creates a subset.

If you use both DISPLAY and ODS statements together, the DISPLAY statement takes precedence over the ODS statements. Note that the ODS EXCLUDE statement processes tables that are sent to the client after they have been filtered by the DISPLAY statement. In some cases, it might appear that the ODS EXCLUDE statement is taking precedence because it can further filter the tables. For more information about ODS, see *SAS Output Delivery System: Procedures Guide*.

You can specify the *table-list* as a list of table names, paths, partial pathnames, and regular expressions.

The table names that you can specify are listed in the section "ODS Table Names" on page 303. A path is a table name that is prefixed with dot-separated grouping information. For example, a SelectionSummary table that a procedure produces during a selection routine might have the path *Bygroup1.Summary.SelectionSummary*. A partial pathname does not include all groups; for example, *SelectionSummary* and *Summary.SelectionSummary* are partial pathnames for *Bygroup1.Summary.SelectionSummary*.

When you specify a table name or partial pathname, all display tables whose paths end in the specified name are selected for display or exclusion. For example, both *SelectionSummary* and *Summary.SelectionSummary* select *Bygroup1.Summary.SelectionSummary*.

A regular expression is enclosed in forward slashes (/). For example, specifying "/tions/" selects all pathnames that contain the substring "tions"; in particular, the *Bygroup1.Summary.SelectionSummary* table is selected. Specifying "!/tions/" selects all pathnames that do not contain the substring "tions"; in particular, the *Bygroup1.Summary.SelectionSummary* table is not selected.

You can specify the following *options* after a slash (/):

CASESENSITIVE
performs a case-sensitive comparison of table names in the *table-list* to display table names when tables are subsetted for display. To preserve case, you must enclose table names in the *table-list* in quotation marks.

EXCLUDE
displays all display tables except those that you specify in the *table-list*.

EXCLUDEALL
suppresses display of all tables. This option takes precedence over the other options.

TRACE
displays the display table names, labels, and paths.

DISPLAYOUT Statement

DISPLAYOUT *table-spec-list* < / *options* > **;**

The DISPLAYOUT statement enables you to create output tables from your displayed output. This statement is similar to the ODS OUTPUT statement. For more information about ODS, see *SAS Output Delivery System: Procedures Guide*.

The *table-spec-list* specifies a list of output tables to create. Each entry in the list has either a *key*=*value* format or a *key* format:

key=*value*	specifies *key* as the ODS table name, path, or partial pathname, and specifies *value* as the output table name.
key	specifies *key* as the ODS table name and also as the output table name.

The ODS table names that you can specify are listed in the section "ODS Table Names" on page 303. You cannot specify the ODS table named OutputCasTables in the *table-spec-list*.

Table names and partial pathnames are discussed under the DISPLAY statement. The DISPLAYOUT statement does not support regular expressions.

You can specify the following *options* after a slash (/):

INCLUDEALL
creates output tables for all display tables. The name of the created output table is the same as the name of the corresponding display table. If you specify this option, the *table-spec-list* specification is ignored.

NOREPLACE
does not replace any existing output table of the same name.

REPEATED
replicates all output tables on all nodes.

FREQ Statement

FREQ *variable* **;**

The *variable* in the FREQ statement identifies a numeric variable in the input data table that contains the frequency of occurrence of each observation. PROC CORRELATION treats each observation as if it appears f times, where f is the value of the FREQ *variable* for the observation. If f is not an integer, it is truncated to an integer. If f is less than 1 or missing, the observation is not used in the analysis. When you omit the FREQ statement, each observation is assigned a frequency of 1.

The effects of the FREQ and WEIGHT statements are similar except when n is not an integer and when degrees of freedom are calculated.

VAR Statement

VAR *variables* **;**

The VAR statement lists *variables* for which to compute correlation coefficients. If the VAR statement is not specified, PROC CORRELATION computes correlations for all numeric variables that are not listed in other statements.

WEIGHT Statement

WEIGHT *variable* **;**

The *variable* in the WEIGHT statement is used in the calculation of Pearson weighted product-moment correlations.

Observations that have missing weights are excluded from the analysis. By default, for observations that have nonpositive weights, weights are set to 0 and the observations are included in the analysis. You can use the EXCLNPWGT option to exclude observations that have negative or zero weights from the analysis. If a WEIGHT statement is not included, all observations that are used in the analysis are assigned a weight of 1.

WITH Statement

WITH *variables* **;**

The WITH statement lists *variables* for which to compute correlation coefficients. The WITH statement requests correlations of the form $r(X_i, Y_j)$, where $Y_1, \ldots, Y_n$ are the row analysis variables that are specified in the WITH statement and $X_1, \ldots, X_m$ are the column analysis variables that are specified in the VAR statement; or, if there is no VAR statement, all numeric variables that are not specified in any other statement. The correlation matrix has a rectangular structure of the form

$$\begin{bmatrix} r(Y_1, X_1) & \cdots & r(Y_1, X_m) \\ \vdots & \ddots & \vdots \\ r(Y_n, X_1) & \cdots & r(Y_n, X_m) \end{bmatrix}$$

For example, the statements

```
proc correlation data=mylib.data;
   var x1 x2;
   with y1 y2 y3;
run;
```

produce correlations for the following combinations:

$$\begin{bmatrix} r(Y1, X1) & r(Y1, X2) \\ r(Y2, X1) & r(Y2, X2) \\ r(Y3, X1) & r(Y3, X2) \end{bmatrix}$$

Details: CORRELATION Procedure

Pearson Product-Moment Correlation

The Pearson product-moment correlation is a parametric measure of association for two variables. It measures both the strength and the direction of a linear relationship. If one variable X is an exact linear function of another variable Y, a positive relationship exists if the correlation is 1, and a negative relationship exists if the correlation is –1. If there is no linear predictability between the two variables, the correlation is 0. If the two variables are normal with correlation 0, the two variables are independent. Correlation does not imply causality because an underlying causal relationship might not exist in some cases.

The formula for the population Pearson product-moment correlation, denoted ρ_{xy}, is

$$\rho_{xy} = \frac{\mathrm{Cov}(x, y)}{\sqrt{\mathrm{V}(x)\mathrm{V}(y)}} = \frac{\mathrm{E}(\,(x - \mathrm{E}(x))(y - \mathrm{E}(y))\,)}{\sqrt{\mathrm{E}(x - \mathrm{E}(x))^2\,\mathrm{E}(y - \mathrm{E}(y))^2}}$$

The sample correlation, such as a Pearson product-moment correlation or weighted product-moment correlation, estimates the population correlation. The formula for the sample Pearson product-moment correlation is

as follows, where $\bar{x}$ is the sample mean of x and $\bar{y}$ is the sample mean of y:

$$r_{xy} = \frac{\sum_i ((x_i - \bar{x})(y_i - \bar{y}))}{\sqrt{\sum_i (x_i - \bar{x})^2 \sum_i (y_i - \bar{y})^2}}$$

The formula for a weighted Pearson product-moment correlation is as follows, where w_i is the weight, $\bar{x}_w$ is the weighted mean of x, and $\bar{y}_w$ is the weighted mean of y:

$$r_{xy} = \frac{\sum_i w_i (x_i - \bar{x}_w)(y_i - \bar{y}_w)}{\sqrt{\sum_i w_i (x_i - \bar{x}_w)^2 \sum_i w_i (y_i - \bar{y}_w)^2}}$$

Probability Values

Probability values for the Pearson correlation are computed by treating the following equation as if it came from a t distribution with $(n - 2)$ degrees of freedom, where r is the sample correlation:

$$t = (n-2)^{1/2} \left(\frac{r^2}{1 - r^2} \right)^{1/2}$$

Cronbach's Coefficient Alpha

Analyzing latent constructs such as job satisfaction, motor ability, sensory recognition, or customer satisfaction requires instruments to accurately measure the constructs. Interrelated items can be summed to obtain an overall score for each participant. Cronbach's coefficient alpha estimates the reliability of this type of scale by determining the internal consistency of the test or the average correlation of items within the test (Cronbach 1951).

When a value is recorded, the observed value contains some degree of measurement error. Two sets of measurements on the same variable for the same individual might not have identical values. However, repeated measurements for a series of individuals do show some consistency. Reliability measures internal consistency from one set of measurements to another. The observed value Y is divided into two components, a true value T and a measurement error E. The measurement error is assumed to be independent of the true value:

$$Y = T + E \quad \mathrm{Cov}(T, E) = 0$$

The reliability coefficient of a measurement test is defined as the squared correlation between the observed value Y and the true value T:

$$r^2(Y, T) = \frac{\mathrm{Cov}(Y, T)^2}{\mathrm{V}(Y)\mathrm{V}(T)} = \frac{\mathrm{V}(T)^2}{\mathrm{V}(Y)\mathrm{V}(T)} = \frac{\mathrm{V}(T)}{\mathrm{V}(Y)}$$

This coefficient is the proportion of the observed variance due to true differences among individuals in the sample. If Y is the sum of several observed variables that measure the same feature, you can estimate $V(T)$. Cronbach's coefficient alpha, which is based on a lower bound for $V(T)$, is an estimate of the reliability coefficient.

Suppose p variables are used with $Y_j = T_j + E_j$ for $j = 1, 2, \ldots, p$, where Y_j is the observed value, T_j is the true value, and E_j is the measurement error. The measurement errors (E_j) are independent of the true

values (T_j) and are also independent of each other. Let $Y_0 = \sum_j Y_j$ be the total observed score, and let $T_0 = \sum_j T_j$ be the total true score. Because

$$(p-1)\sum_j V(T_j) \geq \sum_{i \neq j} \mathrm{Cov}(T_i, T_j)$$

a lower bound for $V(T_0)$ is given by

$$\frac{p}{p-1}\sum_{i \neq j} \mathrm{Cov}(T_i, T_j)$$

With $\mathrm{Cov}(Y_i, Y_j) = \mathrm{Cov}(T_i, T_j)$ for $i \neq j$, a lower bound for the reliability coefficient, $V(T_0)/V(Y_0)$, is then given by Cronbach's coefficient alpha:

$$\alpha = \left(\frac{p}{p-1}\right)\frac{\sum_{i \neq j} \mathrm{Cov}(Y_i, Y_j)}{V(Y_0)} = \left(\frac{p}{p-1}\right)\left(1 - \frac{\sum_j V(Y_j)}{V(Y_0)}\right)$$

If the variances of the items vary widely, you can standardize the items to a standard deviation of 1 before computing the coefficient alpha. If the variables are dichotomous (0,1), the coefficient alpha is equivalent to the Kuder-Richardson 20 (KR-20) reliability measure.

When the correlation between each pair of variables is 1, the coefficient alpha has a maximum value of 1. With negative correlations between some variables, the coefficient alpha can have a value less than 0. The larger the overall alpha coefficient, the more likely that items contribute to a reliable scale. Nunnally and Bernstein (1994) suggest 0.70 as an acceptable reliability coefficient; smaller reliability coefficients are seen as inadequate. However, acceptability varies by discipline.

To determine how each item reflects the reliability of the scale, you calculate a coefficient alpha after deleting each variable independently from the scale. Cronbach's coefficient alpha from all variables except the *k*th variable is given by

$$\alpha_k = \left(\frac{p-1}{p-2}\right)\left(1 - \frac{\sum_{i \neq k} V(Y_i)}{V(\sum_{i \neq k} Y_i)}\right)$$

If the reliability coefficient increases after an item is deleted from the scale, you can assume that the item is not highly correlated with other items in the scale. Conversely, if the reliability coefficient decreases, you can assume that the item is highly correlated with other items in the scale. For more information about how to interpret Cronbach's coefficient alpha, see Yu (2001).

Listwise deletion of observations that have missing values is necessary to correctly calculate Cronbach's coefficient alpha. PROC CORRELATION does not automatically use listwise deletion if you specify the ALPHA option. Therefore, you should use the NOMISS option if the data table contains missing values. Otherwise, PROC CORRELATION prints a warning message that indicates that you need to use the NOMISS option with the ALPHA option.

Missing Values

Observations that have missing values for the variables in the FREQ or WEIGHT statement are omitted from the analysis.

By default, PROC CORRELATION uses *pairwise deletion* when observations contain missing values in the analysis variables for which correlation coefficients are computed. PROC CORRELATION includes all nonmissing pairs of values for each pair of variables in the statistical computations. Therefore, the correlation statistics might be based on different numbers of observations.

If you specify the NOMISS option, PROC CORRELATION uses *listwise deletion* and excludes all observations that have missing values from the analysis. Therefore, the number of observations for each pair of variables is identical.

OUTP= Data Table

If you specify the OUTP= option, PROC CORRELATION creates an output data table that contains statistics for Pearson correlation.

The new data table contains the following variables:

- BY variables, if any
- _TYPE_ variable, which identifies the type of observation
- _NAME_ variable, which identifies the variable that corresponds to a particular row of the correlation matrix
- INTERCEPT variable, which identifies variable sums when the SSCP option is specified
- the column analysis variables that are specified in the VAR statement or, if there is no VAR statement, all numeric variables that are not specified in any other statement

You can use a combination of the _TYPE_ and _NAME_ variables to identify the contents of an observation. The _NAME_ variable indicates which row of the correlation matrix the observation corresponds to. The values of the _TYPE_ variable are as follows:

- SSCP, uncorrected sums of squares and crossproducts
- CSSCP, corrected sums of squares and crossproducts
- COV, covariances
- MEAN, mean of each variable
- STD, standard deviation of each variable
- N, number of nonmissing observations for each variable
- SUMWGT, sum of the weights for each variable when a WEIGHT statement is specified

- CORR, correlation statistics for each variable

If you specify the SSCP option, the OUTP= data table includes an additional observation that contains intercept values. If you specify the ALPHA option, the OUTP= data table also includes observations that have the following _TYPE_ values:

- RAWALPHA, Cronbach's coefficient alpha for raw variables
- STDALPHA, Cronbach's coefficient alpha for standardized variables
- RAWALDEL, Cronbach's coefficient alpha for raw variables after deleting one variable
- STDALDEL, Cronbach's coefficient alpha for standardized variables after deleting one variable
- RAWCTDEL, the correlation between a raw variable and the total of the remaining raw variables
- STDCTDEL, the correlation between a standardized variable and the total of the remaining standardized variables

The output data table does not have a special type like the OUTP= data table that PROC CORR creates. Therefore, if the OUTP= output data table that PROC CORRELATION creates is provided as input to a SAS/STAT procedure that recognizes special data table types (such as the REG and FACTOR procedures), the input type must also be specified. For example, the following statements produce an output data table mylib.outdata:

```
proc correlation data=mylib.data outp=mylib.outdata;
run;

proc factor data=mylib.outdata(Type=CORR);
run;
```

The mylib.outdata data table is then provided to PROC FACTOR as input with the **(Type=CORR)** option to indicate that the input data table contains a correlation matrix. This might save computational time when the initial data table mylib.data is large and the computation of the correlation matrix can be done using multiple threads.

ODS Table Names

PROC CORRELATION assigns a name to each table it creates. You must use these names to refer to tables when you use the DISPLAY statement, the DISPLAYOUT, or the Output Delivery System (ODS). These names are listed in Table 9.4.

Table 9.4 ODS Tables Produced by PROC CORRELATION

ODS Table Name	Description	Option
Cov	Covariances	COV
CronbachAlpha	Coefficient alpha	ALPHA
CronbachAlphaDel	Coefficient alpha with deleted variable	ALPHA
Csscp	Corrected sums of squares and crossproducts	CSSCP
PearsonCorr	Pearson correlations	Default output
SimpleStats	Simple descriptive statistics	Default output
Sscp	Sums of squares and crossproducts	SSCP
VarInformation	Variable information	Default output

Examples: CORRELATION Procedure

The examples in this chapter are available in the GitHub repository located at `https://github.com/sascommunities/doc-supplement-casstat`.

NOTE: Input data must be in a CAS table that is accessible in your CAS session. You must refer to this table by using a two-level name. The first level must be a CAS engine libref, and the second level must be the table name. For more information, see the sections "Using CAS Sessions and CAS Engine Librefs" on page 7 and "Loading a SAS Data Set onto a CAS Server" on page 7 in Chapter 2, "Shared Concepts."

Example 9.1: Computing Correlations between Two Sets of Variables

(View the complete code for this example (cascorrex1.sas) in the example repository.)

The following statements create the data table Setosa, which contains measurements for four iris parts from Fisher's iris data (1936): sepal length, sepal width, petal length, and petal width. The data table has been altered to contain some missing values.

```
*------------------- Data on Iris Setosa --------------------*
| The data table contains 50 iris specimens from the species |
| Iris Setosa with the following four measurements:          |
| SepalLength (sepal length)                                 |
| SepalWidth  (sepal width)                                  |
| PetalLength (petal length)                                 |
| PetalWidth  (petal width)                                  |
| Certain values were changed to missing for the analysis.   |
*------------------------------------------------------------*;
data mylib.Setosa;
  input SepalLength SepalWidth PetalLength PetalWidth @@;
  label sepallength='Sepal Length in mm.'
        sepalwidth='Sepal Width in mm.'
        petallength='Petal Length in mm.'
        petalwidth='Petal Width in mm.';
```

```

```

The following statements request a correlation analysis between two sets of variables, the sepal measurements (length and width) and the petal measurements (length and width):

```
title 'Fisher (1936) Iris Setosa Data';
proc correlation data=mylib.Setosa sscp cov;
   var  sepallength sepalwidth;
   with petallength petalwidth;
run;
```

The "Simple Statistics" table in Output 9.1.1 displays univariate statistics for the analysis variables that are specified in the VAR and WITH statements.

Output 9.1.1 Simple Statistics

Fisher (1936) Iris Setosa Data

The CORRELATION Procedure

Simple Statistics

Variable	N	Mean	Std Dev	Sum	Minimum	Maximum	Label
PetalLength	49	14.71429	1.62019	721.00000	11.00000	19.00000	Petal Length in mm.
PetalWidth	48	2.52083	1.03121	121.00000	1.00000	6.00000	Petal Width in mm.
SepalLength	50	50.06000	3.52490	2503	43.00000	58.00000	Sepal Length in mm.
SepalWidth	50	34.28000	3.79064	1714	23.00000	44.00000	Sepal Width in mm.

When the WITH statement is specified together with the VAR statement, the CORRELATION procedure produces rectangular matrices for statistics such as covariances and correlations. The matrix rows correspond to the variables specified in the WITH statement (PetalLength and PetalWidth), and the matrix columns correspond to the variables specified in the VAR statement (SepalLength and SepalWidth). The CORRELATION procedure uses the WITH variable labels to label the matrix rows.

The SSCP option requests a table of the uncorrected sum of squares and crossproducts matrix, and the COV option requests a table of the covariance matrix.

The sum of squares and crossproducts statistics for each pair of variables are computed by using observations that have nonmissing row and column variable values. The "Sums of Squares and Crossproducts" table in Output 9.1.2 displays the crossproduct, the sum of squares for the row variable, and the sum of squares for the column variable for each pair of variables.

Output 9.1.2 Sums of Squares and Crossproducts

Sums of Squares and Crossproducts
SSCP / Row Var SS / Col Var SS

	SepalLength	SepalWidth
PetalLength	36214.0000	24756.0000
Petal Length in mm.	10735.0000	10735.0000
	123793.0000	58164.0000
PetalWidth	6113.0000	4191.0000
Petal Width in mm.	355.0000	355.0000
	121356.0000	56879.0000

The variances are computed by using observations that have nonmissing values for the analysis variables. The "Variances and Covariances" table in Output 9.1.3 displays the covariance, variance for the row variable, variance for the column variable, and associated degrees of freedom for each pair of variables.

Output 9.1.3 Variances and Covariances

Variances and Covariances
Covariance / Row Var Variance / Col Var Variance / DF

	SepalLength	SepalWidth
PetalLength	1.270833	1.363095
Petal Length in mm.	2.625000	2.625000
	12.333333	14.605442
	48	48
PetalWidth	0.911348	1.048316
Petal Width in mm.	1.063387	1.063387
	11.801418	13.627216
	47	47

When there are missing values in the analysis variables, the "Pearson Correlation Coefficients" table in Output 9.1.4 displays the correlation, the p-value under the null hypothesis of zero correlation, and the number of observations for each pair of variables.

Output 9.1.4 Pearson Correlation Coefficients

Pearson Correlation Coefficients
Prob > |r| under H0: Rho=0
Number of Observations

	Sepal Length in mm.	Sepal Width in mm.
PetalLength	0.2233	0.2201
Petal Length in mm.	0.1229	0.1285
	49	49
PetalWidth	0.2573	0.2754
Petal Width in mm.	0.0775	0.0582
	48	48

Example 9.2: Computing Cronbach's Coefficient Alpha

(View the complete code for this example (correx2.sas) in the example repository.)

The following statements create the data table Fish1. The cubic root of the weight (Weight3) is computed as a one-dimensional measure of the size of a fish.

```
*------------------- Fish Measurement Data -----------------------*
| The data table contains 35 fish from the species Bream caught   |
| in Finland's Lake Laengelmavesi with the following measurements:|
| Weight   (in grams)                                             |
| Length3  (length from the nose to the end of the tail, in cm)   |
| HtPct    (max height, as percentage of Length3)                 |
| WidthPct (max width,  as percentage of Length3)                 |
*-----------------------------------------------------------------*;
data mylib.Fish1 (drop=HtPct WidthPct);
   title 'Fish Measurement Data';
   input Weight Length3 HtPct WidthPct @@;
   Weight3= Weight**(1/3);
   Height=HtPct*Length3/100;
   Width=WidthPct*Length3/100;
   datalines;

850.0 41.6 40.6 14.9    1000.0 42.6 44.5 15.5
920.0 44.1 40.9 14.3     955.0 44.0 41.1 14.3
925.0 45.3 41.4 14.9     975.0 45.9 40.6 14.7
950.0 46.5 37.9 13.7
;
```

The following statements request a correlation analysis and compute Cronbach's coefficient alpha for the variables Weight3, Length3, Height, and Width:

```
title 'Fish Measurement Data';
proc correlation data=mylib.fish1 nomiss alpha;
   var Weight3 Length3 Height Width;
run;
```

The ALPHA option computes Cronbach's coefficient alpha for the analysis variables.

The "Simple Statistics" table in Output 9.2.1 displays univariate descriptive statistics for each analysis variable.

Output 9.2.1 Simple Statistics

Fish Measurement Data

The CORRELATION Procedure

Simple Statistics

Variable	N	Mean	Std Dev	Sum	Minimum	Maximum
Weight3	34	8.44751	0.97574	287.21524	6.23168	10.00000
Length3	34	38.38529	4.21628	1305	30.00000	46.50000
Height	34	15.22057	1.98159	517.49950	11.52000	18.95700
Width	34	5.43805	0.72967	184.89370	4.02000	6.74970

The "Pearson Correlation Coefficients" table in Output 9.2.2 displays Pearson correlation statistics for pairs of analysis variables.

Output 9.2.2 Pearson Correlation Coefficients

Pearson Correlation Coefficients N = 34
Prob > |r| under H0: Rho=0

	Weight3	Length3	Height	Width
Weight3	1.0000	0.9652 <.0001	0.9626 <.0001	0.9279 <.0001
Length3	0.9652 <.0001	1.0000	0.9549 <.0001	0.9217 <.0001
Height	0.9626 <.0001	0.9549 <.0001	1.0000	0.9263 <.0001
Width	0.9279 <.0001	0.9217 <.0001	0.9263 <.0001	1.0000

Because the data table contains only one species of fish, all the variables are highly correlated. Using the ALPHA option, the CORRELATION procedure computes Cronbach's coefficient alpha in Output 9.2.3. The Cronbach's coefficient alpha is a lower bound for the reliability coefficient for the raw variables and the standardized variables. Positive correlation is needed for the alpha coefficient because variables measure a common entity.

Output 9.2.3 Cronbach's Coefficient Alpha

Cronbach Coefficient Alpha

Variables	Alpha
Raw	0.822134
Standardized	0.985145

Because the variances of some variables vary widely, you should use the standardized score to estimate reliability. The overall standardized Cronbach's coefficient alpha of 0.985145 provides an acceptable lower bound for the reliability coefficient. This is much greater than the suggested value of 0.70 given by Nunnally and Bernstein (1994).

The standardized alpha coefficient provides information about how each variable reflects the reliability of the scale with standardized variables. If the standardized alpha decreases after removing a variable from the construct, then this variable is strongly correlated with other variables in the scale. On the other hand, if the

standardized alpha increases after removing a variable from the construct, then removing this variable from the scale makes the construct more reliable. The "Cronbach Coefficient Alpha with Deleted Variables" table in Output 9.2.4 does not show a significant increase or decrease in the standardized alpha coefficients. For more information about Cronbach's alpha, see the section "Cronbach's Coefficient Alpha" on page 300.

Output 9.2.4 Cronbach's Coefficient Alpha with Deleted Variables

Cronbach Coefficient Alpha with Deleted Variable			
Raw Variables		Standardized Variables	
Correlation with Total	Alpha	Correlation with Total	Alpha
0.975379	0.783365	0.973464	0.977103
0.967602	0.881987	0.967177	0.978783
0.964715	0.655098	0.968079	0.978542
0.934635	0.824069	0.937599	0.986626

Example 9.3: Saving Correlations in an Output Data Table

(View the complete code for this example (correx3.sas) in the example repository.)

The following statements compute Pearson correlations for the Fitness data table that is created in the section "Getting Started: CORRELATION Procedure" on page 291:

```
title 'Correlations for a Fitness and Exercise Study';
proc correlation data=mylib.Fitness nomiss outp=mylib.CorrOutp;
   var weight oxygen runtime;
run;
```

The NOMISS option excludes from the analysis observations that have missing values of the variables that are specified in the VAR statement—that is, the same set of 28 observations is used to compute the correlation for each pair of variables. The OUTP= option creates an output data table named CorrOutp to contain the Pearson correlation statistics.

The "Pearson Correlation Coefficients" table in Output 9.3.1 displays the correlation and the *p*-value under the null hypothesis of zero correlation.

Output 9.3.1 Pearson Correlation Coefficients

Correlations for a Fitness and Exercise Study

The CORRELATION Procedure

Pearson Correlation Coefficients N = 28 Prob > |r| under H0: Rho=0			
	Weight	Oxygen	RunTime
Weight	1.0000	-0.1842 0.3481	0.1950 0.3199
Oxygen	-0.1842 0.3481	1.0000	-0.8684 <.0001
RunTime	0.1950 0.3199	-0.8684 <.0001	1.0000

The following statements display the output data table that is shown in Output 9.3.2:

```
title 'Output Data Table from PROC CORRELATION';
proc print data=mylib.CorrOutp noobs;
run;
```

Output 9.3.2 OUTP= Data Table with Pearson Correlations

Output Data Table from PROC CORRELATION

TYPE	_NAME_	Weight	Oxygen	RunTime
MEAN		77.2168	47.1327	10.6954
STD		8.4495	5.5535	1.4127
N		28.0000	28.0000	28.0000
CORR	Weight	1.0000	-0.1842	0.1950
CORR	Oxygen	-0.1842	1.0000	-0.8684
CORR	RunTime	0.1950	-0.8684	1.0000

The output data table can be used as an input data table for regression or other statistical procedures. For example, the following statements request a regression analysis that uses CorrOutp instead of reading the original data in the REG procedure:

```
title 'Input Type CORR Data Set from PROC REG';
proc reg data=mylib.CorrOutp(type=CORR);
   model runtime= weight oxygen;
run;
```

The following statements read the original data and generate the same results as the preceding statements:

```
proc reg data=mylib.Fitness;
   model runtime= weight oxygen;
run;
```

Overview: EFA Procedure

The EFA procedure provides analytic tools that enable you to conduct exploratory common factor analysis in SAS Viya. In the psychometric and behavioral science literature, common factor analysis is often referred to simply as factor analysis.

Common factor analysis was invented by Spearman (1904). Kim and Mueller (1978a, b) provide an elementary discussion of the common factor model. Gorsuch (1974) presents a broad survey of factor analysis, and Gorsuch (1974) and Cattell (1978) offer useful guides to practical research methodology. Harman (1976) gives a lucid discussion of many of the more technical aspects of factor analysis, especially oblique rotation. Morrison (1976) and Mardia, Kent, and Bibby (1979) provide excellent statistical treatments of common factor analysis. Mulaik (1972) provides the most thorough and authoritative general reference on factor analysis; this book is highly recommended to anyone familiar with matrix algebra. Stewart (1981) gives a nontechnical presentation of some issues to consider in deciding whether or not a factor analysis is appropriate.

For more information about the common factor model, see the section "The Common Factor Model" on page 337. For more information about the steps that are involved in exploratory factor analysis, see the section "Factor Analysis in Practice" on page 340.

PROC EFA Features

PROC EFA provides the following features:

- supports the analysis of multivariate input data
- computes and analyzes the correlation matrix for the analysis variables
- provides weighted analysis for multivariate input data
- produces output data tables that contain means, standard deviations, number of observations, and eigenvalues
- supports multiple algorithms for determining the number of factors, including Horn's parallel analysis (Horn 1965) and Velicer's minimum average partial correlation analysis (Velicer 1976)
- supports multiple algorithms for factor extraction, including principal factor extraction (iterated or noniterated), maximum likelihood estimation, and the least squares method
- supports multiple algorithms for factor rotation, including promax and the generalized Crawford-Ferguson family of rotations
- provides various methods (for example, squared multiple correlations) of specifying initial communality estimates

Because PROC EFA runs on SAS Cloud Analytic Services (CAS), it also does the following:

- enables you to run on a cluster of machines that distribute the data and the computations

- enables you to run in single-machine mode
- exploits available cores and concurrent threads

PROC EFA Compared with Other SAS Procedures

The EFA procedure provides functionality to perform exploratory common factor analysis that is comparable to that of the FACTOR procedure in SAS/STAT software.

There are two important differences between PROC EFA and PROC FACTOR. First, in PROC EFA the default prior communality estimates are always squared multiple correlations (that is, PRIORS=SMC is the default option). For PROC FACTOR, the default method of computing prior communalities depends on the factor extraction method. Second, the NFACTORS= option and the NFACTORS statement in PROC EFA enable you to compute and combine an arbitrary number of criteria to determine the number of factors to extract. In PROC FACTOR, the capabilities for exploring multiple criteria to determine the number of factors are more limited.

Additional similarities and differences are summarized in Table 10.1.

Table 10.1 Comparison of PROC EFA and PROC FACTOR

Feature	PROC EFA	PROC FACTOR
Supports multiple simultaneous methods of determining the number of factors to extract	Yes	Partially
Supports BY statement	Yes	Yes
Supports DISPLAY and DISPLAYOUT statements	Yes	No
Supports PLOTS= option	No	Yes
Input data types	Raw data only	Raw data or certain types of special SAS data sets
Threading	Yes	Mostly single-threaded
Displays reference structure for oblique rotations	REFSTRUCT option	Default
Performs factor scoring	No	Yes
Performs standard error estimation for ML	No	Yes
Performs Procrustes rotation to a fixed target	No	Yes

When you specify the PRIORS=ONES and METHOD=PRINCIPAL options in the PROC EFA statement,

the procedure performs a principal component analysis. This analysis is comparable to that performed by the PCA procedure when you specify the METHOD=EIG option.

Using CAS Sessions and CAS Engine Librefs

SAS Cloud Analytic Services (CAS) is the analytic server and associated cloud services in SAS Viya. This section describes how to create a CAS session and set up a CAS engine libref that you can use to connect to the CAS session. It assumes that you have a CAS server already available; contact your system administrator if you need help starting and terminating a server. This CAS server is identified by specifying the host on which it runs and the port on which it listens for communications. To simplify your interactions with this CAS server, the host information and port information for the server are stored as SAS option values that are retrieved automatically whenever this CAS server needs to be accessed. You can examine the host and port values for the server at your site by using the following statements:

```
proc options option=(CASHOST CASPORT);
run;
```

In addition to starting a CAS server, your system administrator might also have created a CAS session and a CAS engine libref for your use. You can define your own sessions and CAS engine librefs that connect to the CAS server as shown in the following statements:

```
cas mysess;
libname mylib cas sessref=mysess;
```

The CAS statement creates the CAS session named mysess, and the LIBNAME statement creates the mylib CAS engine libref that you use to connect to this session. It is not necessary to explicitly name the CASHOST and CASPORT of the CAS server in the CAS statement, because these values are retrieved from the corresponding SAS option values.

If you have created the mysess session, you can terminate it by using the TERMINATE option in the CAS statement as follows:

```
cas mysess terminate;
```

For more information about the CAS and LIBNAME statements, see the section “Introduction to Shared Concepts” on page 6 in Chapter 2, “Shared Concepts.”

Getting Started: EFA Procedure

(View the complete code for this example at https://github.com/sascommunities/doc-supplement-casstat/tree/main/Examples/efags.sas.)

NOTE: Input data must be in a CAS table that is accessible in your CAS session. You must refer to this table by using a two-level name. The first level must be a CAS engine libref, and the second level must be the table name. For more information, see the sections "Using CAS Sessions and CAS Engine Librefs" on page 7 and "Loading a SAS Data Set onto a CAS Server" on page 7 in Chapter 2, "Shared Concepts."

This example demonstrates how you can use the EFA procedure to perform common factor analysis and factor rotation. The example uses the jobratings data set that is described in the examples for the FACTOR procedure in SAS/STAT software. In the original data set, 103 police officers were rated by their supervisors on 14 scales (variables). The current example excludes one of these scales—the overall rating variable.

The following DATA step creates the table jobratings:

```
options validvarname=any;
data mylib.jobratings;
   input ('Communication Skills'n
      'Problem Solving'n
      'Learning Ability'n
      'Judgment under Pressure'n
      'Observational Skills'n
      'Willingness to Confront Problems'n
      'Interest in People'n
      'Interpersonal Sensitivity'n
      'Desire for Self-Improvement'n
      'Appearance'n
      'Dependability'n
      'Physical Ability'n
      'Integrity'n) (1.);
   datalines;
2683885387986
7475887685766
5675786377587
6786977798899
9999779887888
8989789988879
8999988989979
8779479846888
3565233514311

   ... more lines ...

9989989989989
7665639956748
;
```

These statements assume that your libref is named mylib, but you can substitute any appropriately defined libref.

You conduct a common factor analysis on these variables to see what latent factors are operating behind these

ratings. As part of this analysis, you want to determine the number of latent factors that are likely to explain the data.

The following statements invoke the EFA procedure:

```
proc efa data=mylib.jobratings rotate=varimax;
   nfactors type=parallel alpha=0.05 seed=1031 nsimulations=20000;
   nfactors type=parallel alpha=0.05 seed=1128 nsimulations=20000;
   nfactors type=parallel alpha=0.10 seed=1031 nsimulations=20000;
   nfactors type=parallel alpha=0.10 seed=1128 nsimulations=20000;
   nfactors type=eigenvalue threshold=0.5  status=inactive;
   nfactors type=eigenvalue threshold=1.0  status=inactive;
   nfactors type=proportion threshold=0.9  status=inactive;
   nfactors type=proportion threshold=0.95 status=inactive;
   nfactors type=map2 status=inactive;
   nfactors type=map4 status=inactive;
run;
```

In the common factor model, you always assume that observed variables are functions of underlying latent factors. (For more information about the common factor model, see the section "The Common Factor Model" on page 337.) The goal of factor analysis is to extract and interpret a factor pattern that describes these relationships. By default, PROC EFA uses the principal factor extraction method, with prior communalities set to the squared multiple correlations (SMC) of each variable with all the other variables. You can use the METHOD= option to specify a different factor extraction method. You can use the PRIORS= option to specify different prior communality estimates. To facilitate interpretations, the ROTATE= option specifies the varimax orthogonal factor rotation.

PROC EFA supports various criteria that you can use to suggest the number of factors to extract. You use the NFACTORS statement to specify a criterion. You can use multiple NFACTORS statements to specify multiple criteria. In this example, you determine the number of factors to extract by using multiple parallel analyses, each with 20,000 simulations. You include two different thresholds for the parallel analyses and two different random number seeds. By default, the actual number of factors that are extracted is the minimum of the numbers that are suggested by the four parallel analyses. You can use the NFACTORS=*method* option to change this default behavior, where *method* is MIN, MAX, MEDIAN, or MEAN.

In this example, you specify multiple additional NFACTORS statements, all of which include the STATUS=INACTIVE option. When a criterion has an inactive status, it is computed and the results are displayed, but it is not used to determine the final number of factors that are extracted. This can be useful for investigating the robustness of the number of extracted factors to alternative criteria. The minimum eigenvalue criterion (TYPE=EIGENVALUE) computes the number of factors to extract by comparing the eigenvalues of the reduced correlation matrix to a threshold value. The proportion of common variance criterion (TYPE=PROPORTION) computes the number of factors to extract by determining the smallest number of factors such that the cumulative proportion of common variance explained exceeds a threshold value. The minimum average partial correlation analyses (TYPE=MAP2 and MAP4) compute the number of factors by determining the number of principal components that, when partialed out, results in the smallest average squared partial (or residual) correlations.

If you know the exact number of factors that you want to extract in an analysis, you can omit the NFACTORS statement and specify the NFACTORS=*n* option in the PROC EFA statement, where *n* is the number of factors that you want to extract.

The output from the factor analysis is displayed in Figure 10.1 through Figure 10.11.

The first outputs that PROC EFA produces are the "Model Information" table and a table that summarizes the number of observations in the input data table. These are shown in Figure 10.1. Together, these tables summarize important information about the input data that are analyzed as well as the primary analysis options that you specified. For this analysis, the numbers of observations that are used is the same as the number that are read. These numbers would be different if some observations were discarded from the analysis. PROC EFA uses only complete cases for analysis, so a record is discarded if any field contains a missing value.

Figure 10.1 Model Information and Number of Observations

Model Information	
Data Source	JOBRATINGS
Data Type	Raw
Prior Communalities	Squared Multiple Correlations
Factor Extraction	Principal Factor Method
Factor Rotation	Varimax

Number of Observations Read	103
Number of Observations Used	103

Next, the "Simple Statistics" table in Figure 10.2 summarizes the means and standard deviations of the analysis variables.

Figure 10.2 Simple Statistics

Simple Statistics		
Variable	**Mean**	**Standard Deviation**
Communication Skills	6.65049	1.76407
Problem Solving	6.63107	1.59035
Learning Ability	6.99029	1.33941
Judgment under Pressure	6.73786	1.73183

Willingness to Confront Problems	7.29126	1.52516
Interest in People	6.70874	1.89235
Interpersonal Sensitivity	6.62136	1.76077
Desire for Self-Improvement	6.57282	1.72980
Appearance	7.00000	1.79869
Dependability	6.82524	1.91704
Physical Ability	7.20388	1.55525
Integrity	7.21359	1.84524

The summary output for the determination of the number of factors is shown in Figure 10.3. For most of the specified criteria, the results suggest that two latent factors should be retained to explain the data. The minimum eigenvalue criterion, with a threshold of 0.50, and the cumulative proportion criterion, with a threshold of 0.95, suggest the existence of a third latent factor. All four parallel analysis criteria suggest two latent factors, so the final number of latent factors that the analysis suggests is two.

Figure 10.3 Number of Factors

Determination of Number of Factors		
Criterion	**Description**	**Factors**
1	Parallel Analysis (Alpha = 0.05, Seed = 1031, Sims = 20000)	2
2	Parallel Analysis (Alpha = 0.05, Seed = 1128, Sims = 20000)	2
3	Parallel Analysis (Alpha = 0.10, Seed = 1031, Sims = 20000)	2
4	Parallel Analysis (Alpha = 0.10, Seed = 1128, Sims = 20000)	2
5	Minimum Eigenvalue (Eigenvalue > 0.50)	3
6	Minimum Eigenvalue (Eigenvalue > 1.00)	2
7	Total Proportion (Threshold = 0.90)	2
8	Total Proportion (Threshold = 0.95)	3
9	Min Ave Squared Partial Corr (MAP2)	2
10	Min Ave 4th-powered Partial Corr (MAP4)	2
Min = 2, Max = 2, Mean = 2, Median = 2		

Additional information about the minimum eigenvalue and cumulative proportion criteria is presented in the "Eigenvalues of the Reduced Correlation Matrix" table in Figure 10.4. After the data correlation matrix is reduced by replacing its diagonal elements with the SMC prior communality estimates, the largest eigenvalue of the resulting matrix is approximately 6.18, and the corresponding latent factor explains approximately 77% of the common variance of the input data. The second eigenvalue is approximately 1.46, and the latent factors that correspond to these first two eigenvalues explain almost 95% of the common variance. A third eigenvalue has a value of approximately 0.56, and the latent factors that correspond to these three eigenvalues explain more than 100% of the common variance. Thus, two latent factors are sufficient to explain up to 90% of the common variance in the input data, and a third factor is needed to explain more than 95% of the common variance. Similarly, a minimum eigenvalue threshold of 1.00 produces an estimate of two latent factors, whereas a third latent factor is estimated if the minimum eigenvalue threshold is 0.50. (The fourth-largest eigenvalue for the reduced correlation matrix has a value of approximately 0.28.)

Figure 10.4 Eigenvalues and Common Variance Explained

Eigenvalues of the Reduced Correlation Matrix				
	Eigenvalue	**Difference**	**Proportion**	**Cumulative**
1	6.177605	4.715319	0.7660	0.7660

12	-0.148291	0.058236	-0.0184	1.0256
13	-0.206527		-0.0256	1.0000

The parallel analysis results are summarized in the tables in Figure 10.5. For each of the four specified parallel analysis criteria, correlation matrices are simulated from a Wishart distribution. These simulations

represent correlation matrices that might be realized for a data-generating process in which all variables are independently and identically distributed according to the standard normal distribution. The eigenvalues of the simulated correlation matrices are computed and rank-ordered, and the eigenvalues of the input data correlation matrix are compared to the distributions of the eigenvalues at each position (largest eigenvalue, second-largest eigenvalue, and so on). When an eigenvalue of the input data correlation matrix exceeds the eigenvalue at some critical point (for example, the 95th percentile), this is understood to indicate the presence of a latent factor in the data. In all four parallel analyses in this example, the largest and second-largest eigenvalues of the input data correlation matrix exceed the simulated critical values. Thus all four parallel analyses suggest that two latent factors should be retained.

The minimum average partial correlation analysis (MAP) results are summarized in the "Average Partial Correlations Controlling Principal Components" table in Figure 10.6. In this example, analyses are performed that use both squared (MAP2) and fourth-powered (MAP4) partial correlations. These two analyses are summarized in separate columns in the table. The number of latent factors that are estimated by a minimum average partial correlation analysis is the number of principal components that, when partialed out of the correlation matrix, produce the smallest average squared or fourth-powered partial correlations. As shown in Figure 10.6, the minimum value is obtained for both the MAP2 and the MAP4 analysis when two principal components are partialed out.

Now that the number of factors is determined, it is time to extract and rotate a factor pattern that corresponds to a two-factor solution. For this analysis, the prior communality estimates are set to the squared multiple correlations. These are shown in Figure 10.7.

Figure 10.7 Prior Communalities

Prior Communality Estimates							
Communication Skills	**Problem Solving**	**Learning Ability**	**Judgment under Pressure**	**Observational Skills**	**Willingness to Confront Problems**	**Interest in People**	**Interpersonal Sensitivity**
0.62981394	0.58657431	0.61009871	0.63766021	0.67187583	0.64779805	0.75641519	0.75584891

0.57460176	0.45505304	0.63449045	0.42245324	0.68195454

Figure 10.8 displays the initial factor pattern matrix. The factor pattern matrix represents standardized regression coefficients for predicting the variables by using the extracted factors. Because the initial factors are uncorrelated, the pattern matrix is also equal to the correlations between variables and the common factors.

The pattern matrix suggests that Factor1 represents general ability. All loadings for Factor1 in the Factor Pattern are at least 0.5. Factor2 consists of high positive loadings on certain task-related skills (Willingness to Confront Problems, Observational Skills, and Learning Ability) and high negative loadings on some interpersonal skills (Interpersonal Sensitivity, Interest in People, and Integrity). This factor measures individuals' relative strength in these skills. Theoretically, individuals with high positive scores on this factor would exhibit better task-related skills than interpersonal skills. Individuals with high negative scores would exhibit better interpersonal skills than task-related skills. Individuals with scores near zero would have those skills balanced.

Figure 10.8 Initial Factor Pattern

Factor Pattern		
	Factor1	Factor2
Communication Skills	0.75441	0.07707

Willingness to Confront Problems	0.66458	0.47460
Interest in People	0.70770	-0.53427
Interpersonal Sensitivity	0.64668	-0.61284
Desire for Self-Improvement	0.73820	0.12506
Appearance	0.57188	0.20052
Dependability	0.79475	-0.04516
Physical Ability	0.51285	0.10251
Integrity	0.74906	-0.35091

Figure 10.9 displays the proportion of variance explained by each factor and the final communality estimates, including the total communality. The final communality estimates are the proportion of variance of the variables accounted for by the common factors. When the factors are orthogonal, the final communalities are calculated by taking the sum of squares of each row of the factor pattern matrix.

Figure 10.9 Initial Solution: Variance Explained and Final Communality Estimates

Variance Explained by Each Factor	
Factor1	Factor2
6.1776055	1.4622860

Final Communality Estimates: Total = 7.639892							
Communication Skills	Problem Solving	Learning Ability	Judgment under Pressure	Observational Skills	Willingness to Confront Problems	Interest in People	Interpersonal Sensitivity
0.57507775	0.47690128	0.55548854	0.58444301	0.68176986	0.66690409	0.78628588	0.79376521

Desire for Self-Improvement	Appearance	Dependability	Physical Ability	Integrity
0.56057957	0.36724994	0.63367286	0.27352712	0.68422640

Figure 10.10 displays the results of the varimax rotation of the two extracted factors and the corresponding orthogonal transformation matrix. The rotated factor pattern matrix is calculated by postmultiplying the original factor pattern matrix by the transformation matrix.

The rotated factor pattern matrix is somewhat easier to interpret. If a magnitude of at least 0.5 is required to indicate a salient variable-factor relationship, Factor1 now measures job enthusiasm and cognitive skills (Observational Skills, Willingness to Confront Problems, Learning Ability, Desire for Self-Improvement, Communication Skills, Problem Solving, Dependability, and Appearance) and Factor2 represents interpersonal skills (Interpersonal Sensitivity, Interest in People, Integrity, Judgment under Pressure, and Dependability).

Figure 10.10 Transformation Matrix and Rotated Factor Pattern

Orthogonal Transformation Matrix		
	1	**2**
1	0.75128	0.65999
2	0.65999	-0.75128

Rotated Factor Pattern		
	Factor1	**Factor2**
Communication Skills	0.61764	0.44000
Problem Solving	0.56827	0.39239
Learning Ability	0.72485	0.17346
Judgment under Pressure	0.41009	0.64519
Observational Skills	0.81759	0.11538
Willingness to Confront Problems	0.81251	0.08206
Interest in People	0.17906	0.86846
Interpersonal Sensitivity	0.08137	0.88721
Desire for Self-Improvement	0.63713	0.39325
Appearance	0.56198	0.22679
Dependability	0.56727	0.55846
Physical Ability	0.45295	0.26147
Integrity	0.33116	0.75800

To make the rotated factor pattern matrix even easier to interpret, you can use the REORDER option to rearrange the rows of the factor pattern. When you specify the REORDER option, variables whose highest absolute loading (reference structure loading for oblique rotations) is on the first factor are displayed first, from largest to smallest loading, followed by variables whose highest absolute loading is on the second factor, and so on. For an example of how to use the REORDER option, see "Example 10.2: Principal Factor Analysis" on page 355. You can also specify the FUZZ=0.5 option, which causes all the entries of the factor pattern smaller than 0.5 in absolute value to be printed as missing. For an example of how to use the FUZZ= option, see "Example 10.4: Extracting and Interpreting Solutions with Maximum Likelihood Factor Analysis" on page 366.

Figure 10.11 displays the variance explained by each factor and the final communality estimates after the orthogonal rotation. Even though the variances explained by the rotated factors are different from those of the unrotated factors (compare to Figure 10.9), the cumulative variance explained by the common factors remains the same. Note also that the final communalities for variables, as well as the total communality, remain unchanged after rotation. Although rotating a factor solution does not increase or decrease the statistical quality of the factor model, it can simplify the interpretations of the factors and redistribute the variance explained by the factors.

Figure 10.11 Rotated Solution: Variance Explained and Final Communality Estimates

Syntax: EFA Procedure

The following statements are available in the EFA procedure:

PROC EFA < *options* > ;
NFACTORS TYPE=*name* < *options* > ;
PRIORS *communalities* ;
VAR *variables* ;
FREQ *variable* ;
WEIGHT *variable* ;
BY *variables* ;
DISPLAY < *table-list* > < */options* > ;
DISPLAYOUT *table-spec-list* < */options* > ;

The PROC EFA statement is required. You can specify multiple NFACTORS statements. The following sections describe the PROC EFA statement and then describe the other statements in alphabetical order.

PROC EFA Statement

PROC EFA < *options* > ;

The PROC EFA statement invokes the procedure. Table 10.2 summarizes the available options in this statement. The options are described fully after the table.

Table 10.2 Options Available in the PROC EFA Statement

Option	Description
Data Set Option	
DATA=	Specifies the input data table
Factor Extraction and Communalities	
HEYWOOD	Sets to 1 any communality greater than 1
METHOD=	Specifies the estimation method
NFACTORS=	Specifies how to determine the number of factors

Table 10.2 *continued*

Option	Description
PRIORS=	Specifies the method of computing prior communality estimates
SEED=	Specifies the seed for pseudorandom number generation
ULTRAHEYWOOD	Allows communalities to exceed 1
Data Analysis	
NOBS=	Specifies the number of observations
VARDEF=	Specifies the divisor to use in calculating covariances or correlations
Rotation Method and Properties	
GAMMA=	Specifies the orthomax weight
NOPROMAXNORM	Turns off row normalization in promax rotation
NORM=	Specifies the row normalization method in rotation
POWER=	Specifies the power to be used in promax rotation
PREROTATE=	Specifies the prerotation method in promax rotation
RCONVERGE=	Specifies the convergence criterion for rotation cycles
RITER=	Specifies the maximum number of cycles for rotation
ROTATE=	Specifies the rotation method
TAU=	Specifies the oblimin weight
Control Display Output	
FUZZ=	Specifies the maximum absolute value to display as missing in the correlation and loading matrices
REFSTRUCT	Prints the reference structure and reference axis correlations
REORDER	Reorders the rows (variables) of various factor matrices
Numerical Properties	
CONVERGE=	Specifies the convergence criterion
MAXITER=	Specifies the maximum number of iterations
NTHREADS=	Specifies the maximum number of simultaneous computational threads to use
SINGULAR=	Specifies the singularity criterion

CONVERGE=*p*

CONV=*p*

specifies the convergence criterion for the METHOD=ALPHA, METHOD=ML, METHOD=PRINIT, or METHOD=ULS option. Iteration stops when the maximum change in the communalities is less than the value of the CONVERGE= option. By default, CONVERGE=0.001. Negative values are not allowed.

DATA=*libref.data-table*

names the input data table for PROC EFA to use. The default is the most recently created data table. *libref.data-table* is a two-level name, where

libref refers to a collection of information that is defined in the LIBNAME statement and includes the library, which includes a path to the data, and a session identifier, which defaults to the active session but which can be explicitly defined in the LIBNAME statement. For more information about *libref*, see the section "Using CAS Sessions and CAS Engine Librefs" on page 314.

data-table specifies the name of the input data table.

FUZZ=*p*

specifies how certain correlation and factor loading values are printed. When you specify this option, PROC EFA prints elements whose absolute values are less than *p* as missing. The exact values in any matrix can be obtained from the ODS output data sets. Negative values are not allowed.

GAMMA=*p*

specifies the orthomax weight to be used together with the option ROTATE=ORTHOMAX or PREROTATE=ORTHOMAX. Alternatively, you can specify ROTATE=ORTHOMAX(*p*), where *p* represents the orthomax weight. If you specify both GAMMA=*p* and ROTATE=ORTHOMAX(*p*), the ROTATE= option value takes precedence.

There is no restriction on valid values for the orthomax weight, although the most common values are between 0 and the number of variables. By default, GAMMA=1, which results in the varimax rotation. For more information, see the section "Simplicity Functions" on page 347.

HEYWOOD

HEY

sets to 1 any communality greater than 1, allowing iterations to proceed. See the section "Heywood Cases and Other Anomalies of Communality Estimates" on page 344 for a discussion of Heywood cases. This option has no effect if you specify METHOD=PRINCIPAL.

MAXITER=*n*

specifies the maximum number of iterations for factor extraction. You can use the MAXITER= option with the ALPHA, ML, PRINIT, or ULS method. By default, MAXITER=30.

METHOD=*name*

M=*name*

specifies the method of extracting factors. You can specify the following *names*:

ALPHA | A produces alpha factor analysis.

ML | M performs maximum likelihood factor analysis by using an algorithm due, except for minor details, to Fuller (1987). This option requires a nonsingular correlation matrix.

NONE specifies that factor extraction should not be performed. This is useful if you want to use one or more NFACTORS statements to investigate the number of latent factors that should be used to describe the data, but you do not want to extract those factors. You cannot specify this option if you use the NFACTORS=*n* option to specify that *n* factors should be extracted.

PRINCIPAL | PRIN | P performs a principal factor analysis unless you also specify PRIORS=ONE, in which case a principal component analysis is performed.

PRINIT performs an iterated principal factor analysis.

ULS | U performs an unweighted least squares factor analysis.

By default, METHOD=PRINCIPAL.

NFACTORS=*n* | *method*

NFACT=*n* | *method*

N=*n* | *method*

specifies how to determine the number of factors. If you specify a numeric value *n*, then *n* is a positive integer that represents the number of factors to be extracted. Alternatively, you can specify a *method* that is used to determine the number of factors. You can specify the following *methods*:

MAX sets the number of factors to the maximum number that is suggested by the criteria that you specify in the NFACTORS statements.

MEAN sets the number of factors to the mean of the numbers suggested by the criteria that you specify in the NFACTORS statements. If the computed mean is not an integer, the value is rounded to the nearest integer.

MEDIAN sets the number of factors to the median of the numbers suggested by the criteria that you specify in the NFACTORS statements. If the computed median is not an integer, the value is rounded to the nearest integer.

MIN sets the number of factors to the minimum number that is suggested by the criteria that you specify in the NFACTORS statements.

With PROC EFA, you can use one or more NFACTORS statements to specify criteria that are used to suggest numbers of factors to extract. You use the NFACTORS=*method* option in the PROC EFA statement to determine how to combine the numbers from these criteria to produce the final number of factors to extract. Any criteria for which you specify the STATUS=INACTIVE option in the PROC EFA statement are excluded from the calculation.

You must specify either the NFACTORS=*n* option or at least one NFACTORS statement. If you specify multiple NFACTORS statements but not the NFACTORS=*method* option, PROC EFA uses NFACTORS=MIN by default. If you specify both NFACTORS=*n* and one or more NFACTORS statements, the results for the NFACTORS statements are computed and displayed, but *n* factors are extracted.

NOBS=*n*

specifies the number of observations to use when computing significance tests. If the DATA= input data set is a raw data set, this number is defined by default to be the number of observations in the raw data set that are used for the analysis. The NOBS= option overrides this default definition. This option has no effect unless you specify METHOD=ML.

NOPROMAXNORM

NOPMAXNORM

turns off the default row normalization of the prerotated factor pattern, which is used to compute the promax target matrix.

NORM=*method*

specifies the method of normalizing the rows of the factor pattern for rotation. You can specify the following *methods*:

COV rescales the rows of the pattern matrix to represent covariances rather than correlations.

KAISER uses Kaiser's normalization. This means that the rows of the factor pattern matrix are normalized so that the sum of squares of each row is 1 ($\sum_j p_{ij}^2 = 1$).

NONE | RAW turns off row normalization.

WEIGHT weights the rows by the Cureton-Mulaik technique (Cureton and Mulaik 1975).

By default, NORM=KAISER.

NTHREADS=*n*

THREADS=*n*

specifies the number of threads to use in the computation, where *n* is an integer between 1 and 64, inclusive. The default value is the number of CPUs available in the machine.

POWER=*n*

specifies the power to use in computing the target pattern for the option ROTATE=PROMAX. Alternatively, you can specify ROTATE=PROMAX(*p*), where *p* represents the power. If you specify both POWER=*n* and ROTATE=PROMAX(*p*), the ROTATE= option value takes precedence.

Valid values must be integers greater than or equal to 1. By default, POWER=3.

PREROTATE=*name*

PRE=*name*

specifies the prerotation method for the option ROTATE=PROMAX. You can use any rotation method other than promax. See the ROTATE= option for a list of available methods.

By default, PREROTATE=VARIMAX.

PRIORS=*name*

specifies a method of computing prior communality estimates. You can specify the following *names*:

ASMC | A sets the prior communality estimates proportional to the squared multiple correlations but adjusted so their sum is equal to that of the maximum absolute correlations (Cureton 1968).

INPUT | I sets the prior communality estimates to the values that you specify in the PRIORS statement.

MAX | M sets the prior communality estimate for each variable to its maximum absolute correlation with any other variable.

ONE | O sets all prior communalities to 1.

RANDOM | R sets the prior communality estimates to pseudorandom numbers uniformly distributed between 0 and 1. You can use the SEED= option to specify the random number seed to use so that the analysis is repeatable.

SMC | S sets the prior communality estimate for each variable to its squared multiple correlation with all other variables.

By default, PRIORS=SMC.

RCONVERGE=*p*

RCONV=*p*

specifies the convergence criterion value *p* ($p > 0$) for rotation cycles. Rotation stops when the scaled change of the simplicity function value is less than *p*. Mathematically, the convergence criterion is

$$|f_{\text{new}} - f_{\text{old}}|/K < p$$

where f_{new} and f_{old} are simplicity function values of the current cycle and the previous cycle, respectively, and $K = \max(1, |f_{\text{old}}|)$ is a scaling factor. By default, RCONVERGE=1E–9.

REFSTRUCT

RS

prints the reference structure and reference axis correlations. This option has no effect unless you use the ROTATE= option to specify an oblique rotation.

REORDER

RE

reorders the rows (variables) of various factor matrices in the output. Variables whose highest absolute loading (reference structure loading for oblique rotations) is on the first factor are displayed first, from largest to smallest loading, followed by variables whose highest absolute loading is on the second factor, and so on.

RITER=*n*

specifies the maximum number of cycles for factor rotation. Except for promax and Procrustes, you can use this option with all rotation methods. The default *n* is either 10 times the number of variables or 100, whichever is greater.

ROTATE=*name*

R=*name*

specifies the rotation method. By default, ROTATE=NONE.

You can specify the following *name* to skip the factor rotation step:

NONE | N specifies that no rotation be performed, leaving the original orthogonal solution.

You can specify the following *names* for orthogonal rotations:

BIQUARTIMAX | BIQMAX specifies orthogonal biquartimax rotation. This corresponds to specifying ROTATE=ORTHOMAX(.5).

EQUAMAX | E specifies orthogonal equamax rotation. This corresponds to specifying ROTATE=ORTHOMAX with GAMMA=*number of factors*/2.

FACTORPARSIMAX | FPA specifies orthogonal factor parsimax rotation. This corresponds to specifying ROTATE=ORTHOMAX with GAMMA=*number of variables*.

ORTHCF(*p1*,*p2*) | **ORCF**(*p1*,*p2*) specifies the orthogonal Crawford-Ferguson rotation with the weights *p1* and *p2* for variable parsimony and factor parsimony, respectively. See the definitions of weights in the section "Simplicity Functions" on page 347.

ORTHGENCF(*p1*,*p2*,*p3*,*p4*) | **ORGENCF**(*p1*,*p2*,*p3*,*p4*) specifies the orthogonal generalized Crawford-Ferguson rotation with the four weights *p1*, *p2*, *p3*, and *p4*. See the definitions of weights in the section "Simplicity Functions" on page 347.

ORTHOMAX<(*p*)> | **ORMAX**<(*p*)> specifies the orthomax rotation with orthomax weight *p*. When ROTATE=ORTHOMAX, the default *p* value is 1 unless specified otherwise in the GAMMA= option. Alternatively, ROTATE=ORTHOMAX(*p*) specifies *p* as the orthomax weight or the GAMMA= value. See the definition of the orthomax weight in the section "Simplicity Functions" on page 347.

PARSIMAX | PA specifies orthogonal parsimax rotation. This corresponds to specifying ROTATE=ORTHOMAX with

$$\text{GAMMA} = \frac{nvar \times (nfact - 1)}{nvar + nfact - 2}$$

where *nvar* is the number of variables and *nfact* is the number of factors.

QUARTIMAX | QMAX | Q specifies orthogonal quartimax rotation. This corresponds to specifying ROTATE=ORTHOMAX(0).

VARIMAX | V specifies orthogonal varimax rotation. This corresponds to specifying ROTATE=ORTHOMAX with GAMMA=1.

You can specify the following *names* for oblique rotations:

BIQUARTIMIN | BIQMIN specifies biquartimin rotation. This corresponds to specifying ROTATE=OBLIMIN(.5) or ROTATE=OBLIMIN with TAU=0.5.

COVARIMIN | CVMIN specifies covarimin rotation. This corresponds to specifying ROTATE=OBLIMIN(1) or ROTATE=OBLIMIN with TAU=1.

OBBIQUARTIMAX | OBIQMAX specifies oblique biquartimax rotation.

OBEQUAMAX | OE specifies oblique equamax rotation.

OBFACTORPARSIMAX | OFPA specifies oblique factor parsimax rotation.

OBLICF(*p1*,*p2*) | **OBCF**(*p1*,*p2*) specifies the oblique Crawford-Ferguson rotation with the weights *p1* and *p2* for variable parsimony and factor parsimony, respectively. See the definitions of weights in the section "Simplicity Functions" on page 347.

OBLIGENCF(*p1*,*p2*,*p3*,*p4*) | **OBGENCF**(*p1*,*p2*,*p3*,*p4*) specifies the oblique generalized Crawford-Ferguson rotation with the four weights *p1*, *p2*, *p3*, and *p4*. See the definitions of weights in the section "Simplicity Functions" on page 347.

OBLIMIN<(*p*)> | **OBMIN**<(*p*)> specifies the oblimin rotation with oblimin weight *p*. When ROTATE=OBLIMIN, the default *p* value is 0 unless specified otherwise in the TAU= option. Alternatively, ROTATE=OBLIMIN(*p*) specifies *p* as the oblimin weight or the TAU= value. See the definition of the oblimin weight in the section "Simplicity Functions" on page 347.

OBPARSIMAX | OPA specifies oblique parsimax rotation.

OBQUARTIMAX | OQMAX specifies oblique quartimax rotation. This is the same as the quartimin method.

OBVARIMAX | OV specifies oblique varimax rotation.

PROMAX<(*n*)> | P<(*n*)> specifies oblique promax rotation. You can use the PREROTATE= option to specify the desirable prerotation method, either orthogonal or oblique. When used with ROTATE=PROMAX, the POWER= option enables you to specify the power for forming the target. You can also use ROTATE=PROMAX(*n*), where *n* is the POWER= option value.

QUARTIMIN | QMIN specifies quartimin rotation. This is the same as the oblique quartimax method. It also corresponds to specifying ROTATE=OBLIMIN(0) or ROTATE=OBLIMIN with TAU=0.

SEED=*n*

RANDOM=*n*

specifies the initial seed for the pseudorandom number generator for use with the option PRIORS=RANDOM. The value of the SEED= option must be an integer. If you omit the SEED= option or if the specified value is negative or 0, the time of day from the computer's clock is used to obtain the initial seed.

SINGULAR=*p*

SING=*p*

specifies the singularity criterion, where $0 < p < 1$. By default, SINGULAR=1E–8.

TAU=*p*

specifies the oblimin weight to use with the option ROTATE=OBLIMIN or PREROTATE=OBLIMIN. Alternatively, you can use ROTATE=OBLIMIN(*p*), where *p* represents the oblimin weight. If you specify both TAU=*p* and ROTATE=OBLIMIN(*p*), the ROTATE= option value takes precedence.

There is no restriction on valid values for the oblimin weight, although for practical purposes a negative or zero value is recommended. By default TAU=0, which results in the quartimin rotation. See the section "Simplicity Functions" on page 347 for more information.

ULTRAHEYWOOD

ULTRA

allows communalities to exceed 1. This option can cause convergence problems, because communalities can become extremely large and ill-conditioned Hessians might occur. See the section "Heywood Cases and Other Anomalies of Communality Estimates" on page 344 for a discussion of Heywood cases. This option has no effect if you specify METHOD=PRINCIPAL.

VARDEF=DF | N | WDF | WEIGHT | WGT

specifies the divisor to use for calculating variances and covariances. By default, VARDEF=DF. The values and associated divisors are displayed in the following table.

Value	Description	Divisor
DF	Degrees of freedom	$n - 1$
N	Number of observations	n
WDF	Sum of weights DF	$\sum_i w_i - 1$
WEIGHT | WGT	Sum of weights	$\sum_i w_i$

BY Statement

BY *variables* **;**

You can specify a BY statement in PROC EFA to obtain separate analyses of observations in groups that are defined by the values of the BY variables. If you specify more than one BY statement, only the last one specified is used. For more information, see the discussion of BY-group processing in the "Grouping Data" section of *SAS Programmers Guide: Essentials*.

DISPLAY Statement

DISPLAY < *table-list* > < / *options* > **;**

The DISPLAY statement enables you to specify a list of display tables to display or exclude. This statement is similar to the ODS SELECT, ODS EXCLUDE, and ODS TRACE statements. However, the DISPLAY statement can improve performance when a large number of tables could be generated (such as in BY-group processing). The procedure processes the DISPLAY statement on a CAS server and thus sends only a subset of ODS tables to the SAS client. Because ODS statements are processed on a SAS client, first all the generated display tables are sent to the client, and then the client creates a subset.

If you use both DISPLAY and ODS statements together, the DISPLAY statement takes precedence over the ODS statements. Note that the ODS EXCLUDE statement processes tables that are sent to the client after they have been filtered by the DISPLAY statement. In some cases, it might appear that the ODS EXCLUDE statement is taking precedence because it can further filter the tables. For more information about ODS, see *SAS Output Delivery System: Procedures Guide*.

You can specify the *table-list* as a list of table names, paths, partial pathnames, and regular expressions.

The table names that you can specify are listed in the section "ODS Table Names" on page 349. A path is a table name that is prefixed with dot-separated grouping information. For example, a SelectionSummary table that a procedure produces during a selection routine might have the path *Bygroup1.Summary.SelectionSummary*. A partial pathname does not include all groups; for example, *SelectionSummary* and *Summary.SelectionSummary* are partial pathnames for *Bygroup1.Summary.SelectionSummary*.

When you specify a table name or partial pathname, all display tables whose paths end in the specified name are selected for display or exclusion. For example, both *SelectionSummary* and *Summary.SelectionSummary* select *Bygroup1.Summary.SelectionSummary*.

A regular expression is enclosed in forward slashes (/). For example, specifying "/tions/" selects all pathnames that contain the substring "tions"; in particular, the *Bygroup1.Summary.SelectionSummary* table is selected. Specifying "!/tions/" selects all pathnames that do not contain the substring "tions"; in particular, the *Bygroup1.Summary.SelectionSummary* table is not selected.

You can specify the following *options* after a slash (/):

CASESENSITIVE
performs a case-sensitive comparison of table names in the *table-list* to display table names when tables are subsetted for display. To preserve case, you must enclose table names in the *table-list* in quotation marks.

EXCLUDE
displays all display tables except those that you specify in the *table-list*.

EXCLUDEALL
suppresses display of all tables. This option takes precedence over the other options.

TRACE
displays the display table names, labels, and paths.

DISPLAYOUT Statement

DISPLAYOUT *table-spec-list* < / *options* > **;**

The DISPLAYOUT statement enables you to create output tables from your displayed output. This statement is similar to the ODS OUTPUT statement. For more information about ODS, see *SAS Output Delivery System: Procedures Guide*.

The *table-spec-list* specifies a list of output tables to create. Each entry in the list has either a *key*=*value* format or a *key* format:

key=*value*	specifies *key* as the ODS table name, path, or partial pathname, and specifies *value* as the output table name.
key	specifies *key* as the ODS table name and also as the output table name.

The ODS table names that you can specify are listed in the section "ODS Table Names" on page 349. You cannot specify the ODS table named OutputCasTables in the *table-spec-list*.

Table names and partial pathnames are discussed under the DISPLAY statement. The DISPLAYOUT statement does not support regular expressions.

You can specify the following *options* after a slash (/):

INCLUDEALL
creates output tables for all display tables. The name of the created output table is the same as the name of the corresponding display table. If you specify this option, the *table-spec-list* specification is ignored.

NOREPLACE
does not replace any existing output table of the same name.

REPEATED
replicates all output tables on all nodes.

FREQ Statement

FREQ *variable* **;**

The *variable* in the FREQ statement identifies a numeric variable in the input data table that contains the frequency of occurrence of each observation. PROC EFA treats each observation as if it appears f times, where f is the value of the FREQ *variable* for the observation. If f is not an integer, it is truncated to an integer. If f is less than 1 or missing, the observation is not used in the analysis. When you omit the FREQ statement, each observation is assigned a frequency of 1.

NFACTORS Statement

NFACTORS TYPE=*name* < *options* > **;**

The NFACTORS statement specifies a criterion to use for suggesting the number of factors to extract in an analysis. If you use the NFACTORS=*n* option in the PROC EFA statement to specify the number of factors to extract, then the NFACTORS statement is not required. In this case, you can still use the NFACTORS statement to investigate alternative criteria for the number of factors or to assess the robustness of your analysis. If you do not specify the NFACTORS=*n* option in the PROC EFA statement, then you must specify at least one NFACTORS statement.

You must specify the following option:

TYPE=*name*
specifies the criterion to use for suggesting the number of factors to extract. You can specify the following *names*:

EIGENVALUE determines the number of factors to extract by comparing the eigenvalues of the reduced correlation matrix to a threshold value. The threshold value is specified by the THRESHOLD= option. If you omit the THRESHOLD= option, the default value is 1. Each eigenvalue greater than the threshold value indicates the presence of a common factor.

MAP | MAP2 performs a minimum average partial (MAP) correlation analysis (Velicer 1976) to determine the number of factors to extract. This criterion selects the number of factors that corresponds to the number of principal components that are partialed out to yield the smallest average squared partial (residual) correlations among variables.

MAP4 performs a minimum average partial (MAP) correlation analysis similar to that performed by the TYPE=MAP option, but using the smallest average fourth-powered partial (residual) correlations among variables (Velicer, Eaton, and Fava 2000).

PARALLEL performs a parallel analysis as described by Glorfeld (1995) and Horn (1965). This criterion selects the number of factors that corresponds to the first n consecutive eigenvalues of the sample correlation matrix that are significantly greater than the

corresponding eigenvalues of random correlation matrices that are generated from a multivariate standard normal distribution.

To compute a parallel analysis, PROC EFA simulates a large number of random correlation matrices and constructs an empirical distribution for each positional eigenvalue: largest, second-largest, and so on (Glorfeld 1995). You can use the NSIMULATIONS= option to specify the number of simulations to use. If you omit the NSIMULATIONS= option, PROC EFA uses a default value of 10,000. A factor is suggested if an observed eigenvalue is greater than the critical value at a specified one-sided alpha level, with reference to the corresponding simulated distribution of random eigenvalues. You can use the ALPHA= option to specify the alpha level. If you omit the ALPHA= option, PROC EFA uses a default value of 0.05. As soon as an observed eigenvalue is less than or equal to the corresponding critical value, no more factors are counted. In other words, only the first *n* consecutive significant eigenvalues are counted for the number of factors.

Note that the parallel analysis criterion is based on the standard correlation matrix, not the reduced correlation matrix. The choice of prior communalities does not affect the parallel analysis.

PROPORTION determines the number of factors to extract by determining the smallest number of factors such that the cumulative proportion of common variance explained exceeds a threshold value. The threshold value is specified by the THRESHOLD= option. If you omit the THRESHOLD= option, the default value is 1.

For this criterion, the eigenvalues are sorted in descending order, and the proportion of the *common* variance explained by each eigenvalue is computed. Note that the denominator (that is, the total common variance) in computing the proportion here is the sum of the initial communality estimates and not the total variances of variables (which would be the same as the number of variables with a correlation input) unless all prior communality estimates are ones.

The TYPE=EIGENVALUE and TYPE=PROPORTION criteria refer to properties of the reduced correlation matrix. The reduced correlation matrix is the correlation matrix for the analysis variables, but where the diagonal entries of the matrix are replaced by estimates of the communalities for the corresponding variables. For more information about specifying communalities, see the section "Prior Communalities" on page 341.

You can also specify the following additional *options*:

ALPHA=*p*

specifies the one-sided alpha level for computing the critical value at the upper end of the simulated distribution of eigenvalues in a parallel analysis. The value of *p* must be between 0 and 1. By default, ALPHA=0.05. This option has an effect only when you specify TYPE=PARALLEL in the NFACTORS statement.

NSIMULATIONS=*n*

NSIMS=(*n***)**

NSIM=(*n***)**

specifies the number of simulations to use in constructing an empirical distribution of eigenvalues

for a parallel analysis. The value of *n* must be greater than or equal to 200. By default, NSIMULATIONS=10000. This option has an effect only when you specify TYPE=PARALLEL in the NFACTORS statement.

SEED=*n*

specifies the initial seed for the pseudorandom number generator that is used to simulate correlation matrices for a parallel analysis. The value of the SEED= option must be an integer. If you omit the SEED= option or if the specified value is negative or 0, the time of day from the computer's clock is used to obtain the initial seed. This option has an effect only when you specify TYPE=PARALLEL in the NFACTORS statement.

STATUS=ACTIVE | INACTIVE

specifies the status of the criterion for determining the number of factors to extract. By default, STATUS=ACTIVE. A criterion that has an active status is used to determine the final number of factors to extract. A criterion that has an inactive status is computed for informational purposes only and is not used to determine the final number of factors. The final number of factors to extract is computed by combining the numbers of factors that is suggested by all the criteria whose status is active. The numbers are combined according to the value of the NFACTORS= statement in the PROC EFA statement.

THRESHOLD=*p*

specifies the threshold value for either a TYPE=EIGENVALUE or TYPE=PROPORTION criterion. For a TYPE=EIGENVALUE criterion, each eigenvalue greater than the threshold value indicates the presence of a common factor. For a TYPE=PROPORTION criterion, the number of factors that is suggested is the smallest number of eigenvalues that is required so that the proportion of common variance explained exceeds the threshold.

PRIORS Statement

PRIORS *communalities* **;**

The PRIORS statement specifies numeric values between 0.0 and 1.0 for the prior communality estimates for each variable. The first numeric value corresponds to the first variable in the VAR statement, the second value to the second variable, and so on. The number of numeric values must equal the number of variables. For example:

```
proc efa nfactors=1;
   var     x  y  z;
   priors .7 .8 .9;
run;
```

You can specify various methods of computing prior communality estimates by using the PRIORS= option in the PROC EFA statement. See the description of that option for more information about the default prior communality estimates.

VAR Statement

VAR *variables* **;**

The VAR statement specifies the numeric variables to be analyzed. If you omit this statement, all numeric variables that are not specified in other statements are analyzed.

WEIGHT Statement

WEIGHT *variable* **;**

The *variable* that you specify in the WEIGHT statement is used as a weight to perform a weighted analysis of the data. Observations that have nonpositive weights or missing weights are excluded from the analysis. The values of the WEIGHT variable can be nonintegral and are not truncated. When you omit this statement, all observations that are used in the analysis are assigned a weight of 1.

Details: EFA Procedure

The EFA procedure implements methods and algorithms that enable you first to determine the number of common factors to retain in a common factor model and then to extract common factors and rotate the corresponding factor pattern.

When you provide multivariate data as input, PROC EFA first computes the correlation matrix for the analysis variables. It is this correlation matrix that is the object of analysis.

The Common Factor Model

In the common factor model, factors are hypothesized to account for the observed correlations among variables in the data. A *common factor* is an unobserved (or latent) hypothetical variable that contributes to the variance of at least two of the observed variables. The unqualified term "factor" often refers to a common factor. A *unique factor* is an unobservable, hypothetical variable that contributes to the variance of only one of the observed variables. The model for common factor analysis posits one unique factor for each observed variable.

The equation for the common factor model is

$$y_{ij} = x_{i1}b_{1j} + x_{i2}b_{2j} + \cdots + x_{iq}b_{qj} + e_{ij}$$

where

y_{ij} is the value of the ith observation on the jth observed variable.

x_{ik} is the value of the ith observation on the kth common factor; or in the regression analysis context, a factor is an unobserved common predictor of more than one observed variable.

b_{kj} is the factor loading of the jth variable on the kth common factor; or in the regression analysis context, b_{kj} is the regression coefficient of the kth common factor for predicting the jth variable.

e_{ij} is the value of the *i*th observation on the *j*th unique factor; or in the regression analysis context, a unique factor plays the role of the residual in a model equation.

q is the number of common factors, which might not be fixed before the analysis.

Typically, the maximum number of factors that can be extracted is the same as the number of variables that are being factor-analyzed. However, it is likely that the actual number of factors that you want to retain for the extraction is much smaller than the number of variables. In this sense, factor analysis can be viewed as a data reduction technique.

For convenience, it is assumed that all variables have a mean of 0. In matrix terms, these equations are represented as

$$\mathbf{Y} = \mathbf{XB} + \mathbf{E}$$

where $\mathbf{X}$ is the matrix of unobserved factor scores and $\mathbf{B}'$ is the factor pattern (or factor loading) matrix.

The model makes two important assumptions:

- The unique factors are uncorrelated with each other.
- The unique factors are uncorrelated with the common factors.

When the factors are initially extracted, it is also assumed, for convenience, that the common factors are uncorrelated with each other and have unit variance. In this case, the common factor model implies that the covariance s_{jk} between the *j*th and *k*th variables, $j \neq k$, is given by

$$s_{jk} = b_{1j}b_{1k} + b_{2j}b_{2k} + \cdots + b_{qj}b_{qk}$$

or

$$\mathbf{S} = \mathbf{B}'\mathbf{B} + \mathbf{U}^2$$

where $\mathbf{S}$ is the covariance matrix of the observed variables and $\mathbf{U}^2$ is the diagonal covariance matrix of the unique factors.

If the original variables are standardized to unit variance, the preceding formula yields correlations instead of covariances. It is in this sense that common factors explain the correlations among the observed variables. In considering the diagonal elements of standardized $\mathbf{S}$, the variance of the *j*th variable is expressed as

$$s_{jj} = 1 = b_{1j}^2 + b_{2j}^2 + \cdots + b_{qj}^2 + [\mathbf{U}^2]_{jj}$$

where $b_{1j}^2 + b_{2j}^2 + \cdots + b_{qj}^2$ and $[\mathbf{U}^2]_{jj}$ are the *communality* and *uniqueness*, respectively, of the *j*th variable. The communality represents the extent of the overlap with the common factors. In other words, it is the proportion of variance that is accounted for by the common factors.

The difference between the correlation that is predicted by the common factor model and the actual correlation is the *residual correlation*. A good way to assess the goodness of fit of the common factor model is to examine the residual correlations.

The common factor model implies that the partial correlations among the variables, if you remove the effects of the common factors, must all be 0. When you remove the common factors, only unique factors remain; they are by definition uncorrelated.

The assumptions of common factor analysis imply that the common factors are, in general, not linear combinations of the observed variables. In fact, even if the data contain measurements on the entire population of observations, you cannot compute the scores of the observations on the common factors. Although you cannot compute the common factor scores directly, you can estimate them in a variety of ways.

The Exploratory Nature of Common Factor Analysis

In practice, you conduct a common factor analysis so that you can find the smallest number of common factors that can account for the observed correlations or covariances among variables in the data—that is, so that you can minimize the residual correlations. In addition, you are interested in understanding the meanings of the common factors.

For the sample covariance matrix or correlation matrix, a common factor analysis consists of the following four distinct but related tasks:

- determining the number of factors
- extracting factors
- rotating factors
- estimating factor scores

If raw data are provided as input, the sample covariance or correlation matrix of the observed variables is computed from the raw data for analysis.

Common factor analysis in practical applications is often described as *exploratory* (hence the alternative name "exploratory factor analysis"), because you might not start with a fixed number of factors to extract or a fixed coordinate system to interpret the factors. Instead, you might explore different *rotated* factor solutions that use different numbers of factors so that you can choose the optimal solution to interpret the extracted factors. Most of the time, such an optimal solution is also the one that obeys the simplicity principle: it uses the lowest possible number of factors to account for the correlations among observed variables while maintaining the interpretability of common factors with a *simple* rotated factor pattern (in the sense that each column of the rotated factor pattern matrix contains mostly zero loadings).

In fact, your substantive knowledge in a specific domain also plays a critical role in choosing an optimal factor solution in applications. Although PROC EFA cannot replace your domain knowledge, it provides objective analytic tools to facilitate the exploratory process in common factor analysis.

Factor Analysis in Practice

This section provides more details about how you establish or estimate a factor model through the four tasks described in the section "The Exploratory Nature of Common Factor Analysis" on page 339, which emphasizes the exploratory nature of factor analysis in applications.

Determining the Number of Factors

In exploratory factor analysis, usually the first task is to determine the number of factors that suitably account for the correlations in the multivariate data. If you have domain knowledge or a theoretical position about the underlying factors, you can fix the number of factors at this stage for the subsequent tasks of factor analysis. Otherwise, you need to determine the number of factors on the basis of the eigenvalues of the sample correlation matrix or the *reduced* correlation matrix. Whereas the sample correlation matrix contains ones as the diagonal values, a reduced correlation matrix is computed by replacing the diagonal values with *communality estimates* for the variables. A popular choice in common factor analysis is to use the squared multiple correlations (SMCs), which are less than one in most practical situations, as the initial communality estimates. Essentially, the different methods of determining the number of common factors are all based on evaluating the eigenvalues (or their cumulative sums) of the sample or reduced correlation matrix.

Extracting Factors

After you determine the number of factors or a set of plausible numbers of factors, you are ready to extract the common factors. In essence, this means that you estimate the factor pattern matrix $\mathbf{B}'$, given the data and the number of factors. Iterative and noniterative methods have been proposed for this purpose.

Factor extraction as described here is treated as an initial stage of estimation, in which the common factors are uncorrelated with each other. After you extract or estimate the factors, you want to interpret them. This entails assigning to each common factor a name that reflects the *salience* of the factor in predicting each of the observed variables—that is, the salience of the coefficients (or loadings) in the pattern matrix that corresponds to the factor. Factor interpretation is a subjective process. You can sometimes make it less subjective by *rotating* the common factors—in other words, by applying a nonsingular linear transformation to the factor pattern matrix.

Rotating Factors

Rotating a factor pattern is conceptually the same as finding a (suitable) coordinate system for locating and interpreting the extracted factors. The main goal of factor rotation is to find a rotated pattern matrix in which all the coefficients are close to 0 or ± 1. Such a pattern is easier to interpret than a pattern that has many intermediate elements (such as those commonly observed in the initial factor pattern). Therefore, most rotation methods attempt to optimize a simplicity function of the rotated pattern matrix that measures, in some sense, how close the elements are to 0 or ± 1.

If the factors are rotated by an *orthogonal transformation,* the rotated factors are still uncorrelated. If the factors are rotated by an *oblique transformation,* the rotated factors might become correlated. Oblique rotations often produce more useful or interpretable patterns than orthogonal rotations. However, a consequence of correlated factors is that there is no single unambiguous measure of the importance of a factor in explaining a variable. Thus, for oblique rotations, the pattern matrix does not provide all the necessary information for interpreting the factors; you might want to examine the *factor structure* and the *reference structure* to understand the correlations between variables and factors.

Rotating a set of factors does not change the statistical explanatory power of the factors. You cannot say that any rotation is better than any other rotation from a statistical point of view; all rotations, whether orthogonal or oblique, are equally good statistically. Therefore, the choice among different rotations must be based on nonstatistical grounds. For most applications, the preferred rotation is the one that is most easily interpretable or most compatible with substantive theories.

Estimating Factor Scores

In the factor analysis model, the factor scores x_{ik} are not observed. However, after you obtain a factor solution, you can estimate the factor scores by using the parameter estimates (for example, the estimated factor loadings) and the raw data. Estimated factor scores are useful in subsequent statistical analyses, where they can serve as predictors of other outcomes or as classification variables themselves. PROC EFA does not support the computation of factor scores.

Prior Communalities

PROC EFA supports the following methods of specifying or computing prior communality estimates:

- squared multiple correlations (SMC)
- adjusted squared multiple correlations (ASMC)
- maximum absolute correlations
- unit values
- random values
- user-specified values

For SMC priors, the prior communality of each variable is set to the squared multiple correlation of that variable with all other variables. This is the default choice of prior communalities in PROC EFA.

For ASMC priors, the prior communality of each variable is proportional to the squared multiple correlation of that variable with all other variables, but it is adjusted so that the sum of the communalities is equal to the sum of the maximum absolute correlations (Cureton 1968).

For maximum absolute correlations, the prior communality of each variable is equal to its maximum absolute correlation with any other analysis variable. If the correlation matrix for the analysis variables is singular, you should use maximum absolute correlations for prior communalities and not use SMC or ASMC priors.

If you specify unit priors, a prior communality of 1 is assigned to each variable. If you specify random priors, prior communalities are set to pseudorandom numbers that are uniformly distributed between 0 and 1. Finally, you can specify a list of numeric values between 0 and 1 to use as the prior communality estimates for each variable. In this case, the first numeric value corresponds to the first analysis variable, the second value corresponds to the second variable, and so on. The number of numeric values must equal the number of analysis variables.

Determining the Number of Factors

PROC EFA enables you to specify multiple criteria for determining the number of factors. You can also specify the same type of criterion but with different option values. PROC EFA supports the following criteria for determining the number of factors to retain:

- minimum eigenvalue
- proportion of variance explained
- parallel analysis
- minimum average partial correlation analysis

The first two criteria refer to properties of the reduced correlation matrix. The reduced correlation matrix is the correlation matrix for the analysis variables, but in which the diagonal entries of the matrix are replaced by estimates of the communalities for the corresponding variables. For more information about specifying communalities, see the section "Prior Communalities" on page 341.

The minimum eigenvalue criterion determines the number of factors to retain by comparing the eigenvalues of the reduced correlation matrix to a threshold value that you specify. Each eigenvalue that is greater than the threshold value indicates the presence of a common factor. If you do not specify a threshold value, PROC EFA uses a default value of 1; this is a very common practice.

The proportion of variance explained criterion also uses the eigenvalues of the reduced correlation matrix. For this criterion, the eigenvalues are sorted in descending order, and the proportion of the *common* variance that is explained by each eigenvalue is computed. Note that the denominator (that is, the total common variance) in computing the proportion here is the sum of the initial communality estimates and not the total variances of variables (which would be the same as the number of variables with a correlation input) unless all prior communality estimates are ones. The number of factors to retain is estimated as the smallest number of factors such that the cumulative variance explained exceeds a threshold value. If you do not specify a threshold value, PROC EFA uses a default value of 1.

A parallel analysis, first proposed by Horn (1965), selects the number of factors by comparing the eigenvalues in the sample correlation matrix to the eigenvalues of random correlation matrices that are generated from a multivariate standard normal distribution. PROC EFA simulates a large number of random correlation matrices and constructs an empirical distribution for each positional eigenvalue: largest, second-largest, and so on (Glorfeld 1995). If you do not specify the number of simulations to use, PROC EFA uses a default value of 10,000. A factor is suggested if an observed eigenvalue is greater than the critical value at a specified one-sided alpha level, with reference to the corresponding simulated distribution of random eigenvalues. If you do not specify an alpha level, PROC EFA uses a default value of 0.05. As soon as an observed eigenvalue is less than or equal to the corresponding critical value, no more factors are counted. In other words, only the first n consecutive significant eigenvalues are counted for the number of factors.

Note that the parallel analysis criterion is based on the standard correlation matrix, not the reduced correlation matrix. Therefore, the choice of prior communalities does not affect the parallel analysis.

A minimum average partial correlation analysis first performs a principal component analysis on the sample correlation matrix. Next, it computes averages of the squared or fourth-powered partial correlations between the variables after recursively controlling for one component, two components, and so on (Velicer 1976). The

selected number of factors is the number of controlled components that correspond to the smallest average squared or fourth-powered partial correlation.

Note that the minimum average partial correlation analysis criterion is based on the standard correlation matrix, not the reduced correlation matrix. Therefore, the choice of prior communality estimates does not affect the minimum average partial correlation analysis.

Each criterion that you specify is used by PROC EFA to suggest a number of factors to retain. The criteria are independent of one another, but you cannot specify two identical criteria. By default, the final number of factors that PROC EFA suggests is the minimum of the values suggested by the criteria that you specify. You can change this default behavior by specifying the NFACTORS=*method* option, where *method* is MIN, MAX, MEDIAN, or MEAN. You can also use the STATUS=INACTIVE option to specify criteria whose status is inactive. A criterion with an inactive status is computed for informational purposes only and is not used to determine the final number of factors.

Factor Extraction

After you determine the number of common factors to use for an analysis, it is time to extract those factors. That is, you must use the data and the number of factors to estimate the factor pattern matrix $\mathbf{B}'$. (For more information about the factor pattern and its relation to the original data, see the section "The Common Factor Model" on page 337.)

PROC EFA implements the following factor extraction methods:

- principal factor analysis
- iterated principal factor analysis
- unweighted least squares factor analysis
- maximum likelihood (canonical) factor analysis
- alpha factor analysis

The simplest and computationally most efficient method of common factor analysis is principal factor analysis. In a principal factor analysis, you construct the reduced correlation matrix by using the prior communalities, and the factor pattern is computed from the eigenvalues and eigenvectors of the reduced correlation matrix. Note that when the prior communalities are set to ones, a principal factor analysis is equivalent to a principal component analysis.

The remaining four methods use iterative algorithms to compute both the factor pattern and updated estimates of the communalities.

Maximum Likelihood Factor Analysis

Although principal factor analysis is perhaps the most commonly used method of common factor analysis, most statisticians prefer maximum likelihood (ML) factor analysis (Lawley and Maxwell 1971). The ML method of estimation has desirable asymptotic properties (Bickel and Doksum 1977) and produces better estimates than principal factor analysis in large samples. The unrotated ML solution is equivalent to Rao's canonical factor solution (Rao 1955) and Howe's solution that maximizes the determinant of the partial

correlation matrix (Morrison 1976). Thus, as a descriptive method, ML factor analysis does not require a multivariate normal distribution.

With the ML method, you can test hypotheses about the number of common factors. In particular, tests of the following null hypotheses are displayed by default when you specify this method:

- H_0: No common factors
- H_0: Factors retained are sufficient to explain the correlations

The test for no common factors is equivalent to Bartlett's test of sphericity. The variables should have an approximate multivariate normal distribution for the probability levels to be valid. Lawley and Maxwell (1971) suggest that the number of observations should exceed the number of variables by 50 or more, although Geweke and Singleton (1980) claim that as few as 10 observations are adequate with five variables and one common factor. Certain regularity conditions must also be satisfied for Bartlett's χ^2 test to be valid (Geweke and Singleton 1980), but in practice these conditions are usually satisfied.

Other quantities that are computed when you specify the ML method include the following:

- Akaike's information criterion (AIC) (Akaike 1973, 1974, 1987). AIC is a general criterion for estimating the best number of parameters to include in a model when you use ML estimation. The number of factors that yields the smallest value of AIC is considered best. Like the χ^2 test, AIC tends to include factors that are statistically significant but inconsequential for practical purposes.
- Schwarz's Bayesian criterion (SBC) (Schwarz 1978). SBC is another criterion, similar to AIC, for determining the best number of parameters. The number of factors that yields the smallest value of SBC is considered best. SBC seems to be less inclined to include trivial factors than either AIC or the chi-square test.
- Tucker and Lewis's reliability coefficient (Tucker and Lewis 1973)
- Squared canonical correlations. These are the same as the squared multiple correlations for predicting each factor from the variables.

You cannot use the ML method with a singular correlation matrix, and it is especially prone to Heywood cases. (See the section "Heywood Cases and Other Anomalies of Communality Estimates" for a discussion of Heywood cases.) If you have problems with ML, the best alternative is to use unweighted least squares factor analysis.

Heywood Cases and Other Anomalies of Communality Estimates

Because communalities are squared correlations, you would always expect them to lie between 0 and 1. However, it is a mathematical peculiarity of the common factor model that final communality estimates might exceed 1. If a communality equals 1, the situation is referred to as a Heywood case; if a communality exceeds 1, it is an ultra-Heywood case. An ultra-Heywood case implies that some unique factor has negative variance, which is a clear indication that something is wrong. Possible causes include the following:

- bad prior communality estimates

- too many or too few common factors
- not enough data to provide stable estimates
- the common factor model is not an appropriate model for the data

An ultra-Heywood case invalidates a factor solution. Factor analysts disagree about whether a factor solution with a Heywood case can be considered legitimate.

For the iterative extraction methods, PROC EFA stops iterating and returns an error if an estimated communality exceeds 1. To allow processing to continue when a Heywood or ultra-Heywood case is encountered, you can specify the HEYWOOD option to set the upper bound of any communality to 1, or you can specify the ULTRAHEYWOOD option to allow communalities to exceed 1.

Theoretically, the communality of a variable should not exceed its reliability. Violation of this condition is called a quasi-Heywood case and should be regarded with the same suspicion as an ultra-Heywood case.

Elements of the factor structure and reference structure matrices can exceed 1 only in the presence of an ultra-Heywood case. On the other hand, an element of the factor pattern might exceed 1 in an oblique rotation, irrespective of the occurrence of a Heywood case.

The maximum likelihood method is especially susceptible to quasi- or ultra-Heywood cases. During the iteration process, a variable that has high communality is given a high weight; this tends to increase its communality, which increases its weight, and so on.

It is often stated that the squared multiple correlation of a variable with the other variables is a lower bound to its communality. This is true if the common factor model fits the data perfectly, but it is not generally the case for real data. A final communality estimate that is less than the squared multiple correlation can, therefore, indicate poor fit, possibly because there are not enough factors. It is by no means as serious a problem as an ultra-Heywood case. Factor methods that use the Newton-Raphson method, such as the ML method, can actually produce communalities less than 0, which is a result even more disastrous than an ultra-Heywood case.

The squared multiple correlation of a factor with the variables might exceed 1, even in the absence of ultra-Heywood cases. This situation is also cause for alarm. Alpha factor analysis seems to be especially prone to this problem, but it does not occur in maximum likelihood estimation. If a squared multiple correlation is negative, too many factors were retained.

For data that do not fit the common factor model perfectly, you can expect some of the eigenvalues to be negative. If an iterative factor method converges properly, the sum of the eigenvalues that correspond to rejected factors should be 0; hence, some eigenvalues are positive and some are negative. If a principal factor analysis fails to yield any negative eigenvalues, the prior communality estimates are probably too large. Negative eigenvalues cause the cumulative proportion of variance explained to exceed 1 for a sufficiently large number of factors. The cumulative proportion of variance explained by the retained factors should be approximately 1 for principal factor analysis and should converge to 1 for iterative methods. Occasionally, a single factor can explain more than 100% of the common variance in a principal factor analysis, indicating that the prior communality estimates are too low.

If a squared canonical correlation or a coefficient alpha is negative, too many factors were retained.

Rotating Factors

The purpose of factor rotation is to facilitate the interpretation of the common factors that were computed during the extraction stage. When a common factor solution is interpreted, each factor is assigned a name that reflects its importance in predicting each of the observed variables. This process is made easier (or less subjective) if all the coefficients in the factor pattern are close to 0 or ± 1. Thus, the goal of a factor rotation is to apply a nonsingular transformation to the factor pattern matrix in order to optimize a simplicity function that measures how close the elements of the factor pattern are to 0 or ± 1.

The common factors that are initially extracted are uncorrelated with each other. (For more information about factor extraction, see the section "Factor Extraction" on page 343.) If the factors are rotated by an orthogonal transformation, the rotated factors are still uncorrelated. If the factors are rotated by an oblique transformation, the rotated factors become correlated.

Specific methods of orthogonal rotation are as follows:

- varimax
- quartimax
- biquartimax
- equamax
- parsimax
- factor parsimax

Oblique versions of these methods are also available. Other specific methods of (direct) oblique rotation are as follows:

- quartimin
- biquartimin
- covarimin

General methods of orthogonal rotation are as follows:

- orthomax with user-specified gamma
- Crawford-Ferguson family with user-specified weights on variable parsimony and factor parsimony
- generalized Crawford-Ferguson family with user-specified weights

General methods of oblique rotation are as follows:

- direct oblimin with user-specified tau
- Crawford-Ferguson family with user-specified weights on variable parsimony and factor parsimony

- generalized Crawford-Ferguson family with user-specified weights
- promax with user-specified exponent

Crawford and Ferguson (1970) provide an excellent summary of a wide class of analytic rotations. See Harman (1976) and Mulaik (1972) for further information.

Oblique rotations often produce more useful or interpretable patterns than orthogonal rotations. However, a consequence of correlated factors is that there is no single unambiguous measure of the importance of a factor in explaining a variable. Thus, for oblique rotations, the pattern matrix does not provide all the necessary information for interpreting the factors; you must also examine the factor structure and the reference structure.

Note that factor rotation is conceptually and mathematically equivalent to finding a suitable coordinate system for locating the extracted factors. For this reason, factor rotation does not change the statistical explanatory power of the factors, and there is no mathematical or statistical reason to prefer one rotation over another. Rather, the choice is subjective and based on which rotation produces a solution that is most suitable for interpretation. Although rotating a factor solution does not increase or decrease the statistical quality of the factor model, it can simplify the interpretation of the factors and redistribute the variance explained by the factors.

Simplicity Functions

To rotate a factor pattern is to apply a nonsingular linear transformation to the unrotated factor pattern matrix. An optimal transformation is usually defined as a minimum or maximum point of a simplicity function. Different rotation methods are based on different simplicity functions.

For the promax rotation, the simplicity function that is used is the sum of squared differences between the rotated factor pattern and the target matrix. The optimal transformation is obtained by minimizing this simplicity function with respect to the choices of all possible transformation.

For the generalized Crawford-Ferguson family of rotations (Jennrich 1973), the simplicity function that is optimized is

$$f = k_1 Z + k_2 H + k_3 V + k_4 Q$$

where

$$Z = (\sum_j \sum_i b_{ij}^2)^2, \quad H = \sum_i (\sum_j b_{ij}^2)^2$$

$$V = \sum_j (\sum_i b_{ij}^2)^2, \quad Q = \sum_j \sum_i b_{ij}^4$$

and where k_1, k_2, k_3, and k_4 are constants, and b_{ij} represents an element of the rotated pattern matrix. Except in specialized research, it is uncommon in practice to use this simplicity function directly for rotation. However, this simplicity function reduces to many well-known classes of rotations. One of these classes is the Crawford-Ferguson family (Crawford and Ferguson 1970), which minimizes

$$f_{\text{cf}} = c_1(H - Q) + c_2(V - Q)$$

where c_1 and c_2 are constants, $(H - Q)$ represents variable (row) parsimony, and $(V - Q)$ represents factor (column) parsimony. Therefore, the relative importance of both the variable parsimony and the factor

parsimony is adjusted using the constants c_1 and c_2. The orthomax class (see Harman 1976) maximizes the function

$$f_{\text{or}} = pQ - \gamma V$$

where γ is the orthomax weight and is usually between 0 and the number of variables p. The oblimin class minimizes the function

$$f_{\text{ob}} = p(H - Q) - \tau(Z - V)$$

where τ is the oblimin weight. For practical purposes, a negative or 0 value for τ is recommended.

All the preceding definitions are for rotations without row normalization. For rotations that use Kaiser normalization, the definition of b_{ij} is replaced by b_{ij} / h_i, where h_i is the communality estimate of variable i.

Variable Weights and Variance Explained

In PROC EFA, the principal, iterative principal, and unweighted least squares methods perform an unweighted analysis of the input variables. Alpha and ML factor analyses compute variable weights on the basis of the communalities (Harman 1976, pp. 217–218). In alpha factor analysis, the weight of a variable is the reciprocal of its communality. In ML factor analysis, the weight is the reciprocal of the uniqueness.

For uncorrelated factors, the factor pattern is equal to both the matrix of standardized regression coefficients for predicting variables from common factors and the matrix of correlations between variables and common factors. The variance explained by a factor is computed by taking the sum of squares of the corresponding column of the factor pattern, yielding an unweighted result. If the square of each loading is multiplied by the weight of the variable before the sum is taken, the result is the weighted variance explained, which (for the methods that PROC EFA implements) is equal to the corresponding eigenvalue. Whether the weighted or unweighted result is more important depends on the purpose of the analysis.

In the case of correlated factors, the variance explained by a factor can be computed with or without taking the other factors into account. If you want to ignore the other factors, the variance explained is given by the weighted or unweighted sum of squares of the appropriate column of the factor structure, because the factor structure contains simple correlations. If you want to subtract the variance explained by the other factors from the amount explained by the factor in question (the Type II variance explained), you can take the weighted or unweighted sum of squares of the appropriate column of the reference structure, because the reference structure contains semipartial correlations. There are other ways to measure the variance explained. For example, you can eliminate from each factor the variance explained by previous factors and compute a Type I variance explained. Harman (1976, pp. 268–270) provides another method, which is based on direct and joint contributions.

Final communality estimates are the squared multiple correlations for predicting the variables from the estimated factors. You can obtain them by taking the sum of squares of each row of the factor pattern, or a weighted sum of squares if variable weights are used.

Limitations

No computer program can reliably determine the optimal number of factors, because the decision is ultimately subjective. You should not blindly accept the number of factors that is obtained by default. Instead, use your own judgment.

Likewise, the interpretation of a factor solution is subjective. For this reason, there is no combination of extraction and rotation methods that is always correct for a given application. Rather, you should consider the assumptions, advantages, and disadvantages of each method and decide what is appropriate for your application. In an exploratory factor analysis, you might consider trying several different methods or extracting different numbers of factors to see which solution is easiest to interpret.

Singular correlation matrices cause problems for SMC or ASMC priors. Singularities can result from using a variable that is the sum of other variables, coding too many dummy variables from a classification variable, or having more variables than observations.

Missing Values

Observations that have missing values for any analysis variable, frequency variable, or weight variable are omitted from the analysis.

ODS Table Names

Each table that the EFA procedure creates has a name that is associated with it. You must use this name to refer to the table when you use ODS statements. Table 10.3 lists the name of each table and a short description of its contents.

Table 10.3 Tables Produced by PROC EFA

Table Name	Description	Statement	Option
AlphaCoef	Coefficient alpha for each factor	PROC EFA	METHOD=ALPHA
AveParCorrControlPC	Average partial correlations after controlling for principal components	NFACTORS	TYPE=MAP2 or MAP4
CanCorr	Squared canonical correlations	PROC EFA	METHOD=ML
Eigenvalues	Eigenvalues of the reduced correlation matrix	Default output	
FactorPattern	Factor pattern	Default output	
FactorStructure	Factor structure (matrix of correlations between variables and common factors)	PROC EFA	ROTATE= any oblique rotation
FinalCommun	Final communalities	PROC EFA	METHOD=PRINCIPAL, PRINIT, or ULS
FinalCommunWgt	Final communalities with weights	PROC EFA	METHOD=ALPHA or ML
FitMeasures	Measures of fit	PROC EFA	METHOD=ML

Table 10.3 *continued*

Table Name	Description	Statement	Option
InterFactorCorr	Interfactor correlations	PROC EFA	ROTATE= any oblique rotation
IterHistory	Iteration history	PROC EFA	METHOD=ALPHA, ML, PRINIT, or ULS
ModelInfo	Model information	Default output	
NFactors	Number of factors suggested by each criterion	NFACTORS	
NObs	Number of observations read and used	Default output	
NormObliqueTrans	Normalized oblique transformation matrix	PROC EFA	ROTATE=PROMAX
ObliqueRotFactPat	Rotated factor pattern (standardized regression coefficients for predicting the variables from the factors)	PROC EFA	ROTATE= any oblique rotation
ObliqueTrans	Oblique transformation matrix	PROC EFA	ROTATE= any oblique rotation except promax
OrthRotFactPat	Rotated factor pattern	PROC EFA	ROTATE= any orthogonal rotation
OrthTrans	Orthogonal transformation matrix	PROC EFA	ROTATE= any orthogonal rotation
OutputCasTables	A special table that has information about all the data tables that are created during execution	DISPLAYOUT	
ParallelAnalysis	Parallel analysis results	NFACTORS	TYPE=PARALLEL
PriorCommun	Prior communalities	Default output	
ProcrustesTarget	Target matrix for Procrustes transformation	PROC EFA	ROTATE=PROMAX
ProcrustesTrans	Procrustes transformation matrix	PROC EFA	ROTATE=PROMAX
ReferenceAxisCorr	Reference axis correlations (partial correlations between the primary factors when all factors other than the two being correlated are partialed out)	PROC EFA	REFSTRUCT and ROTATE= any oblique rotation
ReferenceStructure	Reference structure (matrix of semipartial correlations between variables and common factors, removing from each common factor the effects of other common factors)	PROC EFA	REFSTRUCT and ROTATE= any oblique rotation
SignifTests	Significance tests	PROC EFA	METHOD=ML
SimpleStatistics	Simple statistics	Default output

Examples: EFA Procedure

The examples in this chapter are available in the GitHub repository located at https://github.com/sascommunities/doc-supplement-casstat.

Example 10.1: Estimating the Number of Factors or Components

(View the complete code for this example (efaex1.sas) in the example repository.)

This example shows how to use the EFA procedure to estimate either the number of common factors or the number of principal components that are likely to explain the observed correlations in a data set. It uses the simulated testdata data set that is described in the examples for the Principal Component Analysis action set in SAS Visual Statistics software. The data table is the result of multiplying two low-rank matrices, **A** and **B**, and adding random noise.

To create the data table testdata, you can modify the DATA step that is used in the Principal Component Analysis action set documentation. For this example, it is assumed that your libref is named mylib, but you can substitute any appropriately defined libref.

In this example, you want to determine how many latent factors are needed to explain the variation in the input data. The following statements perform this analysis:

```
proc efa data=mylib.testdata method=none;
   nfactors type=eigenvalue;
   nfactors type=proportion threshold=0.9;
run;
```

When you use PROC EFA to suggest the number of latent dimensions, you specify one or more NFACTORS statements. Each NFACTORS statement describes a criterion that is used to determine the number of factors to retain.

In this example, you specify two criteria. The first criterion is the eigenvalue criterion. This criterion is based on the eigenvalues of the reduced correlation matrix (that is, the correlation matrix of the input data, but with the diagonal elements replaced by the prior communality estimates). By default, any eigenvalue greater than 1 is assumed to indicate the existence of a latent factor. You can use the THRESHOLD= option to specify a threshold value to use instead of the default value.

The second criterion that you specify is the proportion criterion. This criterion is based on the cumulative fraction of the common variance of the input data set that is explained by the latent factors that correspond to each eigenvalue. In this example, you use the THRESHOLD= option to specify a threshold value of 0.9. At this threshold, the number of factors that the proportion criterion suggests is the smallest number of factors that are necessary to explain 90% of the common variance of the input data set.

By default, PROC EFA uses squared multiple correlations (SMC) for the prior communality estimates. This means that the prior communality estimate for each variable is the squared multiple correlation of that variable with all other variables. The prior communalities are placed on the diagonal of the data correlation matrix before the eigenvalues of that matrix are computed. You can use the PRIORS= option to specify different prior communality estimates.

The "Number of Observations" table in Output 10.1.1 summarizes the number of observations that are read from the input data table and the number of observations that are used for the analysis. For this analysis, these two numbers are the same. These numbers would be different if some observations were discarded from the analysis. PROC EFA uses only complete cases for analysis, so a record is discarded if any field contains a missing value.

Output 10.1.1 Number of Observations

The EFA Procedure

Number of Observations Read	1000000
Number of Observations Used	1000000

The "Simple Statistics" table in Output 10.1.2 summarizes the means and standard deviations of the variables that are included in the analysis.

Output 10.1.2 Simple Statistics

Simple Statistics

Variable	Mean	Standard Deviation
x1	0.00051958	2.03642
x2	0.00171	3.04429
x3	-0.00036170	1.25872
x4	0.00194	1.79332
x5	0.00058028	1.47249
x6	-0.00083852	1.52032
x7	0.00230	1.83223
x8	-0.00357	2.30643
x9	-0.00022835	2.13378
x10	0.00160	3.40267

The primary output of the analysis is shown in the "Determination of Number of Factors" table in Output 10.1.3. In this analysis, the results for both specified criteria suggest that three latent factors are sufficient to describe the input data.

In general, when you specify multiple criteria, PROC EFA must combine the results from all the active criteria to form a final estimate for the number of factors. By default, PROC EFA uses the minimum number

of factors among all the active criteria. You can use the NFACTORS= option to specify a different method to obtain a final estimate. You can use the STATUS= option to change a criterion from active to inactive.

A footnote at the bottom of the table summarizes the minimum and maximum number of factors that are determined by the active criteria. It also summarizes the mean and median values of these numbers. In this analysis, the two criteria suggest the same number of latent factors, so all four summary values are the same. Thus the final result of this analysis is that three factors should be retained.

Output 10.1.3 Number of Factors

Determination of Number of Factors		
Criterion	**Description**	**Factors**
1	Minimum Eigenvalue (Eigenvalue > 1.00)	3
2	Total Proportion (Threshold = 0.90)	3
Min = 3, Max = 3, Mean = 3, Median = 3		

Additional information about the eigenvalue and proportion criteria is presented in the "Eigenvalues of the Reduced Correlation Matrix" table in Output 10.1.4. For the proportion criteria, the number of factors is the minimum number that is required in order for the cumulative common variance to meet or exceed the user-specified threshold. The table shows that three factors are sufficient to explain approximately 93% of the cumulative common variance in the original data. Thus the proportion criterion with the option value THRESHOLD=0.90 produces an estimate of three factors. For the eigenvalue criterion, the third-largest eigenvalue is larger than 1.5, whereas the fourth-largest eigenvalue is much smaller than 1.0. For this reason, the eigenvalue criterion that is specified in this analysis suggests that three factors should be retained.

Output 10.1.4 Eigenvalues and Variance Explained

Eigenvalues of the Reduced Correlation Matrix				
	Eigenvalue	**Difference**	**Proportion**	**Cumulative**
1	5.822573	3.924604	0.5850	0.5850
2	1.897969	0.333507	0.1907	0.7757
3	1.564462	0.886826	0.1572	0.9329
4	0.677636	0.678439	0.0681	1.0009
5	-0.000804	0.000258	-0.0001	1.0009
6	-0.001062	0.000542	-0.0001	1.0008
7	-0.001604	0.000082164	-0.0002	1.0006
8	-0.001686	0.000107	-0.0002	1.0004
9	-0.001794	0.000669	-0.0002	1.0002
10	-0.002462		-0.0002	1.0000

In addition to estimating the number of latent factors, you can also use PROC EFA to estimate the number of principal components that are needed to approximate an input data set. For example, you might want to determine how many components you need to retain to approximate a prespecified proportion of the total variance in the original data set. The following statements perform this analysis:

```
proc efa data=mylib.testdata method=none priors=one;
   nfactors type=proportion threshold=0.90;
   nfactors type=proportion threshold=0.95;
   nfactors type=proportion threshold=0.99;
run;
```

These statements demonstrate how you can specify three different threshold values for the proportion criterion. Each of these threshold values is applied separately to estimate the number of factors in the input data set. The specification of multiple threshold values is a useful technique to assess the degree to which the analysis results are robust to different threshold values.

In this analysis, the PRIORS=ONE option is used to specify that the prior communality estimates for all variables should be set to 1. When you specify this option value, PROC EFA estimates the number of principal components that are needed to approximate the input data set.

The "Number of Observations" and "Simple Statistics" tables for this analysis are identical to those in the previous analysis. The "Determination of Number of Factors" table is shown in Output 10.1.5. Of the three specified threshold values, the first value produces an estimate that three factors should be retained, and the remaining two criteria produce estimates that four factors should be retained.

Output 10.1.5 Number of Factors

The EFA Procedure

Determination of Number of Factors

Criterion	Description	Factors
1	Total Proportion (Threshold = 0.90)	3
2	Total Proportion (Threshold = 0.95)	4
3	Total Proportion (Threshold = 0.99)	4
Min = 3, Max = 4, Mean = 4, Median = 4		

Additional information about the number of components that are suggested by these three criteria is presented in the "Eigenvalues of the Correlation Matrix" table in Output 10.1.6. As in the previous analysis, the proportion criterion examines the cumulative variance explained by eigenvalues and corresponding principal components. For this analysis, the principal components that correspond to the three largest eigenvalues explain just under 93% of the total variance of the input data set. Thus, an estimate of three components is obtained when you set the threshold value to 0.9. When you add a fourth component, the cumulative variance explained exceeds 99%, so that four components are estimated when you set the THRESHOLD= option to 0.95 or 0.99.

Output 10.1.6 Eigenvalues and Variance Explained

Eigenvalues of the Correlation Matrix

	Eigenvalue	Difference	Proportion	Cumulative
1	5.827238	3.924651	0.5827	0.5827
2	1.902587	0.333170	0.1903	0.7730
3	1.569417	0.887490	0.1569	0.9299
4	0.681927	0.676456	0.0682	0.9981
5	0.005471	0.001057	0.0005	0.9987
6	0.004414	0.001209	0.0004	0.9991
7	0.003205	0.000800	0.0003	0.9994
8	0.002405	0.000628	0.0002	0.9997
9	0.001777	0.000218	0.0002	0.9998
10	0.001559		0.0002	1.0000

Example 10.2: Principal Factor Analysis

(View the complete code for this example (efaex2.sas) in the example repository.)

This example shows how to use the EFA procedure to perform a principal factor analysis. It uses the socioeconomics data set that is described in the examples for the FACTOR procedure in SAS/STAT software. This data set contains five variables, which represent total population (Population), median years of school (School), total employment (Employment), miscellaneous professional services (Services), and median house value (HouseValue). Each observation represents one of twelve census tracts in the Los Angeles Standard Metropolitan Statistical Area.

For this example, it is assumed that your libref is named mylib, but you can substitute any appropriately defined libref.

"Example 44.2: Principal Factor Analysis" (Chapter 44, *SAS/STAT User's Guide*) and "Example 44.4: Maximum Likelihood Factor Analysis" (Chapter 44, *SAS/STAT User's Guide*) show that the socioeconomics data set is well described by a two-factor model. The following code uses PROC EFA to perform a principal factor analysis to extract two factors:

```
proc efa data=mylib.socioeconomics nfactors=2
   method=principal rotate=promax reorder;
run;
```

When you use PROC EFA to extract a known number of factors, you use the NFACTORS= option to specify that number of factors. In this example, you specify the METHOD=PRINCIPAL option to perform principal factor extraction. PROC EFA uses squared multiple correlations by default to estimate the prior communalities for an analysis. You can use the PRIORS= option to specify alternative prior communality estimates.

The factors that are initially extracted by this method are orthogonal. To facilitate the interpretation of these factors, you specify the ROTATE=PROMAX option to perform factor rotation by the promax method. By default, the promax rotation first computes an orthogonal varimax prerotation, which is followed by an oblique Procrustes rotation. You can use the PREROTATE= option to specify a different prerotation method, which can be either orthogonal or oblique.

Finally, you specify the REORDER option so that the rows of the various factor matrices are ordered in such a way that variables whose highest absolute loading is on the first factor are displayed first, followed by variables whose highest absolute loading is on the second factor, and so on.

The first outputs that PROC EFA prints are the "Model Information" table and the "Number of Observations" table. These are shown in Output 10.2.1. Together, these tables summarize important information about the input data that are analyzed, as well as the primary analysis options that you specified. Next, the "Simple Statistics" table in Output 10.2.2 summarizes the means and standard deviations of the analysis variables.

Output 10.2.1 Model Information and Number of Observations

The EFA Procedure

Model Information	
Data Source	SOCIOECONOMICS
Data Type	Raw
Prior Communalities	Squared Multiple Correlations
Factor Extraction	Principal Factor Method
Factor Rotation	Promax

Number of Observations Read	12
Number of Observations Used	12

Output 10.2.2 Simple Statistics

Simple Statistics

Variable	Mean	Standard Deviation
Population	6241.66667	3439.99427
School	11.44167	1.78654
Employment	2333.33333	1241.21153
Services	120.83333	114.92751
HouseValue	17000	6367.53128

The prior communality estimates are shown in the table in Output 10.2.3. The prior communalities represent initial estimates of the common variance for each analysis variable. (For more information about communalities and common variance, see the section "The Common Factor Model" on page 337.) The prior communalities are used to compute the reduced correlation matrix. The reduced correlation matrix is the observed correlation matrix for the analysis variables in which the diagonal entries of that matrix are replaced by the prior communalities.

Output 10.2.3 Prior Communalities

The EFA Procedure

Prior Communality Estimates				
Population	**School**	**Employment**	**Services**	**HouseValue**
0.96859160	0.82228514	0.96918082	0.78572440	0.84701921

Next, the eigenvalues of the reduced correlation matrix are computed. These eigenvalues are summarized in the "Preliminary Eigenvalues" table in Output 10.2.4. In this example, the first two largest positive eigenvalues of the reduced correlation matrix account for 101.31% of the common variance. This is possible because the reduced correlation matrix, in general, is not necessarily positive definite, and negative eigenvalues for the matrix are possible. A pattern like this adds further support to the assumption that you might not need more than two common factors in this analysis.

Output 10.2.4 Preliminary Eigenvalues

Eigenvalues of the Reduced Correlation Matrix: Total = 4.39280116 Average = 0.87856023				
	Eigenvalue	Difference	Proportion	Cumulative
1	2.734301	1.018232	0.6225	0.6225
2	1.716069	1.676506	0.3907	1.0131
3	0.039563	0.064086	0.0090	1.0221
4	-0.024523	0.048084	-0.0056	1.0165
5	-0.072608		-0.0165	1.0000

The principal factor pattern with the two extracted factors is displayed in Output 10.2.5. The Services variable has the largest loading on the first factor, and the Population variable has the smallest. The Population and Employment variables have large positive loadings on the second factor, and the HouseValue and School variables have large negative loadings.

Output 10.2.5 Factor Pattern

Factor Pattern		
	Factor1	Factor2
Services	0.87899	-0.15847
HouseValue	0.74215	-0.57806
Employment	0.71447	0.67936
School	0.71370	-0.55515
Population	0.62533	0.76621

The variance explained by the extracted factors is summarized in Output 10.2.6, and the final communality estimates are shown in Output 10.2.7.

Output 10.2.6 Variance Explained (Initial Solution)

Variance Explained by Each Factor	
Factor1	Factor2
2.7343008	1.7160687

Output 10.2.7 Final Communalities (Initial Solution)

Final Communality Estimates: Total = 4.450370				
Population	School	Employment	Services	HouseValue
0.97811334	0.81756387	0.97199928	0.79774304	0.88494998

Next, you want to rotate the factor pattern such that most variables would have zero loadings on most factors. In this example, you specified a promax rotation with a varimax prerotation. To yield the prerotated factor pattern, the initial factor loading matrix is postmultiplied by an orthogonal transformation matrix that satisfies the varimax criterion. This orthogonal transformation matrix, as well as the varimax-rotated factor pattern, is shown in Output 10.2.8. The rotation leads to small loadings of Population and Employment on the first factor and small loadings of HouseValue and School on the second factor. Services appears to have a larger

loading on the first factor than it has on the second factor, although both loadings are substantial. Hence, Services appears to be factorially complex.

The REORDER option helps you see the variable clusters clearly in the factor pattern. The first factor is associated more with the first three variables, HouseValue, School, and Services. The second factor is associated more with the last two variables, Population and Employment. For orthogonal factor solutions such as the current varimax-rotated solution, you can also interpret the values in the factor loading matrix as correlations. For example, HouseValue and Factor1 have a high correlation of 0.94, whereas Population and Factor1 have a low correlation of 0.03.

Output 10.2.8 Orthogonal Transformation and Factor Pattern (Prerotated Solution)

The EFA Procedure

Orthogonal Transformation Matrix

	1	2
1	0.78895	0.61446
2	-0.61446	0.78895

Rotated Factor Pattern

	Factor1	Factor2
HouseValue	0.94072	-0.00004
School	0.90419	0.00055
Services	0.79085	0.41509
Population	0.02255	0.98874
Employment	0.14625	0.97499

The variance explained by the prerotated factors, as well as the final communality estimates, is shown in Output 10.2.9. The variance explained by the factors is more evenly distributed in the varimax-rotated solution than in the unrotated solution. Indeed, this is a typical fact for any kind of factor rotation. In the current example, before the varimax rotation, the two factors explain 2.73 and 1.72, respectively, of the common variance (see Output 10.2.6). After the varimax rotation, the two rotated factors explain 2.35 and 2.10, respectively, of the common variance. However, the total variance explained by the factors remains unchanged after the varimax rotation. This invariance property is also observed for the communalities of the variables after the rotation, as you can see by comparing the current communality estimates in Output 10.2.6 to those in Output 10.2.7.

Output 10.2.9 Variance Explained and Final Communalities (Prerotated Solution)

Variance Explained by Each Factor

Factor1	Factor2
2.3498567	2.1005128

Final Communality Estimates: Total = 4.450370

Population	School	Employment	Services	HouseValue
0.97811334	0.81756387	0.97199928	0.79774304	0.88494998

Some factor analysts believe that common factors are seldom orthogonal. Thus an obliquely rotated factor solution might be more desirable, or at least it should be attempted. In the current example, you

specified the ROTATE=PROMAX option to perform a promax rotation, which allows factors to be correlated. Output 10.2.10 shows the Procrustes target, followed by the Procrustes transformation matrix. This is the matrix that transforms the varimax factor pattern so that the rotated pattern is as close as possible to the Procrustes target, which is created by exponentiating the elements of the prerotated factor pattern (while keeping the signs of the values). However, because the variances of factors must be fixed at 1 during the oblique transformation, a normalized version of the Procrustes transformation matrix is the one that is actually used in the transformation. This normalized transformation matrix is shown at the bottom of Output 10.2.10.

Output 10.2.10 Promax Rotation: Procrustes Target and Transformation Matrices

The EFA Procedure

Target Matrix for Procrustes Transformation

	Factor1	Factor2
HouseValue	1.00000	-0.00000
School	1.00000	0.00000
Services	0.69421	0.10045
Population	0.00001	1.00000
Employment	0.00326	0.96793

Procrustes Transformation Matrix

	1	2
1	1.04117	-0.09865
2	-0.10572	0.96303

Normalized Oblique Transformation Matrix

	1	2
1	0.73803	0.54202
2	-0.70555	0.86528

Using this transformation matrix leads to the promax-rotated factor solution, as shown in Output 10.2.11. After the promax rotation, the factors are no longer uncorrelated. As shown in the "Interfactor Correlations" table, the correlation of the two factors is now 0.20. In the unrotated and the varimax solutions, the two factors are not correlated.

Output 10.2.11 Promax Rotation: Factor Correlations and Rotated Factor Pattern

Interfactor Correlations

	Factor1	Factor2
Factor1	1.00000	0.20188
Factor2	0.20188	1.00000

Output 10.2.11 *continued*

Rotated Factor Pattern (Standardized Regression Coefficients)		
	Factor1	Factor2
HouseValue	0.95558	-0.09792
School	0.91842	-0.09352
Services	0.76053	0.33932
Population	-0.07908	1.00192
Employment	0.04799	0.97509

Unlike orthogonal factor solutions, where you can interpret the factor loadings as correlations between variables and factors, in oblique factor solutions such as the promax solution, you have to turn to the factor structure matrix to examine the correlations between variables and factors. Output 10.2.12 shows the factor structures for the promax-rotated solution. In this example, the factor structure matrix reflects a pattern similar to that of the factor pattern matrix shown in Output 10.2.11. The critical difference is that you can have the correlation interpretation only by using the factor structure matrix. For example, in the factor structure matrix, the correlation between Population and Factor 2 is 0.986. The corresponding value shown in the factor pattern matrix is 1.002, which you certainly cannot interpret as a correlation coefficient.

Output 10.2.12 Factor Structure

Factor Structure (Correlations)		
	Factor1	Factor2
HouseValue	0.93582	0.09500
School	0.89954	0.09189
Services	0.82903	0.49286
Population	0.12319	0.98596
Employment	0.24484	0.98478

When factors are correlated, the common variance explained by each factor is not as straightforward as it is in the case when the factors are uncorrelated. The contributions from the other factors must be either eliminated or ignored. Both computations are shown in Output 10.2.13.

When you ignore the other factor, the common variance explained by the promax-rotated factors is 2.45 and 2.20, respectively. In contrast with orthogonal factor solutions (such as the prerotated varimax solution), the variance explained by these promax-rotated factors (ignoring other factors) does not sum to the total communality estimate of 4.45 (see Output 10.2.14).

Also shown in Output 10.2.13 is the "Variance Explained by Each Factor, Eliminating Other Factors" table. The values in this table represent unique variances explained by the factors, partialing out the variances explained by all other factors (or eliminating all other factors, as the table title suggests). In the current example, Factor1 explains 2.25 of the variable variances, partialing out all variable variances explained by Factor2.

Output 10.2.13 Variance Explained

Variance Explained by Each Factor, Ignoring Other Factors	
Factor1	**Factor2**
2.4473495	2.2022803

Variance Explained by Each Factor, Eliminating Other Factors	
Factor1	**Factor2**
2.2480892	2.0030200

The communalities of the variables, as shown in Output 10.2.14, do not change from rotation to rotation. They are still the same set of communalities in the initial, varimax-rotated, and promax-rotated solutions. This is a basic fact about factor rotations: they redistribute the variance explained by the factors; the total variance explained by the factors for any variable (that is, the communality of the variable) remains unchanged.

Output 10.2.14 Final Communalities

Final Communality Estimates: Total = 4.450370				
Population	**School**	**Employment**	**Services**	**HouseValue**
0.97811334	0.81756387	0.97199928	0.79774304	0.88494998

Example 10.3: Iterative Factor Extraction

(View the complete code for this example (efaex3.sas) in the example repository.)

This example shows how to use the EFA procedure to perform an iterative factor analysis. It uses the socioeconomics data set that is described in the examples for the FACTOR procedure in SAS/STAT software. These are the same data that are analyzed in "Example 10.2: Principal Factor Analysis" on page 355.

For this example, it is assumed that your libref is named mylib, but you can substitute any appropriately defined libref.

In Example 10.2, the socioeconomics data set is used in a principal factor analysis. In that analysis, squared multiple correlations are used for prior communality estimates. After two factors are extracted, the factor pattern is used to compute updated estimates of the communalities. You might wonder whether this process can be repeated. That is, can you use the final communalities as prior communalities in a subsequent analysis? This is a motivation behind iterative methods of factor extraction.

The following code uses PROC EFA to perform an *iterative* principal factor analysis with squared multiple correlations for the prior communality estimates:

```
proc efa data=mylib.socioeconomics nfactors=2 method=prinit heywood;
run;
```

This code is very similar to the code in Example 10.2. The major difference is the use of the METHOD=PRINIT option here to specify an iterative principal factor extraction. This means that the

prior communalities are used to compute an initial factor pattern, which is then used to compute new communalities, which is then used to compute a new factor pattern, and so on. This process continues until the change in the estimated communalities is sufficiently small. You can use the CONVERGE= option to set a specific value for the convergence threshold. The default value is 0.001.

Practically speaking, communalities are squared correlations and so must be bounded above by 1.0. However, during the iterative process of factor extraction, it is possible for a communality to meet or exceed this upper bound. When a communality reaches this bound, it is called a Heywood case. When a communality exceeds this bound, it is called an ultra-Heywood case. (For more information about communalities and Heywood cases, see the section "Heywood Cases and Other Anomalies of Communality Estimates" on page 344.) In this analysis, you use the HEYWOOD option to request that the communalities be bounded above by 1.0 during the iterative process. This means that if a communality exceeds 1.0 during the iterations, it is replaced by a value of 1.0. If you omit the HEYWOOD option, then by default PROC EFA terminates with an error when it encounters a Heywood or ultra-Heywood case.

Note that no rotation is requested in the current analysis. This is simply for clarity of exposition, so that this example can focus on iterative extraction methods. You can use the ROTATE= option to request a rotation for a factor pattern that is extracted using an iterative procedure in the same manner that you would for a noniterative extraction method.

The initial outputs that are produced by PROC EFA are shown in Output 10.3.1 through Output 10.3.4. These are identical to the outputs that are produced when you perform a noniterative principal factor analysis. For a discussion of these outputs, see Example 10.2.

Output 10.3.1 Model Information and Number of Observations

The EFA Procedure

Model Information	
Data Source	SOCIOECONOMICS
Data Type	Raw
Prior Communalities	Squared Multiple Correlations
Factor Extraction	Iterative Principal Factor Method
Factor Rotation	None

Number of Observations Read	12
Number of Observations Used	12

Output 10.3.2 Simple Statistics

Simple Statistics

Variable	Mean	Standard Deviation
Population	6241.66667	3439.99427
School	11.44167	1.78654
Employment	2333.33333	1241.21153
Services	120.83333	114.92751
HouseValue	17000	6367.53128

Output 10.3.3 Prior Communalities

The EFA Procedure

Prior Communality Estimates				
Population	School	Employment	Services	HouseValue
0.96859160	0.82228514	0.96918082	0.78572440	0.84701921

Output 10.3.4 Preliminary Eigenvalues

Preliminary Eigenvalues: Total = 4.39280116 Average = 0.87856023				
	Eigenvalue	Difference	Proportion	Cumulative
1	2.734301	1.018232	0.6225	0.6225
2	1.716069	1.676506	0.3907	1.0131
3	0.039563	0.064086	0.0090	1.0221
4	-0.024523	0.048084	-0.0056	1.0165
5	-0.072608		-0.0165	1.0000

The iterative factor extraction process is summarized in Output 10.3.5. You can see that a Heywood case is encountered in the eighth iteration of the algorithm and remains in place until the algorithm converges.

Output 10.3.5 Iteration History

Iteration	Change	Communalities				
1	0.0379	0.97811	0.81756	0.97200	0.79774	0.88495
2	0.0235	0.98398	0.80831	0.97162	0.80096	0.90845
3	0.0161	0.98814	0.79921	0.97003	0.80132	0.92453

8	0.0040	1.00000	0.77442	0.96030	0.79867	0.96086
9	0.0031	1.00000	0.77232	0.95884	0.79834	0.96395
10	0.0024	1.00000	0.77072	0.95785	0.79810	0.96635
11	0.0019	1.00000	0.76949	0.95717	0.79791	0.96822
12	0.0015	1.00000	0.76854	0.95671	0.79776	0.96967
13	0.0011	1.00000	0.76782	0.95640	0.79764	0.97080
14	0.0009	1.00000	0.76726	0.95618	0.79754	0.97168

The eigenvalues of the reduced correlation matrix, the factor pattern, and the variance explained by the extracted factors are summarized in Output 10.3.6, Output 10.3.7, and Output 10.3.8, respectively. The final communality estimates are displayed in Output 10.3.9. In that table, you can see that the final communality estimate for Population is an ultra-Heywood case. Although the HEYWOOD option causes PROC EFA to replace out-of-bound communality estimates with ones during the iterative steps, this is not sufficient to effectively constrain the final community estimates after factoring the reduced correlation matrix. Consequently, ultra-Heywood cases might still be observed for the iterative principal factor method even if you specify this option. The ultra-Heywood case implies that some unique factor has negative variance—a clear indication that the factor solution in this case is problematic, if not invalid.

Output 10.3.6 Final Eigenvalues

Eigenvalues of the Reduced Correlation Matrix: Total = 4.49264739 Average = 0.89852948				
	Eigenvalue	Difference	Proportion	Cumulative
1	2.755916	1.016328	0.6134	0.6134

Output 10.3.9 Final Communalities

Final Communality Estimates: Total = 4.495504				
Population	School	Employment	Services	HouseValue
1.00285106	0.76725612	0.95618481	0.79753541	0.97167647

You might instead consider an alternative factor extraction method to see if you can obtain a different factor solution. The following code uses maximum likelihood (ML) estimation for factor extraction:

```
proc efa data=mylib.socioeconomics nfactors=2 method=ml heywood;
run;
```

Like iterative principal factor extraction, the ML method is an iterative method. The iteration history is summarized in Output 10.3.10. The ML method converges in only 6 iterations, compared to the 14 iterations that are required for the iterative principal factor extraction method. Both methods encounter a Heywood case; the ML method encounters the Heywood case in the very first iteration.

Output 10.3.10 Maximum Likelihood Iteration History

The EFA Procedure

Iteration	Criterion	Ridge	Change	Communalities			
1	0.4092306	0.0000	0.0908	1.00000	0.79229	0.93333	0.80068	0.93780
2	0.3088104	0.0000	0.0255	1.00000	0.79690	0.95885	0.81497	0.93545
3	0.3069206	0.0000	0.0130	1.00000	0.80872	0.95904	0.81890	0.92249
4	0.3067496	0.0000	0.0035	1.00000	0.80887	0.95952	0.81536	0.92334
5	0.3067333	0.0000	0.0013	1.00000	0.80995	0.95952	0.81589	0.92207
6	0.3067316	0.0000	0.0004	1.00000	0.80992	0.95956	0.81552	0.92219

In ML factor analysis, the eigenvalues of the *weighted* reduced correlation matrix are computed. The weights that are used are the reciprocals of the unique error variances (that is, one minus the communalities). When a Heywood case is encountered, the weight for that variable is not defined. For this reason, one of the eigenvalues in the "Eigenvalues of the Weighted Reduced Correlation Matrix" table in Output 10.3.11 is missing.

Output 10.3.11 Maximum Likelihood Final Eigenvalues

Eigenvalues of the Weighted Reduced Correlation Matrix: Total = 19.8268757 Average = 4.95671892				
	Eigenvalue	Difference	Proportion	Cumulative
1	.	.	.	.
2	19.826875	19.283728	1.0000	1.0000
3	0.543148	0.582869	0.0274	1.0274
4	-0.039721	0.463706	-0.0020	1.0254
5	-0.503427		-0.0254	1.0000

As with iterative principal factor extraction, the ML method encounters a Heywood case. However, unlike the iterative principal factor results, the converged solution for the ML method has only a Heywood case rather than an ultra-Heywood case. You can see this in the "Final Communality Estimates" table in Output 10.3.13. Although a Heywood case does not necessarily invalidate a factor solution, it should raise suspicion and requires further investigation.

Output 10.3.12 Maximum Likelihood Solution

Eigenvalues of the Weighted Reduced Correlation Matrix: Total = 19.8268757 Average = 4.95671892				
	Eigenvalue	Difference	Proportion	Cumulative
1	.	.	.	.

Example 10.4: Extracting and Interpreting Solutions with Maximum Likelihood Factor Analysis

(View the complete code for this example (efaex4.sas) in the example repository.)

This example shows how to use the EFA procedure to perform maximum likelihood factor analysis. It uses the jobratings data set that is described in the examples for the FACTOR procedure in SAS/STAT software. These are the same data that are analyzed in the section "Getting Started: EFA Procedure" on page 315.

For this example, it is assumed that your libref is named mylib, but you can substitute any appropriately defined libref.

In Example 10, the jobratings data set is analyzed to determine the number of latent factors that are likely to explain the data. The results of that analysis indicate that two or three factors are likely to explain the observed covariance among the variables. In the current example, PROC EFA is used to extract and rotate a factor pattern that has either two or three common factors.

First, you can use the following code to extract and rotate a factor pattern that has two factors:

```
proc efa data=mylib.jobratings nfactors=2 method=ml
   rotate=quartimin reorder fuzz=0.4;
run;
```

You use the NFACTORS= option to specify the number of factors to extract in the analysis. In this example, you specify the METHOD=ML option to perform a maximum likelihood (ML) factor analysis. The factors that are initially extracted by the ML method are orthogonal. To facilitate the interpretation of these factors, you specify the ROTATE=QUARTIMIN option to request factor rotation by the quartimin method. This is an oblique rotation, so the rotated factors might not be orthogonal. Finally, you specify the REORDER and FUZZ= options to further facilitate the interpretation of the factor solution. The REORDER option orders the rows of the various factor matrices such that variables whose highest absolute loading is on the first factor are displayed first, followed by variables whose highest absolute loading is on the second factor, and so on. The FUZZ=0.4 option causes all factor loadings less than 0.4 in magnitude to be printed as missing.

The first outputs that PROC EFA prints are the "Model Information" table and the "Number of Observations" table. These are shown in Output 10.4.1. Together, these tables summarize important information about the input data that are analyzed, as well as the primary analysis options that you specified. Next, the "Simple Statistics" table in Output 10.4.2 summarizes the means and standard deviations of the analysis variables.

Output 10.4.1 Model Information and Number of Observations

The EFA Procedure

Model Information	
Data Source	JOBRATINGS
Data Type	Raw
Prior Communalities	Squared Multiple Correlations
Factor Extraction	Maximum Likelihood Method
Factor Rotation	Quartimin

Number of Observations Read	103
Number of Observations Used	103

Output 10.4.2 Simple Statistics

Simple Statistics

Variable	Mean	Standard Deviation
Communication Skills	6.65049	1.76407
Problem Solving	6.63107	1.59035
Learning Ability	6.99029	1.33941
Judgment under Pressure	6.73786	1.73183
Observational Skills	6.93204	1.76158
Willingness to Confront Problems	7.29126	1.52516
Interest in People	6.70874	1.89235
Interpersonal Sensitivity	6.62136	1.76077
Desire for Self-Improvement	6.57282	1.72980

Physical Ability	7.20388	1.55525
Integrity	7.21359	1.84524

Prior communality estimates are shown in the table in Output 10.4.3. For this analysis, the prior communalities are the squared multiple correlations of each analysis variable with the other variables. This is the default setting for PROC EFA. You can use the PRIORS= option to change the default.

Output 10.4.3 Prior Communalities

The EFA Procedure

Prior Communality Estimates

Communication Skills	Problem Solving	Learning Ability	Judgment under Pressure	Observational Skills	Willingness to Confront Problems	Interest in People	Interpersonal Sensitivity
0.62981394	0.58657431	0.61009871	0.63766021	0.67187583	0.64779805	0.75641519	0.75584891

Desire for Self-Improvement	Appearance	Dependability	Physical Ability	Integrity
0.57460176	0.45505304	0.63449045	0.42245324	0.68195454

The prior communalities represent initial estimates of the common variance for each analysis variable. (For more information about communalities and common variance, see the section "The Common Factor Model" on page 337.) The prior communalities are used to compute the reduced correlation matrix.

Next, the eigenvalues of the reduced correlation matrix are computed. In fact, for ML factor analysis, the eigenvalues of the *weighted* reduced correlation matrix are computed. The weights that are used are the reciprocals of the unique error variances (that is, one minus the communalities). These eigenvalues are summarized in the "Preliminary Eigenvalues" table in Output 10.4.4. This table suggests that two factors are sufficient to explain approximately 96.6% of the common variance in the original data, whereas three factors are required in order for the cumulative variance explained to exceed 1.0. For a more detailed investigation of the tools that you can use to investigate the number of factors in the jobratings data set, see Example 10.

Output 10.4.4 Preliminary Eigenvalues

Preliminary Eigenvalues:
Total = 23.3301805 Average = 1.79462927

	Eigenvalue	Difference	Proportion	Cumulative
1	17.712722	12.878127	0.7592	0.7592
2	4.834595	3.455987	0.2072	0.9664

13	-0.533685		-0.0229	1.0000

ML factor analysis is an iterative procedure in which the prior communality estimates are used to compute the reduced the correlation matrix, then common factors are extracted from the reduced correlation matrix, and finally those common factors are used to compute updated communalities. This process is repeated until the communalities converge. A summary of this iterative process is shown in Output 10.4.5.

Output 10.4.5 Iteration History

Iteration	Criterion	Ridge	Change	Communalities									
1	1.1432750	0.0000	0.1624	0.56731	0.45839	0.54823	0.56927	0.69972	0.67780	0.80341	0.82730	0.56493	0.34689

Integrity	0.68494568	3.17353979

To facilitate the interpretation of the factor solution, it is often helpful to rotate the initial factor pattern. For the current analysis, a factor rotation by the quartimin method was specified. This is an oblique rotation,

so the rotated factors are likely to be correlated. The oblique transformation matrix (that is, the matrix that maps the initial factor pattern into the rotated factor pattern) is shown in Output 10.4.12, as is the "Interfactor Correlations" table, which summarizes the correlations between the rotated factors. For this analysis, the two factors are moderately correlated with each other.

Output 10.4.12 Oblique Transformation Matrix

The EFA Procedure

Oblique Transformation Matrix		
	1	2
1	0.50933	0.64767
2	1.02518	-0.94389

Interfactor Correlations		
	Factor1	Factor2
Factor1	1.00000	0.48670
Factor2	0.48670	1.00000

The rotated factor pattern is shown in Output 10.4.13. Again, the FUZZ= option causes factor loadings whose absolute values are less than 0.4 to be printed as missing. Such smaller factor loadings are not considered to be salient, and printing the values as missing makes it easier to distinguish the relationships between the analysis variables and the computed factors. In the rotated factor pattern, almost all variables load primarily on one factor (Dependability is the exception). The factor pattern can be interpreted as the standardized regression coefficients for predicting the effects of the factors on the variables.

Output 10.4.13 Rotated Factor Pattern

Rotated Factor Pattern (Standardized Regression Coefficients)		
	Factor1	Factor2
Observational Skills	0.91294	.
Willingness to Confront Problems	0.90372	.
Learning Ability	0.75778	.
Desire for Self-Improvement	0.62848	.

Appearance	0.34463311	1.52589948
Dependability	0.63877379	2.76805050
Physical Ability	0.27320906	1.37572027
Integrity	0.68494568	3.17353979

To fully investigate the possibility that three factors rather than just two should be extracted, you can repeat the preceding analysis and change only the number of factors. The following code performs such an analysis:

```
proc efa data=mylib.jobratings nfactors=3 method=ml
   rotate=quartimin reorder fuzz=0.4;
run;
```

Much of the initial analysis is the same as when two factors are extracted. First, the prior communalities are computed and used to form the reduced correlation matrix. This reduced correlation matrix is the input for an iterative process in which the final communalities and the initial factor pattern are computed.

The tables in Output 10.4.17 show the tests of significance and measures of fit when three factors are extracted from the jobratings data set. You can see that Akaike's information criterion obtains a lower value for the three-factor model than for the two-factor model. On the other hand, Schwarz's Bayesian criterion obtains a lower value for the two-factor model. Thus there is still ambiguity regarding the number of factors that should be estimated from the data.

Output 10.4.17 Significance Tests and Measures of Fit (Three-Factor Model)

The EFA Procedure

Significance Tests Based on 103 Observations

Test	DF	Chi-Square	Pr > ChiSq
H0: No common factors	78	852.5129	<.0001
HA: At least one common factor			
H0: 3 Factors are sufficient	42	63.3931	0.0181
HA: More factors are needed			

Chi-Square without Bartlett's Correction	68.18380
Akaike's Information Criterion	-15.81620
Schwarz's Bayesian Criterion	-126.47482
Tucker and Lewis's Reliability Coefficient	0.94870

The initial factor pattern for the three-factor solution is shown in Output 10.4.18. As before, the quartimin rotation is applied to this initial factor pattern. The "Oblique Transformation Matrix" and "Interfactor Correlations" tables are shown in Output 10.4.19. For the three-factor solution, the first and third factors are moderately correlated with each other.

Output 10.4.18 Factor Pattern

Physical Ability	0.48145	.	.
Willingness to Confront Problems	0.57538	0.58409	.

Values less than 0.4 are not printed.

Output 10.4.19 Oblique Transformation Matrix

The EFA Procedure

Oblique Transformation Matrix

	1	2	3
1	0.41909	0.58067	0.27177
2	0.82170	-0.92004	0.17477
3	0.79867	0.17078	-1.14008

Interfactor Correlations

	Factor1	Factor2	Factor3
Factor1	1.00000	0.39510	0.52069
Factor2	0.39510	1.00000	0.32454
Factor3	0.52069	0.32454	1.00000

The rotated factor pattern is shown in Output 10.4.20. This factor pattern is qualitatively similar to the rotated factor pattern for the two-factor solution. Each factor explains a subset of the analysis variables, and each analysis variable loads primarily on one or two of the common factors.

Output 10.4.20 Rotated Factor Pattern

Rotated Factor Pattern (Standardized Regression Coefficients)			
	Factor1	Factor2	Factor3
Observational Skills	0.88114	.	.
Willingness to Confront Problems	0.77606	.	.
Desire for Self-Improvement	0.65025	.	.
Dependability	0.54878	0.41841	.

Judgment under Pressure	.	0.46714	0.44509
Problem Solving	.	.	0.77844
Communication Skills	.	.	0.45834

Values less than 0.4 are not printed.

Finally, the common variance explained by the factors is summarized in the tables in Output 10.4.15.

Output 10.4.21 Variance Explained

Variance Explained by Each Factor, Ignoring Other Factors		
Factor	Weighted	Unweighted
Factor1	15.184488	5.030941
Factor2	16.519540	4.038321
Factor3	11.157355	3.441515

Variance Explained by Each Factor, Eliminating Other Factors		
Factor	Weighted	Unweighted
Factor1	6.125759	2.123909
Factor2	10.228793	2.177506
Factor3	3.043214	0.904367

In this example, even after you extract and rotate a two-factor model and a three-factor model, there remains some ambiguity about which solution you should prefer. In this case, you might justify your decision by determining which solution is easier to interpret or is more consistent with existing theory or future experiments. You should also consider the possibility that the common factor model is not appropriate for the current data. In that case, you might consider a more complex model, such as a structural equation model.

Overview: FREQTAB Procedure

The FREQTAB procedure produces one-way to *n*-way frequency and crosstabulation (contingency) tables, together with a variety of tests and measures to analyze these tables.

For one-way frequency tables, PROC FREQTAB provides chi-square goodness-of-fit tests for equal proportions and for specified null proportions. It also provides several types of confidence limits for binomial proportions and binomial proportion tests (which include noninferiority and equivalence tests).

For two-way crosstabulation tables, PROC FREQTAB computes a variety of statistics to examine the relationships between the two classification variables. These statistics include the following:

- chi-square tests and measures
- measures and tests of association
- measures and tests of agreement
- tests for trend
- Cochran-Mantel-Haenszel statistics

For 2×2 tables, PROC FREQTAB provides several confidence limit types and tests for the following statistics:

- risk (proportion) differences
- odds ratios
- relative risks

For multiway (*n*-way) tables, PROC FREQTAB performs stratified analysis by computing statistics within strata (two-way tables) and across strata. These statistics include Cochran-Mantel-Haenszel statistics and measures of agreement. For multiway 2×2 tables, PROC FREQTAB provides confidence limits and tests for the common (stratified) risk difference, odds ratio, and relative risks.

By default, PROC FREQTAB computes asymptotic standard errors, confidence limits, and tests. Exact tests and confidence limits are also available for many statistics and measures.

PROC FREQTAB Features

The FREQTAB procedure offers the following functionality:

- provides TABLES statements to specify frequency and crosstabulation tables
- provides options for statistical analyses of frequency and crosstabulation tables
- provides an EXACT statement for exact tests and confidence limits
- provides a TEST statement for tests of measures of association and agreement
- provides a WEIGHT statement for weighted analyses
- produces ODS tables of tabulation and statistical analysis results
- uses ODS graphics to produce statistical plots as part of the output

Because the FREQTAB procedure constructs the frequency and crosstabulation tables on CAS, it also does the following:

- enables you to construct tables on a cluster of machines that distribute the data and the computations
- enables you to construct tables in single-machine mode on CAS
- exploits all the available cores and concurrent threads for table construction. For information about how PROC FREQTAB uses threads, see the section "Multithreading" on page 102 in Chapter 2, "Shared Concepts."

PROC FREQTAB Compared with the FREQ Procedure

The FREQTAB procedure provides tabulation and statistical analysis capabilities that are very similar to the capabilities of the FREQ procedure in SAS/STAT software. Table 11.1 shows the major functional similarities and differences between these two procedures.

Table 11.1 Comparison of PROC FREQTAB and PROC FREQ

Feature	PROC FREQTAB	PROC FREQ
Provides statistical analysis of frequency and crosstabulation tables	Yes	Yes
Provides OUT=, OUTPUT, and ODS output data sets	Yes	Yes
Threading	Executes on multiple threads	Executes on a single thread
Supports MISSING option	In PROC FREQTAB statement	In TABLES statements
Supports SPARSE option	No	Yes
Supports CHISQ(TESTP=*data-table*)	No	Yes

Using CAS Sessions and CAS Engine Librefs

SAS Cloud Analytic Services (CAS) is the analytic server and associated cloud services in SAS Viya. This section describes how to create a CAS session and set up a CAS engine libref that you can use to connect to the CAS session. It assumes that you have a CAS server already available; contact your system administrator if you need help starting and terminating a server. This CAS server is identified by specifying the host on which it runs and the port on which it listens for communications. To simplify your interactions with this CAS server, the host information and port information for the server are stored as SAS option values that are retrieved automatically whenever this CAS server needs to be accessed. You can examine the host and port values for the server at your site by using the following statements:

```
proc options option=(CASHOST CASPORT);
run;
```

In addition to starting a CAS server, your system administrator might also have created a CAS session and a CAS engine libref for your use. You can define your own sessions and CAS engine librefs that connect to the CAS server as shown in the following statements:

```
cas mysess;
libname mylib cas sessref=mysess;
```

The CAS statement creates the CAS session named mysess, and the LIBNAME statement creates the mylib CAS engine libref that you use to connect to this session. It is not necessary to explicitly name the CASHOST and CASPORT of the CAS server in the CAS statement, because these values are retrieved from the corresponding SAS option values.

If you have created the mysess session, you can terminate it by using the TERMINATE option in the CAS statement as follows:

```
cas mysess terminate;
```

For more information about the CAS and LIBNAME statements, see the section “Introduction to Shared Concepts” on page 6 in Chapter 2, “Shared Concepts.”

Getting Started: FREQTAB Procedure

(View the complete code for this example at https://github.com/sascommunities/doc-supplement-casstat/tree/main/Examples/freqtgs.sas.)

This example shows you how to use the FREQTAB procedure to construct crosstabulation tables and produce chi-square statistics and measures of association.

The data table mylib.School_Survey consists of hypothetical data that are based on a customer satisfaction survey for a school information system. This data table includes the following variables for the survey respondents: ID (respondent identification), Response, SchoolType, and State. Figure 11.1 displays the first 20 observations of the data table.

Figure 11.1 School_Survey Data Table (First 20 Observations)

Obs	ID	Response	SchoolType	State
1	26629	Satisfied	Middle School (Public)	TN
2	25834	Neutral	High School (Public)	TN
3	14821	Very Satisfied	High School (Private)	NC
4	4153	Neutral	Middle School (Private)	GA
5	6185	Very Satisfied	High School (Private)	GA
6	6164	Unsatisfied	High School (Public)	GA
7	6386	Neutral	Middle School (Public)	GA
8	1011	Neutral	High School (Private)	GA
9	28916	Very Satisfied	High School (Private)	TN
10	10601	Neutral	High School (Public)	NC
11	17900	Satisfied	High School (Private)	NC
12	2935	Unsatisfied	High School (Private)	GA
13	9799	Unsatisfied	High School (Private)	NC
14	23754	Very Satisfied	Middle School (Public)	TN
15	9516	Neutral	Middle School (Public)	NC
16	4614	Very Unsatisfied	Middle School (Private)	GA
17	12443	Unsatisfied	Middle School (Public)	NC
18	5356	Very Satisfied	High School (Public)	GA
19	15189	Unsatisfied	High School (Private)	NC
20	3309	Satisfied	High School (Public)	GA

NOTE: Input data must be in a CAS table that is accessible in your CAS session. You must refer to this table by using a two-level name. The first level must be a CAS engine libref, and the second level must be the table name. For more information, see the sections "Using CAS Sessions and CAS Engine Librefs" on page 7 and "Loading a SAS Data Set onto a CAS Server" on page 7 in Chapter 2, "Shared Concepts."

The following PROC FREQTAB statements request a two-way crosstabulation of SchoolType and Response. These statements assume that your libref is named mylib, but you can substitute any appropriately defined libref.

```
proc freqtab data=mylib.School_Survey;
   tables SchoolType * Response /
      crosslist chisq measures(cl);
run;
```

The PROC FREQTAB statement invokes the procedure and identifies the data table to be analyzed. The TABLES statement requests a two-way crosstabulation of SchoolType and Response. The table request syntax in PROC FREQTAB is identical to the table request syntax in the FREQ procedure. You can specify one-way, two-way, and multiway table requests. You can specify more than one table request in the same TABLES statement, and you can specify multiple TABLES statements in the same invocation of the procedure.

The CROSSLIST option displays the crosstabulation table in column format; by default, PROC FREQTAB displays crosstabulation tables in table cell format. The CHISQ option requests chi-square tests, and the MEASURES option requests measures of association for this two-way crosstabulation table. The MEASURES(CL) option requests confidence limits for the measures of association.

Figure 11.2 shows the crosstabulation table of SchoolType by Response. You can customize the contents of this table by specifying options in the TABLES statement. For example, the NOCOL option suppresses the column percentages, the EXPECTED option displays the expected cell frequencies (under independence), and the STDRES option displays the standardized residuals.

Figure 11.2 Crosstabulation Table

The FREQTAB Procedure

Table of SchoolType by Response

SchoolType	Response	Frequency	Percent	Row Percent	Column Percent
Middle School (Private)	Very Satisfied	594	1.83	15.77	12.05

Sample Size = 32459

PROC FREQTAB can produce plots as part of its output by using ODS Graphics. The following statements show how to produce a frequency plot and a mosaic plot for a two-way crosstabulation table. The ODS GRAPHICS ON statement enables ODS Graphics, which is required in order to produce plots.

The PLOTS=FREQPLOT option in the TABLES statement requests a frequency plot of the two-way table of Response by SchoolType. The TWOWAY=CLUSTER *plot-option* requests a cluster grouped bar chart. The ORIENT=H *plot-option* specifies horizontal orientation, which places the variable levels on the Y-axis and the percentages on the X-axis. The SCALE=GROUPPERCENT *plot-option* requests a plot of group (column) percentages (instead of frequencies).

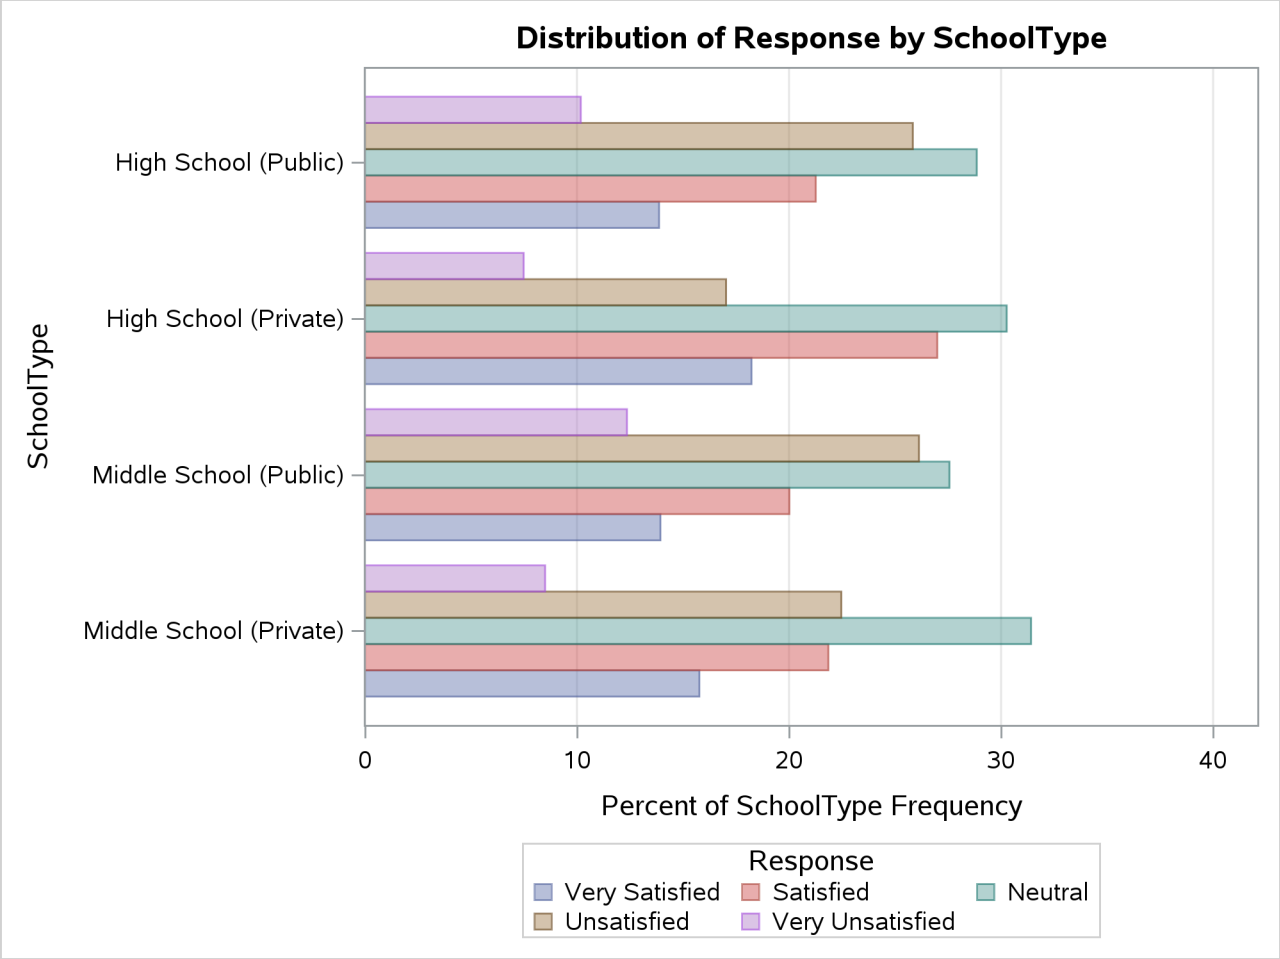
The PLOTS=MOSAICPLOT option requests a mosaic plot of Response by SchoolType. The COLORSTAT=STDRES *plot-option* colors the mosaic plot tiles according to the standardized residuals of the corresponding table cells.

```
ods graphics on;
proc freqtab data=mylib.School_Survey;
   tables Response * SchoolType /
      plots=(freqplot(twoway=cluster orient=h scale=grouppercent)
```

```
            mosaicplot(colorstat=stdres));
run;
ods graphics off;
```

Figure 11.5 displays the two-way frequency plot of SchoolType and Response. Figure 11.6 displays the mosaic plot of this crosstabulation.

Figure 11.5 Frequency Plot (Grouped Bar Chart)



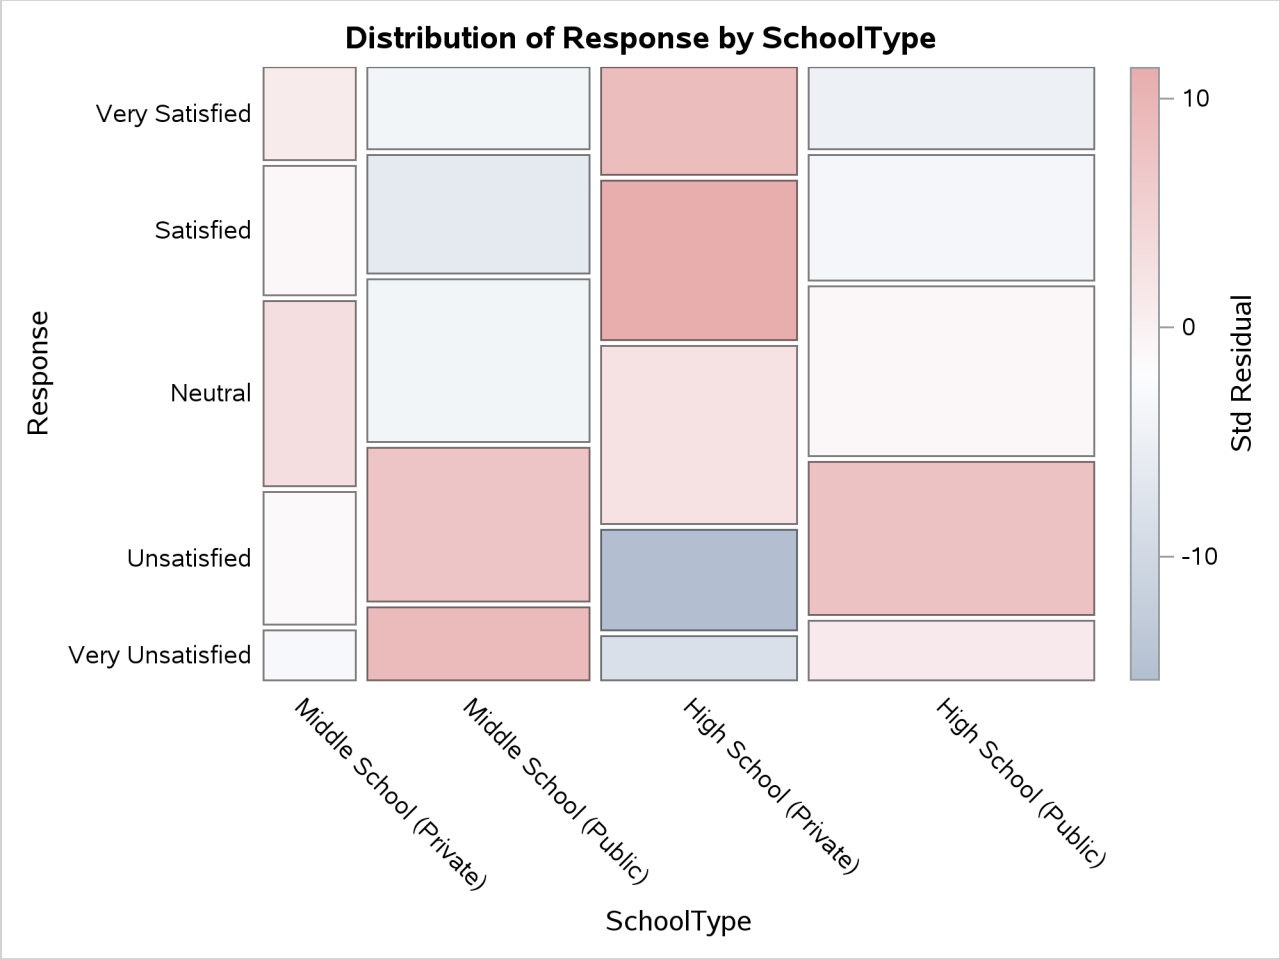


Figure 11.6 Mosaic Plot

The following PROC FREQTAB statements produce a multiway table of State by SchoolType by Response. The TABLES statement requests the multiway table in which SchoolType is the row variable, Response is the column variable, and State is the stratum variable. This request produces a separate two-way table of SchoolType by Response for each level (stratum) of the variable State. The CMH option in the TABLES statement requests stratified analysis, which adjusts for the effect of State.

```
proc freqtab data=mylib.School_Survey;
   tables State * SchoolType * Response / cmh;
run;
```

Figure 11.7 displays the two-way table of SchoolType and Response for State = 'GA'. PROC FREQTAB also produces two-way tables for the other states, but these results are not displayed here. Figure 11.8 displays the CMH summary statistics.

Figure 11.7 Two-Way Table for State=GA

The FREQTAB Procedure

2	Row Mean Scores Differ	3	406.7786	<.0001
3	General Association	12	508.7656	<.0001

Total Sample Size = 32459

Syntax: FREQTAB Procedure

The following statements are available in the FREQTAB procedure:

PROC FREQTAB < *options* > ;
BY *variables* ;
EXACT *statistic-options* < / *computation-options* > ;
OUTPUT < **OUT=***data-table* > *output-options* ;
TABLES *requests* < / *options* > ;
TEST *options* ;
WEIGHT *variable* < / *option* > ;

The PROC FREQTAB statement is the only required statement for the FREQTAB procedure. If you specify the following statements, PROC FREQTAB produces a one-way frequency table for each variable in the most recently created data table.

```
proc freqtab;
run;
```

Table 11.2 summarizes the basic functions of the procedure statements. The following sections provide detailed syntax information for the BY, EXACT, OUTPUT, TABLES, TEST, and WEIGHT statements in alphabetical order after the description of the PROC FREQTAB statement.

Table 11.2 Summary of PROC FREQTAB Statements

Statement	Description
BY	Provides separate analyses for each BY group
EXACT	Requests exact tests
OUTPUT	Requests an output data set of statistics
TABLES	Specifies tables and requests analyses
TEST	Requests tests for measures of association and agreement
WEIGHT	Identifies a weight variable

PROC FREQTAB Statement

PROC FREQTAB < *options* > ;

The PROC FREQTAB statement invokes the FREQTAB procedure. Optionally, it also identifies the input data table. By default, the procedure uses the most recently created data table.

Table 11.3 lists the *options* available in the PROC FREQTAB statement. Descriptions of the *options* follow in alphabetical order.

Table 11.3 PROC FREQTAB Statement Options

Option	Description
COMPRESS	Begins the next one-way table on the current page
DATA=	Names the input data table
FORMCHAR=	Specifies outline and cell-divider characters for cell-format crosstabulation tables
MISSING	Treats missing values as a valid level
MISSPRINT	Displays missing levels
NLEVELS	Displays the number of levels for each TABLES statement variable
NOPRINT	Suppresses all displayed output
ORDER=	Specifies the order for reporting variable values
PAGE	Displays one table per page

You can specify the following *options*:

COMPRESS
begins display of the next one-way frequency table on the same page as the preceding one-way table if there is enough space to begin the table. By default, the next one-way table begins on the current page only if the entire table fits on that page. The COMPRESS option is not valid with the PAGE option.

DATA=*libref.data-table*
names the input data table for PROC FREQTAB to use. The default is the most recently created data table. *libref.data-table* is a two-level name, where

libref refers to a collection of information that is defined in the LIBNAME statement and includes the library, which includes a path to the data, and a session identifier, which defaults to the active session but which can be explicitly defined in the LIBNAME statement. For more information about *libref*, see the section "Using CAS Sessions and CAS Engine Librefs" on page 382.

data-table specifies the name of the input data table.

FORMCHAR(1,2,7)=*'formchar-string'*
defines the characters to use to construct cell outlines and dividers for crosstabulation tables. This option affects only the SAS monospace output destination.

PROC FREQTAB uses 3 of the 20 formatting characters that SAS provides. You can specify three characters in *formchar-string* to draw the vertical separators (1), the horizontal separators (2), and the vertical-horizontal intersections (7) in crosstabulation tables. By default, PROC FREQTAB uses FORMCHAR(1,2,7)='|-+'. Table 11.4 summarizes the formatting characters that PROC FREQTAB uses.

Table 11.4 Formatting Characters Used by PROC FREQTAB

Position	Default	Used to Draw
1	|	Vertical separators
2	-	Horizontal separators
7	+	Intersections of vertical and horizontal separators

To produce crosstabulation tables that have no cell outlines or dividers, you can specify all blanks in *formchar-string*—for example, FORMCHAR(1,2,7)=‘ ’ (three blanks).

You can use any characters in *formchar-string*. If you use hexadecimal characters, you must put **x** after the closing quotation mark. For information about which hexadecimal codes to use for which characters, see the documentation for your hardware.

For more information about formatting characters, see the TABULATE procedure in the *Base SAS Procedures Guide*.

MISSING

treats missing values as a valid nonmissing level for all classification variables that you specify in the TABLES statements. This option displays missing levels in frequency and crosstabulation tables and includes the frequencies (of missing levels) in the computation of the frequency total, percentages, and statistics.

By default (if you do not specify the MISSING or MISSPRINT option), PROC FREQTAB excludes an observation from a table if the observation contains a missing value for any variable in the table request. For more information, see the section “Missing Values” on page 473.

MISSPRINT

displays missing levels in frequency tables but does not include the corresponding frequencies in the computation of totals, percentages, or statistics. This option is available for one-way frequency tables and for tables in list format (which you can request by specifying the LIST option in the TABLES statement).

By default (if you do not specify the MISSING or MISSPRINT option), PROC FREQTAB excludes an observation from a table if the observation contains a missing value for any variable in the table request. For more information, see the section “Missing Values” on page 473.

NLEVELS

displays the “Number of Variable Levels” table, which provides the number of levels for each variable that you name in a TABLES statement. PROC FREQTAB determines the variable levels by using the formatted variable values.

NOPRINT

suppresses the display of all output. You can use the NOPRINT option when you only want to create an output data set. For more information about the output data sets that PROC FREQTAB produces, see the section “Output Data Sets” on page 551. The NOPRINT option temporarily disables the Output Delivery System (ODS). For more information, see the *SAS Output Delivery System: User’s Guide*.

NOTE: A NOPRINT option is also available in the TABLES statement. This option suppresses display of the crosstabulation tables but allows display of the statistics tables.

ORDER=< FORMATTED | FREQ | INTERNAL > < (*variable1*='*level1*' '*level2*' ... *variable2*= ...) >

specifies the order of the variable levels in the frequency and crosstabulation tables, which you request in the TABLES statement. The following table shows how to interpret the ORDER= keywords:

Value of ORDER=	Levels Ordered By
FORMATTED	External formatted value (in ascending order)
FREQ	Descending frequency count
INTERNAL	Unformatted value

By default, ORDER=INTERNAL. The formatted and internal orders are machine-dependent. When you specify ORDER=FORMATTED, numeric variables that have no explicit format are sorted by their unformatted (internal) value.

When you specify ORDER=FREQ, levels that have larger frequencies (more observations) appear first in the order. ORDER=FREQ is not available when you specify a WEIGHT statement.

You can also specify a particular order for variables by listing, in parentheses, each variable followed by its levels in quotes in the desired order. For example, the following option specifies that the levels of all variables except the pet variable are to be sorted by their formatted value:

```
order = formatted (pet = 'dog' 'cat')
```

Any level of the pet variable that you do not specify is added to the end of the list in formatted order.

The ORDER= option does not apply to missing values, which are always ordered first.

For more information about sort order, see the chapter on the SORT procedure in the *Base SAS Procedures Guide* and the discussion of BY-group processing in *SAS Programmers Guide: Essentials*.

PAGE

displays only one table per page. Otherwise, PROC FREQTAB displays multiple tables per page as space permits. The PAGE option is not valid when you specify the COMPRESS option.

BY Statement

BY *variables* **;**

You can specify a BY statement in PROC FREQTAB to obtain separate analyses of observations in groups that are defined by the values of the BY variables. If you specify more than one BY statement, only the last one specified is used. For more information, see the discussion of BY-group processing in the "Grouping Data" section of *SAS Programmers Guide: Essentials*.

EXACT Statement

EXACT *statistic-options* < / *computation-options* > **;**

The EXACT statement requests exact tests and confidence limits for selected statistics. The *statistic-options* identify which statistics to compute, and the *computation-options* specify options for computing exact statistics. For more information, see the section "Exact Statistics" on page 547.

NOTE: PROC FREQTAB computes exact tests by using fast and efficient algorithms that are superior to direct enumeration. Exact tests are appropriate when a data set is small, sparse, skewed, or heavily tied. For some large problems, computation of exact tests might require a large amount of time and memory. Consider using asymptotic tests for such problems. Alternatively, when asymptotic methods might not be sufficient for such large problems, consider using Monte Carlo estimation of exact *p*-values. You can request Monte Carlo estimation by specifying the MC *computation-option* in the EXACT statement. For more information, see the section "Computational Resources" on page 549.

Statistic Options

The *statistic-options* specify which exact tests and confidence limits to compute. Table 11.5 lists the available *statistic-options* and the exact statistics that are computed. Descriptions of the *statistic-options* follow Table 11.5 in alphabetical order.

For one-way tables, PROC FREQTAB provides exact p-values for the binomial proportion test, the chi-square goodness-of-fit test, and the likelihood ratio chi-square test. PROC FREQTAB also provides exact (Clopper-Pearson) confidence limits for the binomial proportion.

For two-way tables, PROC FREQTAB provides exact p-values for the following tests: Pearson chi-square test, likelihood ratio chi-square test, Mantel-Haenszel chi-square test, Fisher's exact test, Jonckheere-Terpstra test, Cochran-Armitage test for trend, and the symmetry test. PROC FREQTAB also provides exact p-values for tests of the following statistics: Pearson correlation coefficient, Spearman correlation coefficient, Kendall's tau-b, Stuart's tau-c, Somers' $D(C|R)$, Somers' $D(R|C)$, simple kappa coefficient, and weighted kappa coefficient.

For 2×2 tables, PROC FREQTAB provides the exact McNemar's test, exact confidence limits for the odds ratio, and Barnard's unconditional exact test for the risk (proportion) difference. PROC FREQTAB also provides exact unconditional confidence limits for the risk (proportion) difference and for the relative risk (ratio of proportions). For stratified 2×2 tables, PROC FREQTAB provides Zelen's exact test for equal odds ratios, exact confidence limits for the common odds ratio, and an exact test for the common odds ratio.

Most of the *statistic-option* names listed in Table 11.5 are identical to the corresponding option names in the TABLES and OUTPUT statements. You can request exact computations for groups of statistics by using *statistic-options* that are identical to the TABLES statement options CHISQ, MEASURES, and AGREE. For example, when you specify the CHISQ *statistic-option* in the EXACT statement, PROC FREQTAB computes exact p-values for the Pearson chi-square, likelihood ratio chi-square, and Mantel-Haenszel chi-square tests for two-way tables. You can request an exact test for an individual statistic by specifying the corresponding *statistic-option* from the list in Table 11.5.

Using the EXACT Statement with the TABLES Statement

You must use a TABLES statement with the EXACT statement. If you use only one TABLES statement, you do not need to specify the same options in both the TABLES and EXACT statements; when you specify a *statistic-option* in the EXACT statement, PROC FREQTAB automatically invokes the corresponding TABLES statement option. However, when you use an EXACT statement with multiple TABLES statements, you must specify options in the TABLES statements to request statistics. PROC FREQTAB then provides exact tests or confidence limits for those statistics that you also specify in the EXACT statement.

Table 11.5 EXACT Statement Statistic Options

Statistic Option	Exact Statistics
AGREE	McNemar's test (for 2×2 tables), simple kappa test, weighted kappa test
BARNARD	Barnard's test (for 2×2 tables)
BINOMIAL | BIN	Binomial proportion tests for one-way tables
CHISQ	Chi-square goodness-of-fit test for one-way tables; Pearson chi-square, likelihood ratio chi-square, and Mantel-Haenszel chi-square tests for two-way tables

Table 11.5 *continued*

Statistic Option	Exact Statistics
COMOR	Confidence limits for the common odds ratio, common odds ratio test (for $h \times 2 \times 2$ tables)
EQOR | ZELEN	Zelen's test for equal odds ratios (for $h \times 2 \times 2$ tables)
FISHER	Fisher's exact test
JT	Jonckheere-Terpstra test
KAPPA	Test for the simple kappa coefficient
KENTB | TAUB	Test for Kendall's tau-b
LRCHI	Likelihood ratio chi-square test (one-way and two-way tables)
MCNEM	McNemar's test (for 2×2 tables)
MEASURES	Tests for the Pearson correlation and Spearman correlation, confidence limits for the odds ratio (for 2×2 tables)
MHCHI	Mantel-Haenszel chi-square test
OR | ODDSRATIO	Confidence limits for the odds ratio (for 2×2 tables)
PCHI	Pearson chi-square test (one-way and two-way tables)
PCORR	Test for the Pearson correlation coefficient
RELRISK	Confidence limits for the relative risk (for 2×2 tables)
RISKDIFF	Confidence limits for the risk difference (for 2×2 tables)
SCORR	Test for the Spearman correlation coefficient
SMDCR	Test for Somers' $D(C \mid R)$
SMDRC	Test for Somers' $D(R \mid C)$
STUTC | TAUC	Test for Stuart's tau-c
SYMMETRY | BOWKER	Symmetry test
TREND	Cochran-Armitage test for trend
WTKAPPA | WTKAP	Test for the weighted kappa coefficient

You can specify the following *statistic-options*:

AGREE

requests McNemar's exact test, an exact test for the simple kappa coefficient, and an exact test for the weighted kappa coefficient. For more information, see the sections "Tests and Measures of Agreement" on page 529 and "Exact Statistics" on page 547.

For McNemar's test, you can specify the null hypothesis ratio of discordant proportions by using the AGREE(MNULLRATIO=) option in the TABLES statement; by default, MNULLRATIO=1. For the weighted kappa coefficient, you can request Fleiss-Cohen weights by specifying the AGREE(WT=FC) option in the TABLES statement; by default, PROC FREQTAB computes the weighted kappa coefficient by using Cicchetti-Allison agreement weights.

McNemar's test is available for 2×2 tables. Kappa coefficients are defined only for square two-way tables, where the number of rows equals the number of columns. If your table is not square because some observations have weights of 0, you can specify the ZEROS option in the WEIGHT statement to include these observations in the analysis. For more information, see the section "Tables with Zero-Weight Rows or Columns" on page 536.

For 2×2 tables, the weighted kappa coefficient is equivalent to the simple kappa coefficient, and PROC FREQTAB displays only analyses for the simple kappa coefficient.

BARNARD

requests Barnard's exact unconditional test for the risk (proportion) difference for 2×2 tables. For more information, see the section "Barnard's Unconditional Exact Test" on page 510.

To request exact unconditional confidence limits for the risk difference. you can specify the RISKDIFF option in the EXACT statement. The RISKDIFF option in the TABLES statement provides asymptotic tests and several types of confidence limits for the risk difference. For more information, see the section "Risks and Risk Differences" on page 501.

BINOMIAL

BIN

requests an exact test for the binomial proportion (for one-way tables). For more information, see the section "Binomial Tests" on page 495. You can specify the null hypothesis proportion by using the BINOMIAL(P=) option in the TABLES statement; by default, P=0.5.

The BINOMIAL option in the TABLES statement provides exact (Clopper-Pearson) confidence limits for the binomial proportion by default. You can specify the BINOMIAL(CL=MIDP) option in the TABLES statement to request exact mid-p confidence limits for the binomial proportion. The BINOMIAL option in the TABLES statement also provides asymptotic (Wald) tests and several other confidence limit types for the binomial proportion. For more information, see the section "Binomial Proportion" on page 491.

CHISQ

requests the following exact chi-square tests for two-way tables: Pearson chi-square, likelihood ratio chi-square, and Mantel-Haenszel chi-square. For more information, see the section "Chi-Square Tests and Statistics" on page 476. The CHISQ option in the TABLES statement provides asymptotic tests for these statistics.

For one-way tables, the CHISQ option requests an exact chi-square goodness-of-fit test. You can specify null hypothesis proportions for this test by using the CHISQ(TESTP=) option in the TABLES statement. By default, the one-way chi-square test is based on the null hypothesis of equal proportions. For more information, see the section "Chi-Square Test for One-Way Tables" on page 477.

COMOR

requests an exact test and exact confidence limits for the common odds ratio for multiway 2×2 tables. For more information, see the section "Exact Confidence Limits for the Common Odds Ratio" on page 544. The CMH option in the TABLES statement provides Mantel-Haenszel and logit estimates of the common odds ratio along with their asymptotic confidence limits.

EQOR

ZELEN

requests Zelen's exact test for equal odds ratios for multiway 2×2 tables. For more information, see the section "Zelen's Exact Test for Equal Odds Ratios" on page 543. The CMH option in the TABLES statement provides an (asymptotic) Breslow-Day test for homogeneity of odds ratios.

FISHER

requests Fisher's exact test. For more information, see the sections "Fisher's Exact Test" on page 480 and "Exact Statistics" on page 547. For 2×2 tables, the CHISQ option in the TABLES statement provides Fisher's exact test. For general $R \times C$ tables, Fisher's exact test is also known as the Freeman-Halton test.

JT

requests an exact Jonckheere-Terpstra test. For more information, see the sections "Jonckheere-Terpstra Test" on page 527 and "Exact Statistics" on page 547. The JT option in the TABLES statement provides an asymptotic Jonckheere-Terpstra test.

KAPPA

requests an exact test for the simple kappa coefficient. For more information, see the sections "Simple Kappa Coefficient" on page 530 and "Exact Statistics" on page 547. The AGREE option in the TABLES statement provides the simple kappa estimate, standard error, and confidence limits. The KAPPA option in the TEST statement provides an asymptotic test for the simple kappa coefficient.

Kappa coefficients are defined only for square two-way tables, where the number of rows equals the number of columns. If your table is not square because some observations have weights of 0, you can specify the ZEROS option in the WEIGHT statement to include these observations in the analysis. For more information, see the section "Tables with Zero-Weight Rows or Columns" on page 536.

KENTB

TAUB

requests an exact test for Kendall's tau-*b*. For more information, see the sections "Kendall's Tau-b" on page 484 and "Exact Statistics" on page 547. The MEASURES option in the TABLES statement provides an estimate and standard error of Kendall's tau-*b*. The KENTB option in the TEST statement provides an asymptotic test for Kendall's tau-*b*.

LRCHI

requests an exact test for the likelihood ratio chi-square for two-way tables. For more information, see the sections "Likelihood Ratio Chi-Square Test" on page 479 and "Exact Statistics" on page 547. The CHISQ option in the TABLES statement provides an asymptotic likelihood ratio chi-square test for two-way tables.

For one-way tables, the LRCHI option requests an exact likelihood ratio goodness-of-fit test. You can specify null hypothesis proportions by using the CHISQ(TESTP=) option in the TABLES statement. By default, the one-way test is based on the null hypothesis of equal proportions. For more information, see the section "Likelihood Ratio Chi-Square Test for One-Way Tables" on page 478.

MCNEM

requests an exact McNemar's test. For more information, see the sections "McNemar's Test" on page 529 and "Exact Statistics" on page 547. You can specify the null hypothesis ratio of discordant proportions by using the AGREE(MNULLRATIO=) option in the TABLES statement; by default, MNULLRATIO=1. The AGREE option in the TABLES statement provides an asymptotic McNemar's test.

MEASURES

requests exact tests for the Pearson and Spearman correlations. For more information, see the sections "Pearson Correlation Coefficient" on page 485, "Spearman Rank Correlation Coefficient" on page 486, and "Exact Statistics" on page 547. The PCORR and SCORR options in the TEST statement provide asymptotic tests for the Pearson and Spearman correlations, respectively.

The MEASURES option also requests exact confidence limits for the odds ratio for 2×2 tables. For more information, see the subsection Exact Confidence Limits in the section "Confidence Limits for the Odds Ratio" on page 516. You can also request exact confidence limits for the odds ratio by specifying the OR option in the EXACT statement.

MHCHI

requests an exact test for the Mantel-Haenszel chi-square. For more information, see the sections "Mantel-Haenszel Chi-Square Test" on page 480 and "Exact Statistics" on page 547. The CHISQ option in the TABLES statement provides an asymptotic Mantel-Haenszel chi-square test.

OR

ODDSRATIO

requests exact confidence limits for the odds ratio for 2×2 tables. For more information, see the subsection "Exact Confidence Limits" in the section "Confidence Limits for the Odds Ratio" on page 516.

You can request exact mid-p confidence limits for the odds ratio by specifying the OR(CL=MIDP) option in the TABLES statement. The OR(CL=) option in the TABLES statement also provides other types of confidence limits for the odds ratio. For more information, see the section "Confidence Limits for the Odds Ratio" on page 516.

The ALPHA= option in the TABLES statement determines the confidence level of the exact confidence limits; by default, ALPHA=0.05, which produces 95% confidence limits for the odds ratio.

PCHI

requests an exact test for the Pearson chi-square for two-way tables. For more information, see the sections "Pearson Chi-Square Test for Two-Way Tables" on page 477 and "Exact Statistics" on page 547. The CHISQ option in the TABLES statement provides an asymptotic Pearson chi-square test.

For one-way tables, the PCHI option requests an exact chi-square goodness-of-fit test. You can specify null hypothesis proportions by using the CHISQ(TESTP=) option in the TABLES statement. By default, the goodness-of-fit test is based on the null hypothesis of equal proportions. For more information, see the section "Chi-Square Test for One-Way Tables" on page 477.

PCORR

requests an exact test for the Pearson correlation coefficient. For more information, see the sections "Pearson Correlation Coefficient" on page 485 and "Exact Statistics" on page 547. The MEASURES option in the TABLES statement provides the estimate and standard error of the Pearson correlation. The PCORR option in the TEST statement provides an asymptotic test for the Pearson correlation.

RELRISK < (*options*) >

requests exact unconditional confidence limits for the relative risk for 2×2 tables. By default, the exact confidence limits are computed by inverting two separate one-sided exact tests that are based on the score statistic (Chan and Zhang 1999). For more information, see the subsection "Exact Unconditional Confidence Limits" in the section "Confidence Limits for the Relative Risk" on page 519.

The RELRISK(CL=) option in the TABLES statement provides additional types of confidence limits for the relative risk. For more information, see the section "Confidence Limits for the Risk Difference" on page 502.

The ALPHA= option in the TABLES statement determines the confidence level; by default, ALPHA=0.05, which produces 95% confidence limits for the relative risk.

You can specify the following *options*:

COLUMN=1 | 2 | BOTH
specifies the table column of the relative risk. By default, COLUMN=1, which provides exact confidence limits for the column 1 relative risk. COLUMN=BOTH provides exact confidence limits for both column 1 and column 2 relative risks.

METHOD=NOSCORE | SCORE | SCORE2
specifies the computation method for the exact confidence limits. By default, METHOD=SCORE.

You can specify one of the following methods:

NOSCORE
computes the exact confidence limits by inverting two separate one-sided exact tests that are based on the unstandardized relative risk (Santner and Snell 1980). For more information, see the subsection "Exact Unconditional Confidence Limits" in the section "Confidence Limits for the Relative Risk" on page 519.

SCORE
computes the exact confidence limits by inverting two separate one-sided exact tests that are based on the score statistic (Chan and Zhang 1999). For more information, see the subsection "Exact Unconditional Confidence Limits" in the section "Confidence Limits for the Relative Risk" on page 519.

SCORE2
computes the exact confidence limits by inverting a single two-sided exact test that is based on the score statistic (Agresti and Min 2001). For more information, see the subsection "Exact Unconditional Confidence Limits" in the section "Confidence Limits for the Relative Risk" on page 519.

RISKDIFF < (*options*) >
requests exact unconditional confidence limits for the risk difference for 2×2 tables. By default, the exact confidence limits are computed by inverting two separate one-sided exact tests that are based on the score statistic (Chan and Zhang 1999). For more information, see the subsection "Exact Unconditional Confidence Limits" in the section "Confidence Limits for the Risk Difference" on page 502.

The RISKDIFF(CL=) option in the TABLES statement provides additional types of confidence limits for the risk difference. For more information, see the section "Confidence Limits for the Risk Difference" on page 502.

The ALPHA= option in the TABLES statement determines the confidence level; by default, ALPHA=0.05, which produces 95% confidence limits for the risk difference.

You can specify the following *options*:

COLUMN=1 | 2 | BOTH
specifies the table column of the risk difference. By default, COLUMN=BOTH and the exact confidence limits are displayed in the 'Risk Estimates' tables. If you specify the RISKDIFF(NORISKS) option in the TABLES statement to suppress the 'Risk Estimates' tables, by default, COLUMN=1 and the exact confidence limits are displayed in the 'Risk Difference Confidence Limits' table.

METHOD=NOSCORE | SCORE | SCORE2

specifies the computation method for the exact confidence limits. By default, METHOD=SCORE.

You can specify one of the following methods:

NOSCORE

computes the exact confidence limits by inverting two separate one-sided exact tests that are based on the unstandardized risk difference (Santner and Snell 1980). For more information, see the subsection "Exact Unconditional Confidence Limits" in the section "Confidence Limits for the Risk Difference" on page 502.

SCORE

computes the exact confidence limits by inverting two separate one-sided exact tests that are based on the score statistic (Chan and Zhang 1999). For more information, see the subsection "Exact Unconditional Confidence Limits" in the section "Confidence Limits for the Risk Difference" on page 502.

SCORE2

computes the exact confidence limits by inverting a single two-sided exact test that is based on the score statistic (Agresti and Min 2001). For more information, see the subsection "Exact Unconditional Confidence Limits" in the section "Confidence Limits for the Risk Difference" on page 502.

SCORR

requests an exact test for the Spearman correlation coefficient. For more information, see the sections "Spearman Rank Correlation Coefficient" on page 486 and "Exact Statistics" on page 547. The MEASURES option in the TABLES statement provides the estimate and standard error of the Spearman correlation. The SCORR option in the TEST statement provides an asymptotic test for the Spearman correlation.

SMDCR

requests an exact test for Somers' $D(C|R)$. For more information, see the sections "Somers' D" on page 485 and "Exact Statistics" on page 547. The MEASURES option in the TABLES statement provides the estimate and standard error of Somers' $D(C|R)$. The SMDCR option in the TEST statement provides an asymptotic test for Somers' $D(C|R)$.

SMDRC

requests an exact test for Somers' $D(R|C)$. For more information, see the sections "Somers' D" on page 485 and "Exact Statistics" on page 547. The MEASURES option in the TABLES statement provides the estimate and standard error of Somers' $D(R|C)$. The SMDRC option in the TEST statement provides an asymptotic test for Somers' $D(C|R)$.

STUTC

TAUC

requests an exact test for Stuart's tau-c. For more information, see the sections "Stuart's Tau-c" on page 484 and "Exact Statistics" on page 547. The MEASURES option in the TABLES statement provides the estimate and standard error of Stuart's tau-c. The STUTC option in the TEST statement provides an asymptotic test for Stuart's tau-c.

SYMMETRY

BOWKER

requests an exact symmetry test. This test is available for square $R \times R$ two-way tables where the table dimension R is greater than 2. For more information, see the section "Exact Symmetry Test" on page 530. The AGREE option in the TABLES statement provides an asymptotic symmetry test.

TREND

requests the exact Cochran-Armitage test for trend. For more information, see the sections "Cochran-Armitage Test for Trend" on page 526 and "Exact Statistics" on page 547. The TREND option in the TABLES statement provides an asymptotic Cochran-Armitage test for trend. This test is available for tables of dimensions $2 \times C$ or $R \times 2$.

WTKAPPA

WTKAP

requests an exact test for the weighted kappa coefficient. For more information, see the sections "Weighted Kappa Coefficient" on page 532 and "Exact Statistics" on page 547. By default, PROC FREQTAB computes the weighted kappa coefficient by using Cicchetti-Allison agreement weights. You can request Fleiss-Cohen agreement weights by specifying the AGREE(WT=FC) option in the TABLES statement.

Kappa coefficients are defined only for square two-way tables, where the number of rows equals the number of columns. If your table is not square because some observations have weights of 0, you can specify the ZEROS option in the WEIGHT statement to include these observations in the analysis. For more information, see the section "Tables with Zero-Weight Rows or Columns" on page 536.

For 2×2 tables, the weighted kappa coefficient is equivalent to the simple kappa coefficient, and PROC FREQTAB displays only analyses for the simple kappa coefficient.

Computation Options

The *computation-options* specify options for computing exact statistics. You can specify the following *computation-options*:

ALPHA=α

specifies the level of the confidence limits for Monte Carlo p-value estimates. The value of α must be between 0 and 1; a confidence level of α produces $100(1-\alpha)\%$ confidence limits. By default ALPHA=0.01, which produces 99% confidence limits for the Monte Carlo estimates.

This option invokes the MC option.

MAXTIME=*value*

specifies the maximum clock time (in seconds) that PROC FREQTAB can use to compute an exact p-value. If the procedure does not complete the computation within the specified time, the computation terminates. The maximum time *value* must be a positive number. This option is available for exact p-value computation and for Monte Carlo estimation of exact p-values. For more information, see the section "Computational Resources" on page 549.

MC

requests Monte Carlo estimation of exact *p*-values instead of direct exact *p*-value computation. Monte Carlo estimation can be useful for large problems where exact computations require a substantial amount of time and memory but asymptotic approximations might not be sufficient. For more information, see the section "Monte Carlo Estimation" on page 550.

This option is available for all EXACT *statistic-options* except the BINOMIAL option and the following options that apply only to 2×2 or $h \times 2 \times 2$ tables: BARNARD, COMOR, EQOR, MCNEM, OR, RELRISK, and RISKDIFF. PROC FREQTAB always computes exact tests or confidence limits (not Monte Carlo estimates) for these statistics.

The ALPHA=, N=, and SEED= options invoke the MC option.

MIDP

requests exact mid *p*-values for the exact tests. The exact mid *p*-value is defined as the exact *p*-value minus half the exact point probability. For more information, see the section "Definition of *p*-Values" on page 548.

The MIDP option is available for all EXACT statement *statistic-options* except the following: BARNARD, EQOR, OR, RELRISK, and RISKDIFF. You cannot specify both the MIDP option and the MC option.

N=*n*

specifies the number of samples for Monte Carlo estimation. The value of *n* must be a positive integer. Larger values of *n* produce more precise estimates of exact *p*-values. Because larger values of *n* generate more samples, the computation time increases. By default, N=10,000.

This option invokes the MC option.

PFORMAT=*format-name* **| EXACT**

specifies the display format for exact *p*-values. PROC FREQTAB applies this format to one- and two-sided exact *p*-values, exact point probabilities, and exact mid *p*-values. By default, PROC FREQTAB displays exact *p*-values in the PVALUE6.4 format.

You can provide a *format-name* or you can specify PFORMAT=EXACT to control the format of exact *p*-values. The value of *format-name* can be any standard SAS numeric format or a user-defined format. The format length must not exceed 24. For more information, see the discussion of the FORMAT procedure in the *Base SAS Procedures Guide* and the discussion of SAS formats in *SAS Formats and Informats: Reference*.

If you specify PFORMAT=EXACT, PROC FREQTAB uses the 6.4 format to display exact *p*-values that are greater than or equal to 0.001; the procedure uses the E10.3 format to display values that are between 0.000 and 0.001.

POINT

requests exact point probabilities for the exact tests. The exact point probability is the exact probability that the test statistic equals the observed value. For more information, see the section "Definition of *p*-Values" on page 548.

The POINT option is available for all EXACT statement *statistic-options* except the following: BARNARD, EQOR, OR, RELRISK, and RISKDIFF. You cannot specify both the POINT option and the MC option.

SEED=*number*

specifies the initial seed for random number generation for Monte Carlo estimation. The value of the SEED= option must be an integer. If you do not specify the SEED= option or if the SEED= value is negative or 0, PROC FREQTAB uses the time of day from the computer's clock to obtain the initial seed.

This option invokes the MC option.

OUTPUT Statement

OUTPUT <**OUT=***data-table*> *output-options* **;**

The OUTPUT statement creates an output data table that stores statistics that PROC FREQTAB computes. Table 11.6 lists the statistics that are available in the output data table. You can identify which statistics to include by specifying *output-options*.

When you specify an OUTPUT statement, you must also specify a TABLES statement, which defines tables and requests statistical analyses. The OUTPUT statement stores statistics for a single table request. If you use multiple TABLES statements, the contents of the output data set correspond to the last TABLES statement. If you use multiple table requests in a single TABLES statement, the contents of the output data set correspond to the last table request. Only one OUTPUT statement is allowed in a single invocation of PROC FREQTAB.

For a one-way or two-way table, the output data set contains one observation that stores statistics for the table. For a multiway table, the output data set contains an observation for each two-way table (stratum) of the multiway table. If you request summary statistics for the multiway table, the output data set also contains an observation that includes the across-strata summary statistics. If you specify a BY statement, the output data set contains an observation or set of observations for each BY group. For more information, see the section "Contents of the OUTPUT Statement Output Data Set" on page 553.

The output data set (which the OUTPUT statement produces) is not the same as the output data set that the OUT= option in the TABLES statement produces. The OUTPUT statement creates a data set that contains statistics (such as the Pearson chi-square and its *p*-value), while the OUT= option in the TABLES statement creates a data set that contains frequency table counts and percentages. For more information, see the section "Output Data Sets" on page 551.

You can also use the Output Delivery System (ODS) to store statistics that PROC FREQTAB computes. ODS can create a SAS data set from any table that PROC FREQTAB produces. For more information, see the section "ODS Table Names" on page 565 and Chapter 23, "Using the Output Delivery System" (*SAS/STAT User's Guide*).

You can specify the following *options* in the OUTPUT statement:

OUT=*data-table*

specifies the name of the output data table. When you use an OUTPUT statement but do not use the OUT= option, PROC FREQTAB creates a data set and names it by using the DATA*n* convention.

output-options

specify the statistics to include in the output data set. Table 11.6 lists the *output-options* that are available in the OUTPUT statement together with the TABLES statement options that are required to produce the statistics. Descriptions of the *output-options* follow the table in alphabetical order.

You can specify *output-options* to request individual statistics, or you can request groups of statistics by using *output-options* that are identical to the group options in the TABLES statement (for example, the CHISQ, MEASURES, CMH, AGREE, and ALL options).

When you specify an *output-option*, the output data set includes statistics from the corresponding analysis. In addition to the estimate or test statistic, the output data set includes associated values such as standard errors, confidence limits, p-values, and degrees of freedom. For more information, see the section "Contents of the OUTPUT Statement Output Data Set" on page 553.

To store a statistic in the output data set, you must also request computation of that statistic with the appropriate TABLES, EXACT, or TEST statement option. For example, the PCHI *output-option* includes the Pearson chi-square in the output data set. You must also request computation of the Pearson chi-square by specifying the CHISQ option in the TABLES statement. Or, if you use only one TABLES statement, you can request computation of the Pearson chi-square by specifying the PCHI or CHISQ option in the EXACT statement. Table 11.6 lists the TABLES statement options that are required to produce the OUTPUT data set statistics.

Table 11.6 OUTPUT Statement Output Options

Output Option	Output Data Set Statistics	Required TABLES Statement Option
AGREE	McNemar's test (2×2 tables), Bowker's test, simple and weighted kappas; for multiple strata, overall simple and weighted kappas, tests for equal kappas, and Cochran's Q ($2 \times 2 \times \cdots \times 2$ tables)	AGREE
AJCHI	Continuity-adjusted chi-square (2×2 tables)	CHISQ
ALL	CHISQ, MEASURES, and CMH statistics; N (number of observations)	ALL
BDCHI	Breslow-Day test ($h \times 2 \times 2$ tables)	CMH, CMH1, or CMH2
BINOMIAL | BIN	Binomial statistics (one-way tables)	BINOMIAL
CHISQ	For one-way tables, goodness-of-fit test; for two-way tables, Pearson, likelihood ratio, continuity-adjusted, and Mantel-Haenszel chi-squares, Fisher's exact test (2×2 tables), phi and contingency coefficients, Cramér's V	CHISQ
CMH	Cochran-Mantel-Haenszel (CMH) correlation, row mean scores (ANOVA), and general association statistics; for 2×2 tables, logit and Mantel-Haenszel common odds ratios and relative risks, Breslow-Day test	CMH
CMH1	CMH statistics, except row mean scores (ANOVA) and general association statistics	CMH or CMH1
CMH2	CMH statistics, except general association statistic	CMH or CMH2
CMHCOR	CMH correlation statistic	CMH, CMH1, or CMH2
CMHGA	CMH general association statistic	CMH
CMHRMS	CMH row mean scores (ANOVA) statistic	CMH or CMH2

Table 11.6 *continued*

Output Option	Output Data Set Statistics	Required TABLES Statement Option
COCHQ	Cochran's Q ($2 \times 2 \times \cdots \times 2$ tables)	AGREE or CQ
CONTGY	Contingency coefficient	CHISQ
CRAMV	Cramér's V	CHISQ
EQKAP	Test for equal simple kappas	AGREE
EQOR | ZELEN	Zelen's test for equal odds ratios ($h \times 2 \times 2$ tables)	CMH and EXACT EQOR
EQWKP	Test for equal weighted kappas	AGREE
FISHER	Fisher's exact test	CHISQ or FISHER [1]
GAILSIMON | GS	Gail-Simon test	GAILSIMON
GAMMA	Gamma	MEASURES
JT	Jonckheere-Terpstra test	JT
KAPPA	Simple kappa coefficient	AGREE
KENTB | TAUB	Kendall's tau-b	MEASURES
LAMCR	Lambda asymmetric $(C\|R)$	MEASURES
LAMDAS	Lambda symmetric	MEASURES
LAMRC	Lambda asymmetric $(R\|C)$	MEASURES
LGOR	Logit common odds ratio	CMH, CMH1, or CMH2
LGRRC1	Logit common relative risk, column 1	CMH, CMH1, or CMH2
LGRRC2	Logit common relative risk, column 2	CMH, CMH1, or CMH2
LRCHI	Likelihood ratio chi-square	CHISQ
MCNEM	McNemar's test (2×2 tables)	AGREE
MEASURES	Gamma, Kendall's tau-b, Stuart's tau-c, Somers' $D(C\|R)$ and $D(R\|C)$, Pearson and Spearman correlations, lambda asymmetric $(C\|R)$ and $(R\|C)$, lambda symmetric, uncertainty coefficients $(C\|R)$ and $(R\|C)$, symmetric uncertainty coefficient; odds ratio and relative risks (2×2 tables)	MEASURES
MHCHI	Mantel-Haenszel chi-square	CHISQ
MHOR | COMOR	Mantel-Haenszel common odds ratio	CMH, CMH1, or CMH2
MHRRC1	Mantel-Haenszel common relative risk, column 1	CMH, CMH1, or CMH2
MHRRC2	Mantel-Haenszel common relative risk, column 2	CMH, CMH1, or CMH2
N	Number of nonmissing observations	
NMISS	Number of missing observations	
OR | ODDSRATIO	Odds ratio (2×2 tables)	MEASURES, OR, or RELRISK
PCHI	Chi-square goodness-of-fit test (one-way tables), Pearson chi-square (two-way tables)	CHISQ
PCORR	Pearson correlation coefficient	MEASURES
PHI	Phi coefficient	CHISQ
PLCORR	Polychoric correlation coefficient	PLCORR
RDIF1	Column 1 risk difference (row 1 – row 2)	RISKDIFF

[1] CHISQ computes Fisher's exact test for 2×2 tables. Use the FISHER option to compute Fisher's exact test for general $r \times c$ tables.

Table 11.6 *continued*

Output Option	Output Data Set Statistics	Required TABLES Statement Option
RDIF2	Column 2 risk difference (row 1 – row 2)	RISKDIFF
RELRISK	Odds ratio and relative risks (2×2 tables)	MEASURES or RELRISK
RISKDIFF	Risks and risk differences (2×2 tables)	RISKDIFF
RISKDIFF1	Risks and risk difference, column 1	RISKDIFF
RISKDIFF2	Risks and risk difference, column 2	RISKDIFF
RRC1 | RELRISK1	Relative risk, column 1	MEASURES or RELRISK
RRC2 | RELRISK2	Relative risk, column 2	MEASURES or RELRISK
RSK1 | RISK1	Column 1 overall risk	RISKDIFF
RSK11 | RISK11	Column 1 risk for row 1	RISKDIFF
RSK12 | RISK12	Column 2 risk for row 1	RISKDIFF
RSK2 | RISK2	Column 2 overall risk	RISKDIFF
RSK21 | RISK21	Column 1 risk for row 2	RISKDIFF
RSK22 | RISK22	Column 2 risk for row 2	RISKDIFF
SCORR	Spearman correlation coefficient	MEASURES
SMDCR	Somers' $D(C\|R)$	MEASURES
SMDRC	Somers' $D(R\|C)$	MEASURES
STUTC | TAUC	Stuart's tau-c	MEASURES
TREND	Cochran-Armitage test for trend	TREND
TSYMM | BOWKER	Bowker's symmetry test	AGREE
U	Symmetric uncertainty coefficient	MEASURES
UCR	Uncertainty coefficient $(C\|R)$	MEASURES
URC	Uncertainty coefficient $(R\|C)$	MEASURES
WTKAPPA | WTKAP	Weighted kappa coefficient	AGREE

You can specify the following *output-options*:

AGREE

includes the following tests and measures of agreement in the output data set: McNemar's test (for 2×2 tables), Bowker's symmetry test, the simple kappa coefficient, and the weighted kappa coefficient. For multiway tables, the AGREE option also includes the following statistics in the output data set: overall simple and weighted kappa coefficients, tests for equal simple and weighted kappa coefficients, and Cochran's Q test (for $2 \times 2 \times \cdots \times 2$ tables).

AGREE statistics are computed only for square tables, where the number of rows equals the number of columns. PROC FREQTAB provides Bowker's symmetry test and weighted kappa coefficients for tables larger than 2×2. (For 2×2 tables, Bowker's test is identical to McNemar's test, and the weighted kappa coefficient equals the simple kappa coefficient.) Cochran's Q is available for $2 \times 2 \times \cdots \times 2$ tables.

The AGREE option in the TABLES statement requests computation of tests and measures of agreement. For more information, see the section "Tests and Measures of Agreement" on page 529.

AJCHI

includes the continuity-adjusted chi-square in the output data set. The continuity-adjusted chi-square is available for 2×2 tables and is provided by the CHISQ option in the TABLES statement. For more information, see the section "Continuity-Adjusted Chi-Square Test" on page 479.

ALL

includes all statistics that are requested by the CHISQ, MEASURES, and CMH *output-options* in the output data set. ALL also includes the number of nonmissing observations (total frequency), which can be requested separately by the N *output-option*.

BDCHI

includes the Breslow-Day test in the output data set. The Breslow-Day test for homogeneity of odds ratios is computed for multiway 2×2 tables and is provided by the CMH, CMH1, and CMH2 options in the TABLES statement. For more information, see the section "Breslow-Day Test for Homogeneity of the Odds Ratios" on page 542.

BINOMIAL

BIN

includes the following binomial statistics for one-way tables: number of observations (total frequency), number of successes (frequency of designated level), binomial proportion estimate, confidence limits, and tests. The BINOMIAL option in the TABLES statement requests computation of binomial statistics, which are available for one-way tables. For more information, see the section "Binomial Proportion" on page 491.

CHISQ

includes the following chi-square tests and measures in the output data set for two-way tables: Pearson chi-square, likelihood ratio chi-square, Mantel-Haenszel chi-square, phi coefficient, contingency coefficient, and Cramér's V. For 2×2 tables, CHISQ also includes Fisher's exact test and the continuity-adjusted chi-square in the output data set. For more information, see the section "Chi-Square Tests and Statistics" on page 476. For one-way tables, CHISQ includes the chi-square goodness-of-fit test in the output data set. For more information, see the section "Chi-Square Test for One-Way Tables" on page 477. The CHISQ option in the TABLES statement requests computation of these statistics.

If you specify the CHISQ(WARN=OUTPUT) option in the TABLES statement, the CHISQ option also includes the variable WARN_PCHI in the output data set. This variable indicates the validity warning for the asymptotic Pearson chi-square test.

CMH

includes the following Cochran-Mantel-Haenszel statistics in the output data set: correlation, row mean scores (ANOVA), and general association. For 2×2 tables, the CMH option also includes the Mantel-Haenszel and logit estimates of the common odds ratio and relative risks. For multiway (stratified) 2×2 tables, the CMH option includes the Breslow-Day test for homogeneity of odds ratios. The CMH option in the TABLES statement requests computation of these statistics. For more information, see the section "Cochran-Mantel-Haenszel Statistics" on page 536.

If you specify the CMH(MANTELFLEISS) option in the TABLES statement, the CMH option includes the Mantel-Fleiss analysis in the output data set. The variables MF_CMH and WARN_CMH contain the Mantel-Fleiss criterion and the warning indicator, respectively.

CMH1
includes the CMH statistics in the output data set, with the exception of the row mean scores (ANOVA) statistic and the general association statistic. The CMH1 option in the TABLES statement requests computation of these statistics. For more information, see the section "Cochran-Mantel-Haenszel Statistics" on page 536.

CMH2
includes the CMH statistics in the output data set, with the exception of the general association statistic. The CMH2 option in the TABLES statement requests computation of these statistics. For more information, see the section "Cochran-Mantel-Haenszel Statistics" on page 536.

CMHCOR
includes the Cochran-Mantel-Haenszel correlation statistic in the output data set. The CMH option in the TABLES statement requests computation of this statistic. For more information, see the section "Correlation Statistic" on page 538.

CMHGA
includes the Cochran-Mantel-Haenszel general association statistic in the output data set. The CMH option in the TABLES statement requests computation of this statistic. For more information, see the section "General Association Statistic" on page 539.

CMHRMS
includes the Cochran-Mantel-Haenszel row mean scores (ANOVA) statistic in the output data set. The CMH option in the TABLES statement requests computation of this statistic. For more information, see the section "ANOVA (Row Mean Scores) Statistic" on page 538.

COCHQ
includes Cochran's Q test in the output data set. Both the AGREE option and the CQ option in the TABLES statement request computation of this test, which is available for multiway tables in which each variable has two levels ($2 \times 2 \times \cdots \times 2$ tables). For more information, see the section "Cochran's Q Test" on page 535.

CONTGY
includes the contingency coefficient in the output data set. The CHISQ option in the TABLES statement requests computation of the contingency coefficient. For more information, see the section "Contingency Coefficient" on page 481.

CRAMV
includes Cramér's V in the output data set. The CHISQ option in the TABLES statement requests computation of Cramér's V. For more information, see the section "Cramér's V" on page 481.

EQKAP
includes the test for equal simple kappa coefficients in the output data set. The AGREE option in the TABLES statement requests computation of this test, which is available for multiway, square ($h \times r \times r$) tables. For more information, see the section "Tests for Equal Kappa Coefficients" on page 535.

EQOR

ZELEN

includes Zelen's exact test for equal odds ratios in the output data set. The EQOR option in the EXACT statement requests computation of this test, which is available for multiway 2×2 tables. For more information, see the section "Zelen's Exact Test for Equal Odds Ratios" on page 543.

EQWKP

includes the test for equal weighted kappa coefficients in the output data set. The AGREE option in the TABLES statement requests computation of this test. The test for equal weighted kappas is available for multiway, square ($h \times r \times r$) tables where $r > 2$. For more information, see the section "Tests for Equal Kappa Coefficients" on page 535.

FISHER

includes Fisher's exact test in the output data set. For 2×2 tables, the CHISQ option in the TABLES statement provides Fisher's exact test. For tables larger than 2×2, the FISHER option in the EXACT statement provides Fisher's exact test. For more information, see the section "Fisher's Exact Test" on page 480.

GAILSIMON

GS

includes the Gail-Simon test for qualitative interaction in the output data set. The GAILSIMON option in the TABLES statement requests computation of this test. For more information, see the section "Gail-Simon Test for Qualitative Interactions" on page 546.

GAMMA

includes the gamma statistic in the output data set. The MEASURES option in the TABLES statement requests computation of the gamma statistic. For more information, see the section "Gamma" on page 483.

JT

includes the Jonckheere-Terpstra test in the output data set. The JT option in the TABLES statement requests the Jonckheere-Terpstra test. For more information, see the section "Jonckheere-Terpstra Test" on page 527.

KAPPA

includes the simple kappa coefficient in the output data set. The AGREE option in the TABLES statement requests computation of kappa, which is available for square tables (where the number of rows equals the number of columns). For multiway square tables, the KAPPA option also includes the overall kappa coefficient in the output data set. For more information, see the sections "Simple Kappa Coefficient" on page 530 and "Overall Kappa Coefficient" on page 535.

KENTB

TAUB

includes Kendall's tau-*b* in the output data set. The MEASURES option in the TABLES statement requests computation of Kendall's tau-*b*. For more information, see the section "Kendall's Tau-b" on page 484.

LAMCR
includes the asymmetric lambda $\lambda(C|R)$ in the output data set. The MEASURES option in the TABLES statement requests computation of lambda. For more information, see the section "Lambda (Asymmetric)" on page 489.

LAMDAS
includes the symmetric lambda in the output data set. The MEASURES option in the TABLES statement requests computation of lambda. For more information, see the section "Lambda (Symmetric)" on page 490.

LAMRC
includes the asymmetric lambda $\lambda(R|C)$ in the output data set. The MEASURES option in the TABLES statement requests computation of lambda. For more information, see the section "Lambda (Asymmetric)" on page 489.

LGOR
includes the logit estimate of the common odds ratio in the output data set. The CMH option in the TABLES statement requests computation of this statistic, which is available for 2×2 tables. For more information, see the section "Adjusted Odds Ratio and Relative Risk Estimates" on page 540.

LGRRC1
includes the logit estimate of the common relative risk (column 1) in the output data set. The CMH option in the TABLES statement requests computation of this statistic, which is available for 2×2 tables. For more information, see the section "Adjusted Odds Ratio and Relative Risk Estimates" on page 540.

LGRRC2
includes the logit estimate of the common relative risk (column 2) in the output data set. The CMH option in the TABLES statement requests computation of this statistic, which is available for 2×2 tables. For more information, see the section "Adjusted Odds Ratio and Relative Risk Estimates" on page 540.

LRCHI
includes the likelihood ratio chi-square in the output data set. The CHISQ option in the TABLES statement requests computation of the likelihood ratio chi-square. For more information, see the section "Likelihood Ratio Chi-Square Test" on page 479.

MCNEM
includes McNemar's test (for 2×2 tables) in the output data set. The AGREE option in the TABLES statement requests computation of McNemar's test. For more information, see the section "McNemar's Test" on page 529.

MEASURES
includes the following measures of association in the output data set: gamma, Kendall's tau-*b*, Stuart's tau-*c*, Somers' $D(C|R)$, Somers' $D(R|C)$, Pearson and Spearman correlation coefficients, lambda (symmetric and asymmetric), and uncertainty coefficients (symmetric and asymmetric). For 2×2 tables, the MEASURES option also includes the odds ratio, column 1 relative risk, and column 2 relative risk. The MEASURES option in the TABLES statement requests computation of these statistics. For more information, see the section "Measures of Association" on page 482.

MHCHI

includes the Mantel-Haenszel chi-square in the output data set. The CHISQ option in the TABLES statement requests computation of the Mantel-Haenszel chi-square. For more information, see the section "Mantel-Haenszel Chi-Square Test" on page 480.

MHOR

COMOR

includes the Mantel-Haenszel estimate of the common odds ratio in the output data set. The CMH option in the TABLES statement requests computation of this statistic, which is available for 2×2 tables. For more information, see the section "Adjusted Odds Ratio and Relative Risk Estimates" on page 540.

MHRRC1

includes the Mantel-Haenszel estimate of the common relative risk (column 1) in the output data set. The CMH option in the TABLES statement requests computation of this statistic, which is available for 2×2 tables. For more information, see the section "Adjusted Odds Ratio and Relative Risk Estimates" on page 540.

MHRRC2

includes the Mantel-Haenszel estimate of the common relative risk (column 2) in the output data set. The CMH option in the TABLES statement requests computation of this statistic, which is available for 2×2 tables. For more information, see the section "Adjusted Odds Ratio and Relative Risk Estimates" on page 540.

N

includes the number of nonmissing observations (total frequency) for the table request.

NMISS

includes the number (frequency) of missing observations for the table request. For more information, see the section "Missing Values" on page 473.

OR

ODDSRATIO

RROR

includes the odds ratio (for 2×2 tables) in the output data set. The MEASURES, OR, and RELRISK options in the TABLES statement request this statistic. For more information, see the section "Odds Ratio" on page 516.

PCHI

includes the Pearson chi-square in the output data set for two-way tables. For more information, see the section "Pearson Chi-Square Test for Two-Way Tables" on page 477. For one-way tables, the PCHI option includes the chi-square goodness-of-fit test in the output data set. For more information, see the section "Chi-Square Test for One-Way Tables" on page 477. The CHISQ option in the TABLES statement requests computation of these statistics.

If you specify the CHISQ(WARN=OUTPUT) option in the TABLES statement, the PCHI option also includes the variable WARN_PCHI in the output data set. This variable indicates the validity warning for the asymptotic Pearson chi-square test.

PCORR
includes the Pearson correlation coefficient in the output data set. The MEASURES option in the TABLES statement requests computation of the Pearson correlation. For more information, see the section "Pearson Correlation Coefficient" on page 485.

PHI
includes the phi coefficient in the output data set. The CHISQ option in the TABLES statement requests computation of the phi coefficient. For more information, see the section "Phi Coefficient" on page 481.

PLCORR
includes the polychoric correlation coefficient in the output data set. For 2×2 tables, this statistic is known as the tetrachoric correlation coefficient. The PLCORR option in the TABLES statement requests computation of the polychoric correlation. For more information, see the section "Polychoric Correlation" on page 488.

RDIF1
includes the column 1 risk difference (row 1 – row 2) in the output data set. The RISKDIFF option in the TABLES statement requests computation of risks and risk differences, which are available for 2×2 tables. For more information, see the section "Risks and Risk Differences" on page 501.

RDIF2
includes the column 2 risk difference (row 1 – row 2) in the output data set. The RISKDIFF option in the TABLES statement requests computation of risks and risk differences, which are available for 2×2 tables. For more information, see the section "Risks and Risk Differences" on page 501.

RELRISK
includes the column 1 and column 2 relative risks (for 2×2 tables) in the output data set. The MEASURES and RELRISK options in the TABLES statement request these statistics. For more information, see the section "Relative Risks" on page 519.

RISKDIFF
includes risks (binomial proportions) and risk differences for 2×2 tables in the output data set. These statistics include the row 1 risk, row 2 risk, total (overall) risk, and risk difference (row 1 – row 2) for column 1 and column 2. The RISKDIFF option in the TABLES statement requests computation of these statistics. For more information, see the section "Risks and Risk Differences" on page 501.

RISKDIFF1
includes column 1 risks (binomial proportions) and risk differences for 2×2 tables in the output data set. These statistics include the row 1 risk, row 2 risk, total (overall) risk, and risk difference (row 1 – row 2). The RISKDIFF option in the TABLES statement requests computation of these statistics. For more information, see the section "Risks and Risk Differences" on page 501.

RISKDIFF2
includes column 2 risks (binomial proportions) and risk differences for 2×2 tables in the output data set. These statistics include the row 1 risk, row 2 risk, total (overall) risk, and risk difference (row 1 – row 2). The RISKDIFF option in the TABLES statement requests computation of these statistics. For more information, see the section "Risks and Risk Differences" on page 501.

RRC1

RELRISK1

includes the column 1 relative risk in the output data set. The MEASURES and RELRISK options in the TABLES statement request relative risks, which are available for 2×2 tables. For more information, see the section "Odds Ratio and Relative Risks" on page 516.

RRC2

RELRISK2

includes the column 2 relative risk in the output data set. The MEASURES and RELRISK options in the TABLES statement request relative risks, which are available for 2×2 tables. For more information, see the section "Odds Ratio and Relative Risks" on page 516.

RSK1

RISK1

includes the overall column 1 risk in the output data set. The RISKDIFF option in the TABLES statement requests computation of risks and risk differences, which are available for 2×2 tables. For more information, see the section "Risks and Risk Differences" on page 501.

RSK11

RISK11

includes the column 1 risk for row 1 in the output data set. The RISKDIFF option in the TABLES statement requests computation of risks and risk differences, which are available for 2×2 tables. For more information, see the section "Risks and Risk Differences" on page 501.

RSK12

RISK12

includes the column 2 risk for row 1 in the output data set. The RISKDIFF option in the TABLES statement requests computation of risks and risk differences, which are available for 2×2 tables. For more information, see the section "Risks and Risk Differences" on page 501.

RSK2

RISK2

includes the overall column 2 risk in the output data set. The RISKDIFF option in the TABLES statement requests computation of risks and risk differences. For more information, see the section "Risks and Risk Differences" on page 501.

RSK21

RISK21

includes the column 1 risk for row 2 in the output data set. The RISKDIFF option in the TABLES statement requests computation of risks and risk differences, which are available for 2×2 tables. For more information, see the section "Risks and Risk Differences" on page 501.

RSK22

RISK22

includes the column 2 risk for row 2 in the output data set. The RISKDIFF option in the TABLES statement requests computation of risks and risk differences, which are available for 2×2 tables. For more information, see the section "Risks and Risk Differences" on page 501.

SCORR
includes the Spearman correlation coefficient in the output data set. The MEASURES option in the TABLES statement requests computation of the Spearman correlation. For more information, see the section "Spearman Rank Correlation Coefficient" on page 486.

SMDCR
includes Somers' $D(C|R)$ in the output data set. The MEASURES option in the TABLES statement requests computation of Somers' D. For more information, see the section "Somers' D" on page 485.

SMDRC
includes Somers' $D(R|C)$ in the output data set. The MEASURES option in the TABLES statement requests computation of Somers' D. For more information, see the section "Somers' D" on page 485.

STUTC
TAUC
includes Stuart's tau-c in the output data set. The MEASURES option in the TABLES statement requests computation of tau-c. For more information, see the section "Stuart's Tau-c" on page 484.

TREND
includes the Cochran-Armitage test for trend in the output data set. The TREND option in the TABLES statement requests computation of the trend test. This test is available for tables of dimension $2 \times C$ or $R \times 2$. For more information, see the section "Cochran-Armitage Test for Trend" on page 526.

TSYMM
BOWKER
includes Bowker's symmetry test in the output data set. The AGREE option in the TABLES statement requests computation of Bowker's test. For more information, see the section "Bowker's Symmetry Test" on page 529.

U
includes the uncertainty coefficient (symmetric) in the output data set. The MEASURES option in the TABLES statement requests computation of the uncertainty coefficient. For more information, see the section "Uncertainty Coefficient (Symmetric)" on page 491.

UCR
includes the asymmetric uncertainty coefficient $U(C|R)$ in the output data set. The MEASURES option in the TABLES statement requests computation of the uncertainty coefficient. For more information, see the section "Uncertainty Coefficients (Asymmetric)" on page 490.

URC
includes the asymmetric uncertainty coefficient $U(R|C)$ in the output data set. The MEASURES option in the TABLES statement requests computation of the uncertainty coefficient. For more information, see the section "Uncertainty Coefficients (Asymmetric)" on page 490.

WTKAPPA
WTKAP
includes the weighted kappa coefficient in the output data set. The AGREE option in the TABLES statement requests computation of weighted kappa, which is available for square tables larger than 2×2. For multiway tables, the WTKAPPA option also includes the overall weighted kappa coefficient in the output data set. For more information, see the sections "Weighted Kappa Coefficient" on page 532 and "Overall Kappa Coefficient" on page 535.

TABLES Statement

TABLES *requests* < / *options* > **;**

The TABLES statement requests one-way to *n*-way frequency and crosstabulation tables and statistics for those tables.

If you omit the TABLES statement, PROC FREQTAB generates one-way frequency tables for all data set variables that are not listed in the other statements.

The following argument is required in the TABLES statement.

requests

specify the frequency and crosstabulation tables to produce. A request is composed of one variable name or several variable names separated by asterisks. To request a one-way frequency table, use a single variable. To request a two-way crosstabulation table, use an asterisk between two variables. To request a multiway table (an *n*-way table, where $n > 2$), separate the variables with asterisks. The unique values of these variables form the rows, columns, and strata of the table. You can include up to 50 variables in a single multiway table request.

For two-way to multiway tables, the values of the last variable form the crosstabulation table columns, and the values of the next-to-last variable form the rows. Each level (or combination of levels) of the other variables forms one stratum. PROC FREQTAB produces a separate crosstabulation table for each stratum. For example, a specification of A*B*C*D in a TABLES statement produces *k* tables, where *k* is the number of different combinations of values for A and B. Each table lists the values for C down the side and the values for D across the top.

You can use multiple TABLES statements in the PROC FREQTAB step. PROC FREQTAB builds all the table requests in one pass of the data, so that there is essentially no loss of efficiency. You can also specify any number of table requests in a single TABLES statement. To specify multiple table requests quickly, use a grouping syntax by placing parentheses around several variables and joining other variables or variable combinations. For example, the statements shown in Table 11.7 illustrate grouping syntax.

Table 11.7 Grouping Syntax

TABLES Request	Equivalent to
A*(B C)	A*B A*C
(A B)*(C D)	A*C B*C A*D B*D
(A B C)*D	A*D B*D C*D
A – C	A B C
(A – C)*D	A*D B*D C*D

The TABLES statement variables are one or more variables from the DATA= input data table. These variables can be either character or numeric, but the procedure treats them as categorical variables. PROC FREQTAB uses the formatted values of the TABLES variable to determine the categorical variable levels. For more information, see the discussion of the FORMAT procedure in the *Base SAS Procedures Guide* and the discussion of SAS formats in *SAS Formats and Informats: Reference*.

By default, the frequency or crosstabulation table lists the values of both character and numeric variables in ascending order based on internal (unformatted) variable values. You can change the order of the values in the table by specifying the ORDER= option in the PROC FREQTAB statement. To list the values in ascending order by formatted value, use ORDER=FORMATTED.

Without Options

If you request a one-way frequency table without specifying any options, PROC FREQTAB provides the following for each table level or cell: frequency, cumulative frequency, percentage of the total frequency, and cumulative percentage. If you request a two-way or multiway (n-way) crosstabulation table without specifying any options, PROC FREQTAB provides the following for each table cell; frequency, percentage of the total frequency, percentage of the row frequency, and percentages of the column frequency. PROC FREQTAB also displays the frequency of missing values after the table. For more information, see the section "Displayed Output" on page 554.

Options

Table 11.8 lists the *options* available in the TABLES statement. Descriptions of the *options* follow in alphabetical order.

Table 11.8 TABLES Statement Options

Option	Description
Control Statistical Analysis	
AGREE	Requests tests and measures of classification agreement
ALL	Requests tests and measures of association produced by the CHISQ, MEASURES, and CMH options
ALPHA=	Sets confidence level for confidence limits
BINOMIAL | BIN	Requests binomial proportions, confidence limits, and tests for one-way tables
CHISQ	Requests chi-square tests and measures based on chi-square
CL	Requests confidence limits for MEASURES statistics
CMH	Requests all Cochran-Mantel-Haenszel statistics
CMH1	Requests CMH correlation statistic, adjusted odds ratios, and adjusted relative risks
CMH2	Requests CMH correlation and row mean scores (ANOVA) statistics, adjusted odds ratios, and adjusted relative risks
COMMONRISKDIFF	Requests common risk difference for $h \times 2 \times 2$ tables
CQ	Requests Cochran's Q test
FISHER	Requests Fisher's exact test for tables larger than 2×2
GAILSIMON	Requests Gail-Simon test for qualitative interactions
JT	Requests Jonckheere-Terpstra test
MEASURES	Requests measures of association
OR	Requests the odds ratio for 2×2 tables
PLCORR	Requests polychoric correlation
RELRISK	Requests relative risks for 2×2 tables
RISKDIFF	Requests risks and risk differences for 2×2 tables
SCORES=	Specifies type of row and column scores

Table 11.8 *continued*

Option	Description
SENSPEC	Requests sensitivity and specificity for 2 × 2 tables
TREND	Requests Cochran-Armitage test for trend
Control Additional Table Information	
CELLCHI2	Displays cell contributions to the Pearson chi-square statistic
CUMCOL	Displays cumulative column percentages
DEVIATION	Displays deviations of cell frequencies from expected values
EXPECTED	Displays expected cell frequencies
PRINTKWTS	Displays kappa coefficient weights
SCOROUT	Displays row and column scores
TOTPCT	Displays percentages of total frequency for n-way tables ($n > 2$)
Control Displayed Output	
CROSSLIST	Displays crosstabulation tables in ODS column format
FORMAT=	Formats frequencies in crosstabulation tables
FORMATP=	Formats percentages in crosstabulation tables
LIST	Displays two-way and n-way tables in list format
MAXLEVELS=	Specifies maximum number of levels to display in one-way tables
NOCOL	Suppresses display of column percentages
NOCUM	Suppresses display of cumulative frequencies and percentages
NOFREQ	Suppresses display of frequencies
NOPERCENT	Suppresses display of percentages
NOPRINT	Suppresses display of crosstabulation tables but displays statistics
NOROW	Suppresses display of row percentages
NOSPARSE	Suppresses zero-frequency levels in the CROSSLIST table, LIST table, and OUT= data table
NOWARN	Suppresses log warning message for the chi-square test
ONEWAY	Specifies content of one-way frequency tables
Produce Statistical Graphics	
PLOTS=	Requests plots from ODS Graphics
Create an Output Data Set	
OUT=	Names an output data table to contain frequency counts
OUTCUM	Includes cumulative frequencies and percentages in the output data set
OUTEXPECT	Includes expected frequencies in the output data set
OUTPCT	Includes row, column, and two-way table percentages in the output data set

You can specify the following *options*:

AGREE < (*agree-options*) >

requests tests and measures of classification agreement for square tables. This option provides the simple and weighted kappa coefficients along with their standard errors and confidence limits. For multiway tables, this option also produces the overall simple and weighted kappa coefficients (along with their standard errors and confidence limits) and tests for equal kappas among strata. For 2×2 tables, this option provides McNemar's test; for square tables that have more than two response categories (levels), this option provides Bowker's symmetry test. For multiway tables in which each variable has two levels, this option also produces Cochran's Q test. (You can request Cochran's Q test separately by specifying the CQ option.) For more information, see the section "Tests and Measures of Agreement" on page 529.

Measures of agreement can be computed only for square tables, where the number of rows equals the number of columns. If your table is not square because some observations have weights of 0, you can specify the ZEROS option in the WEIGHT statement to include these observations in the analysis. For more information, see the section "Tables with Zero-Weight Rows or Columns" on page 536.

For 2×2 tables, the weighted kappa coefficient is equivalent to the simple kappa coefficient, and PROC FREQTAB displays only analyses for the simple kappa coefficient.

You can specify the confidence level in the ALPHA= option. By default, ALPHA=0.05, which produces 95% confidence limits.

You can specify the EXACT statement to request McNemar's exact test (for 2×2 tables), an exact symmetry test, and exact tests for the simple and weighted kappa coefficients. For more information, see the section "Exact Statistics" on page 547.

You can specify the following *agree-options*:

AC1

requests the AC1 agreement coefficient. For more information, see the section "AC1 Agreement Coefficient" on page 534.

DFSYM=*df* | ADJUST

controls the degrees of freedom for Bowker's symmetry test. You can specify the value of the degrees of freedom (*df*), or you can specify DFSYM=ADJUST to adjust the degrees of freedom for empty table cells. The value of *df* must be a positive number. By default, *df* is $R(R-1)/2$, where R is the dimension of the two-way table.

When you specify DFSYM=ADJUST, the degrees of freedom are reduced by the number of off-diagonal table-cell pairs that have a total frequency of 0. By default, the degrees of freedom count all off-diagonal table-cell pairs. For more information, see the section "Bowker's Symmetry Test" on page 529.

KAPPADETAILS

DETAILS

displays the "Kappa Details" table, which includes the following statistics for the simple kappa coefficient: observed agreement, chance-expected agreement, maximum kappa, and the B_n measure. If the two-way table is 2×2, the "Kappa Details" table also includes the prevalence index and the bias index. For more information, see the section "Simple Kappa Coefficient" on page 530.

If the two-way table is larger than 2×2, this option also displays the "Weighted Kappa Details" table, which includes the observed agreement and chance-expected agreement components of the

weighted kappa coefficient. For more information, see the section "Weighted Kappa Coefficient" on page 532.

MNULLRATIO=*value*
specifies the null *value* of the ratio of discordant proportions for McNemar's test. By default, MNULLRATIO=1. For more information, see the section "McNemar's Test" on page 529.

NULLKAPPA=*value*
requests the simple kappa coefficient test and specifies the null *value* for the test. The null value must be between –1 and 1. By default, NULLKAPPA=0. For more information, see the section "Simple Kappa Coefficient" on page 530.

This option is not available when you specify the KAPPA option in the EXACT statement, which requests an exact test for the kappa coefficient.

NULLWTKAPPA=*value*
requests the weighted kappa coefficient test and specifies the null *value* for the test. The null value must be between –1 and 1. By default, NULLWTKAPPA=0. For more information, see the section "Weighted Kappa Coefficient" on page 532.

This option is not available when you specify the WTKAPPA option in the EXACT statement, which requests an exact test for the weighted kappa coefficient.

PABAK
requests the prevalence-adjusted bias-adjusted kappa coefficient. For more information, see the section "Prevalence-Adjusted Bias-Adjusted Kappa" on page 534.

PRINTKWTS
displays the agreement weights that PROC FREQTAB uses to compute the weighted kappa coefficient. Agreement weights reflect the relative agreement between pairs of variable levels. By default, PROC FREQTAB uses Cicchetti-Allison agreement weights. If you specify the WT=FC option, the procedure uses Fleiss-Cohen agreement weights. For more information, see the section "Weighted Kappa Coefficient" on page 532.

TABLES=RESTORE
displays the following agreement tables (which are produced by the AGREE option) in factoid (label-value) format: "McNemar's Test," "Symmetry Test," "Monte Carlo Exact Symmetry Test," "Simple Kappa Coefficient," "Simple Kappa Test," "Weighted Kappa Coefficient," "Weighted Kappa Test," "Monte Carlo Estimates for the Exact Test," "Overall Kappa Coefficient," "Tests for Equal Kappa Coefficients," and "Cochran's Q."

By default, PROC FREQTAB displays all agreement tables in tabular format.

WT=FC
specifies Fleiss-Cohen agreement weights in the computation of the weighted kappa coefficient. Agreement weights reflect the relative agreement between pairs of variable levels. By default, PROC FREQTAB uses Cicchetti-Allison agreement weights to compute the weighted kappa coefficient. For more information, see the section "Weighted Kappa Coefficient" on page 532.

WTKAPPADETAILS
displays the "Weighted Kappa Details" table, which includes the observed agreement and chance-expected agreement components of the weighted kappa coefficient. This information is available for two-way tables that are larger than 2×2. For more information, see the section "Weighted Kappa Coefficient" on page 532.

ALL
requests all tests and measures that are produced by the CHISQ, MEASURES, and CMH options. You can control the number of CMH statistics to compute by specifying the CMH1 or CMH2 option.

ALPHA=α
specifies the level of confidence limits. The value of α must be between 0 and 1; a confidence level of α produces $100(1-\alpha)\%$ confidence limits. By default ALPHA=0.05, which produces 95% confidence limits.

This option applies to confidence limits that you request in the TABLES statement. The ALPHA= option in the EXACT statement applies to confidence limits for Monte Carlo estimates of exact p-values, which you request by specifying the MC option in the EXACT statement.

BINOMIAL < (*binomial-options*) >
BIN < (*binomial-options*) >
requests the binomial proportion for one-way tables. By default, PROC FREQTAB provides the asymptotic standard error, asymptotic Wald and exact (Clopper-Pearson) confidence limits, and the asymptotic equality test for the binomial proportion.

You can specify *binomial-options* in parentheses after the BINOMIAL option. The LEVEL= *binomial-option* identifies the variable level for which to compute the proportion. If you do not specify this option, PROC FREQTAB computes the proportion for the first level that appears in the one-way frequency table. The P= *binomial-option* specifies the null proportion for the binomial tests. If you do not specify this option, PROC FREQTAB uses 0.5 as the null proportion for the binomial tests.

You can also specify *binomial-options* to request additional tests and confidence limits for the binomial proportion. The EQUIV, NONINF, and SUP *binomial-options* request tests of equivalence, noninferiority, and superiority, respectively. The CL= *binomial-option* requests confidence limits for the binomial proportion.

You can specify the level for the binomial confidence limits in the ALPHA= option. By default, ALPHA=0.05, which produces 95% confidence limits. As part of the noninferiority, superiority, and equivalence analyses, PROC FREQTAB provides null-based equivalence limits that have a confidence coefficient of $100(1-2\alpha)\%$ (Schuirmann 1999). In these analyses, the default of ALPHA=0.05 produces 90% equivalence limits. For more information, see the sections "Noninferiority Test" on page 496 and "Equivalence Test" on page 498.

To request exact tests for the binomial proportion, you can specify the BINOMIAL option in the EXACT statement. PROC FREQTAB computes exact p-values for all binomial tests that you request, which can include noninferiority, superiority, and equivalence tests, in addition to the equality test that the BINOMIAL option produces by default.

For more information, see the section "Binomial Proportion" on page 491.

Table 11.9 summarizes the *binomial-options*.

Table 11.9 BINOMIAL Options

Option	Description
CORRECT	Requests continuity correction
LEVEL=	Specifies the variable level
OUTLEVEL	Includes the level in the output data sets
P=	Specifies the null proportion
Request Confidence Limits	
CL=AGRESTICOULL | AC	Requests Agresti-Coull confidence limits
CL=BLAKER	Requests Blaker confidence limits
CL=EXACT | CLOPPERPEARSON	Requests exact (Clopper-Pearson) confidence limits
CL=JEFFREYS	Requests Jeffreys confidence limits
CL=LIKELIHOODRATIO | LR	Requests likelihood ratio confidence limits
CL=LOGIT	Requests logit confidence limits
CL=MIDP	Requests exact mid-*p* confidence limits
CL=WALD	Requests Wald confidence limits
CL=WILSON | SCORE	Requests Wilson (score) confidence limits
Request Tests	
EQUIV | EQUIVALENCE	Requests an equivalence test
MARGIN=	Specifies the test margin
NONINF | NONINFERIORITY	Requests a noninferiority test
SUP | SUPERIORITY	Requests a superiority test
VAR=NULL | SAMPLE	Specifies the test variance

You can specify the following *binomial-options*:

CL=*type* **|** **(***types***)**
requests confidence limits for the binomial proportion. You can specify one or more *types* of confidence limits. When you specify only one *type*, you can omit the parentheses around the request. PROC FREQTAB displays the confidence limits in the "Binomial Confidence Limits" table.

The ALPHA= option determines the level of the confidence limits that the CL= *binomial-option* provides. By default, ALPHA=0.05, which produces 95% confidence limits for the binomial proportion.

You can specify the CL= *binomial-option* with or without requests for binomial tests. The confidence limits that CL= produces do not depend on the tests that you request and do not use the value of the test margin (which you can specify in the MARGIN= *binomial-option*).

If you do not specify the CL= *binomial-option*, the BINOMIAL option displays Wald and exact (Clopper-Pearson) confidence limits in the "Binomial Proportion" table.

You can specify the following *types*:

AGRESTICOULL

AC

requests Agresti-Coull confidence limits for the binomial proportion. For more information, see the section "Agresti-Coull Confidence Limits" on page 493.

BLAKER

requests Blaker confidence limits for the binomial proportion. For more information, see the section "Blaker Confidence Limits" on page 493.

EXACT

CLOPPERPEARSON

requests exact (Clopper-Pearson) confidence limits for the binomial proportion. For more information, see the section "Exact (Clopper-Pearson) Confidence Limits" on page 492.

If you do not specify the CL= *binomial-option*, PROC FREQTAB displays Wald and exact (Clopper-Pearson) confidence limits in the "Binomial Proportion" table. To request exact tests for the binomial proportion, you can specify the BINOMIAL option in the EXACT statement.

JEFFREYS < (*option*) >

requests Jeffreys confidence limits for the binomial proportion. For more information, see the section "Jeffreys Confidence Limits" on page 493.

You can specify the following *option*:

MODIFY

provides modified Jeffreys confidence limits (Brown, Cai, and DasGupta 2001) to improve the coverage of the confidence limits for proportions near 0 or 1. For more information, see the section "Jeffreys Confidence Limits" on page 493.

LIKELIHOODRATIO

LR

requests likelihood ratio confidence limits for the binomial proportion. For more information, see the section "Likelihood Ratio Confidence Limits" on page 494.

LOGIT

requests logit confidence limits for the binomial proportion. For more information, see the section "Logit Confidence Limits" on page 494.

MIDP

requests exact mid-*p* confidence limits for the binomial proportion. For more information, see the section "Mid-*p* Confidence Limits" on page 494.

WALD < (CORRECT) >

requests Wald confidence limits for the binomial proportion. For more information, see the section "Wald Confidence Limits" on page 492.

If you specify CL=WALD(CORRECT), the Wald confidence limits include a continuity correction. If you specify the CORRECT *binomial-option*, both the Wald confidence limits and the Wald tests include continuity corrections.

If you do not specify the CL= *binomial-option*, PROC FREQTAB displays Wald and exact (Clopper-Pearson) confidence limits in the "Binomial Proportion" table.

WILSON <(*option*)>

SCORE <(*option*)>

requests Wilson confidence limits for the binomial proportion. These are also known as *score* confidence limits. For more information, see the section "Wilson (Score) Confidence Limits" on page 495.

You can specify one of the following *options*:

ADAPT

provides adapted Wilson confidence limits (Agresti and Coull 1998) to improve the coverage of the confidence limits for proportions near 0 or 1. Adapted confidence limits are computed when the number of successes is 1 or $n - 1$. For more information, see the section "Wilson (Score) Confidence Limits" on page 495.

CORRECT

includes a continuity correction in the Wilson confidence limits. For more information, see the section "Wilson (Score) Confidence Limits" on page 495.

MODIFY

provides modified Wilson confidence limits (Brown, Cai, and DasGupta 2001) to improve the coverage of the confidence limits for proportions near 0 or 1. For more information, see the section "Wilson (Score) Confidence Limits" on page 495.

CORRECT

includes a continuity correction in the Wald confidence limits, Wald tests, and Wilson confidence limits.

You can request continuity corrections individually for Wald or Wilson confidence limits by specifying the CL=WALD(CORRECT) or CL=WILSON(CORRECT) *binomial-option*, respectively.

EQUIV

EQUIVALENCE

requests a test of equivalence for the binomial proportion. For more information, see the section "Equivalence Test" on page 498. You can specify the equivalence test margins, the null proportion, and the variance type in the MARGIN=, P=, and VAR= *binomial-options*, respectively. To request an exact equivalence test, you can specify the BINOMIAL option in the EXACT statement.

LEVEL=*level-number* | '*level-value*'

specifies the variable level for the binomial proportion. You can specify the *level-number*, which is the order in which the level appears in the one-way frequency table. Or you can specify the *level-value*, which is the formatted value of the variable level. The *level-number* must be a positive integer. You must enclose the *level-value* in single quotes.

By default, PROC FREQTAB computes the binomial proportion for the first variable level that appears in the one-way frequency table.

MARGIN=*value* | **(***lower***,** *upper***)**

specifies the margin for the noninferiority, superiority, and equivalence tests, which you can request by specifying the NONINF, SUP, and EQUIV *binomial-options*, respectively. By default, MARGIN=0.2.

For noninferiority and superiority tests, specify a single *value* in the MARGIN= option. The MARGIN= *value* must be a positive number. You can specify *value* as a number between 0 and 1. Or you can specify *value* in percentage form as a number between 1 and 100, and PROC FREQTAB converts that number to a proportion. PROC FREQTAB treats the value 1 as 1%.

For noninferiority and superiority tests, the test limits must be between 0 and 1. The limits are determined by the null proportion value (which you can specify in the P= *binomial-option*) and by the margin value. The noninferiority limit is the null proportion minus the margin. By default, the null proportion is 0.5 and the margin is 0.2, which produces a noninferiority limit of 0.3. The superiority limit is the null proportion plus the margin, which is 0.7 by default.

For an equivalence test, you can specify a single MARGIN= *value*, or you can specify both *lower* and *upper* values. If you specify a single MARGIN= *value*, it must be a positive number, as described previously. If you specify a single MARGIN= *value* for an equivalence test, PROC FREQTAB uses –*value* as the lower margin and *value* as the upper margin for the test. If you specify both *lower* and *upper* values for an equivalence test, you can specify them in proportion form as numbers between –1 and 1. Or you can specify them in percentage form as numbers between –100 and 100, and PROC FREQTAB converts the numbers to proportions. The value of *lower* must be less than the value of *upper*.

The equivalence limits must be between 0 and 1. The equivalence limits are determined by the null proportion value (which you can specify in the P= *binomial-option*) and by the margin values. The lower equivalence limit is the null proportion plus the lower margin. By default, the null proportion is 0.5 and the lower margin is –0.2, which produces a lower equivalence limit of 0.3. The upper equivalence limit is the null proportion plus the upper margin, which is 0.7 by default.

For more information, see the sections "Noninferiority Test" on page 496 and "Equivalence Test" on page 498.

NONINF

NONINFERIORITY

requests a test of noninferiority for the binomial proportion. For more information, see the section "Noninferiority Test" on page 496. You can specify the noninferiority test margin, the null proportion, and the variance type in the MARGIN=, P=, and VAR= *binomial-options*, respectively. To request an exact noninferiority test, you can specify the BINOMIAL option in the EXACT statement.

OUTLEVEL

includes the variables LevelNumber and LevelValue in all ODS output data sets that PROC FREQTAB produces when you specify the BINOMIAL option in the TABLES statement. The OUTLEVEL option also includes the variables LevelNumber and LevelValue in the statistics output data set that PROC FREQTAB produces when you specify the BINOMIAL option in the OUTPUT statement.

The LevelNumber and LevelValue variables identify the analysis variable level for which PROC FREQTAB computes the binomial proportion. The value of LevelNumber is the order of the level

in the one-way frequency table. The value of LevelValue is the formatted value of the level. You can specify the OUTLEVEL *binomial-option* with or without the LEVEL= *binomial-option*.

P=*value*
specifies the null hypothesis proportion for the binomial tests. The null proportion *value* must be a positive number. You can specify *value* as a number between 0 and 1. Or you can specify *value* in percentage form (as a number between 1 and 100), and PROC FREQTAB converts that number to a proportion. PROC FREQTAB treats the value 1 as 1%. By default, P=0.5.

SUP
SUPERIORITY
requests a test of superiority for the binomial proportion. For more information, see the section "Superiority Test" on page 498. You can specify the superiority test margin, the null proportion, and the variance type in the MARGIN=, P=, and VAR= *binomial-options*, respectively. To request an exact superiority test, you can specify the BINOMIAL option in the EXACT statement.

VAR=NULL | SAMPLE
specifies the type of variance to use in the Wald tests of noninferiority, superiority, and equivalence. If you specify VAR=SAMPLE, PROC FREQTAB computes the variance estimate by using the sample proportion. If you specify VAR=NULL, PROC FREQTAB computes a test-based variance by using the null hypothesis proportion (which you can specify in the P= *binomial-option*). For more information, see the sections "Noninferiority Test" on page 496 and "Equivalence Test" on page 498. By default, VAR=SAMPLE.

CELLCHI2
displays cell chi-squares in the crosstabulation table. A cell chi-square is the table cell's contribution to the Pearson chi-square statistic. The cell chi-square is computed as $(frequency - expected)^2/expected$, where *frequency* is the table cell frequency (count) and *expected* is the expected cell frequency, which is computed under the null hypothesis that the row and column variables are independent. For more information, see the section "Pearson Chi-Square Test for Two-Way Tables" on page 477.

This option applies to two-way and multiway tables that are displayed in the default crosstabulation cell format or in CROSSLIST format. This option has no effect for one-way frequency tables or for tables that are produced by the LIST option. To display cell chi-squares in one-way frequency tables, you can specify the ONEWAY(CELLCHI2) option.

CHISQ < (*chisq-options***) >**
requests chi-square tests of homogeneity or independence and measures of association that are based on the chi-square statistic. For two-way tables, the chi-square tests include the Pearson chi-square, likelihood ratio chi-square, and Mantel-Haenszel chi-square tests. The chi-square measures include the phi coefficient, contingency coefficient, and Cramér's V. For 2×2 tables, the CHISQ option also provides Fisher's exact test and the continuity-adjusted chi-square test. For more information, see the section "Chi-Square Tests and Statistics" on page 476.

For one-way tables, the CHISQ option provides the Pearson chi-square goodness-of-fit test. You can also request the likelihood ratio goodness-of-fit test for one-way tables by specifying the LRCHI *chisq-option* in parentheses after the CHISQ option. By default, the one-way chi-square tests are based on the null hypothesis of equal proportions. Alternatively, you can provide null hypothesis proportions or frequencies by specifying the TESTP= or TESTF= *chisq-option*, respectively. See the section "Chi-Square Test for One-Way Tables" on page 477 for more information.

To request Fisher's exact test for tables larger than 2×2, specify the FISHER option in the EXACT statement. Exact p-values are also available for the Pearson, likelihood ratio, and Mantel-Haenszel chi-square tests. See the description of the EXACT statement for more information.

You can specify the following *chisq-options*:

DF=*df*

specifies the degrees of freedom for the chi-square tests. The value of *df* must not be 0. If the value of *df* is positive, PROC FREQTAB uses *df* as the degrees of freedom for the chi-square tests. If the value of *df* is negative, PROC FREQTAB uses *df* to adjust the default degrees of freedom for the chi-square tests.

By default for one-way tables, the value of *df* is $(n - 1)$, where n is the number of variable levels in the table. By default for two-way tables, the value of *df* is $(r - 1)\ (c - 1)$, where r is the number of rows in the table and c is the number of columns. See the sections "Chi-Square Test for One-Way Tables" on page 477 and "Chi-Square Tests and Statistics" on page 476 for more information.

If you specify a negative value of *df*, PROC FREQTAB adjusts the default degrees of freedom by adding the (negative) value of *df* to the default value to produce the adjusted degrees of freedom. The adjusted degrees of freedom must be positive.

The DF= *chisq-option* specifies or adjusts the degrees of freedom for the following chi-square tests: the Pearson and likelihood ratio goodness-of-fit tests for one-way tables; and the Pearson, likelihood ratio, and Mantel-Haenszel chi-square tests for two-way tables.

LRCHI

requests the likelihood ratio goodness-of-fit test for one-way tables. See the section "Likelihood Ratio Chi-Square Test for One-Way Tables" on page 478 for more information.

By default, this test is based on the null hypothesis of equal proportions. You can provide null hypothesis proportions or frequencies by specifying the TESTP= or TESTF= *chisq-option*, respectively. You can request an exact likelihood ratio goodness-of-fit test by specifying the LRCHI option in the EXACT statement.

TESTF=(*values***)**

specifies null hypothesis frequencies for chi-square tests for one-way tables (goodness-of-fit tests). For more information, see the section "Chi-Square Test for One-Way Tables" on page 477.

You can separate the *values* by using blanks or commas, and you must enclose the list of values in parentheses. The *values* must be positive numbers. The number of *values* must equal the number of variable levels in the one-way table. The sum of the *values* must equal the total frequency in the one-way table. List the *values* in the same order in which the corresponding variable levels appear in the output.

TESTP=(*values***)**

specifies null hypothesis proportions for chi-square tests for one-way tables (goodness-of-fit tests). For more information, see the section "Chi-Square Test for One-Way Tables" on page 477.

You can separate the *values* by using blanks or commas, and you must enclose the list of values in parentheses. The *values* must be positive numbers. The number of *values* must equal the number of variable levels in the one-way table. List the *values* in the same order in which the corresponding variable levels appear in the output.

You can specify *values* in probability form as numbers between 0 and 1, where the proportions sum to 1. Or you can specify *values* in percentage form as numbers between 0 and 100, where the percentages sum to 100. PROC FREQTAB treats the value 1 as the percentage form 1%.

WARN=*type* | **(***types***)**
controls the warning message for the validity of the asymptotic Pearson chi-square test. By default, PROC FREQTAB displays a warning message when more than 20% of the table cells have expected frequencies that are less than 5. If you specify the NOPRINT option in the PROC FREQTAB statement, the procedure displays the warning in the log; otherwise, the procedure displays the warning as a footnote in the chi-square table. You can use the WARN= option to suppress the warning and to include a warning indicator in the output data set.

You can specify one or more of the following *types* in the WARN= option. If you specify more than one *type* value, enclose the values in parentheses after WARN=. For example, `warn = (output noprint)`.

Value of WARN=	Description
OUTPUT	Adds a warning indicator variable to the output data set
NOLOG	Suppresses the chi-square warning message in the log
NOPRINT	Suppresses the chi-square warning message in the display
NONE	Suppresses the chi-square warning message entirely

If you specify the WARN=OUTPUT option, the ODS output data set ChiSq contains a variable named Warning that equals 1 for the Pearson chi-square observation when more than 20% of the table cells have expected frequencies that are less than 5 and equals 0 otherwise. If you specify WARN=OUTPUT and also specify the CHISQ option in the OUTPUT statement, the statistics output data set contains a variable named WARN_PCHI that indicates the warning.

The WARN=NOLOG option has the same effect as the NOWARN option in the TABLES statement.

CL
requests confidence limits for the measures of association, which you can request by specifying the MEASURES option. For more information, see the sections "Measures of Association" on page 482 and "Confidence Limits" on page 482. You can set the level of the confidence limits by using the ALPHA= option; by default, ALPHA=0.05, which produces 95% confidence limits.

If you omit the MEASURES option, the CL option invokes MEASURES. The CL option is equivalent to the MEASURES(CL) option.

CMH <(*cmh-options***)>**
requests Cochran-Mantel-Haenszel statistics, which test for association between the row and column variables after adjusting for the remaining variables in a multiway table. The Cochran-Mantel-Haenszel statistics include the nonzero correlation statistic, the row mean scores (ANOVA) statistic, and the general association statistic. In addition, for 2×2 tables, the CMH option provides the adjusted Mantel-Haenszel and logit estimates of the odds ratio and relative risks, together with their confidence limits. For stratified 2×2 tables, the CMH option provides the Breslow-Day test for homogeneity of odds ratios. (To request Tarone's adjustment for the Breslow-Day test, specify the BDT *cmh-option*.) For more information, see the section "Cochran-Mantel-Haenszel Statistics" on page 536.

You can use the CMH1 or CMH2 option to control the number of CMH statistics that PROC FREQTAB computes.

For stratified 2×2 tables, you can request Zelen's exact test for equal odds ratios by specifying the EQOR option in the EXACT statement. For more information, see the section "Zelen's Exact Test for Equal Odds Ratios" on page 543. You can request exact confidence limits for the common odds ratio by specifying the COMOR option in the EXACT statement. This option also provides a common odds ratio test. For more information, see the section "Exact Confidence Limits for the Common Odds Ratio" on page 544.

You can specify the following *cmh-options* in parentheses after the CMH option. These *cmh-options* are also available with the CMH1 or CMH2 option.

BDT
requests Tarone's adjustment in the Breslow-Day test for homogeneity of odds ratios. For more information, see the section "Breslow-Day Test for Homogeneity of the Odds Ratios" on page 542.

GAILSIMON < (COLUMN=1 | 2) >
GS < (COLUMN=1 | 2) >
requests the Gail-Simon test for qualitative interaction, which applies to stratified 2×2 tables. For more information, see the section "Gail-Simon Test for Qualitative Interactions" on page 546.

The COLUMN= option specifies the column of the risk differences to use to compute the Gail-Simon test. By default, PROC FREQTAB uses column 1 risk differences. If you specify COLUMN=2, PROC FREQTAB uses column 2 risk differences.

The GAILSIMON *cmh-option* is equivalent to the GAILSIMON option in the TABLES statement.

I2
requests the I-square measure of heterogeneity for stratified 2×2 tables. I-square is computed from a Q test that is based on odds ratios. The I2 *cmh-option* invokes the QOR *cmh-option*. For more information, see the section "I-Square Measure of Heterogeneity" on page 543.

MANTELFLEISS
MF
requests the Mantel-Fleiss criterion for the Mantel-Haenszel statistic for stratified 2×2 tables. For more information, see the section "Mantel-Fleiss Criterion" on page 539.

QOR
requests a Q test for heterogeneity of odds ratios for stratified 2×2 tables. For more information, see the section "Q Test for Homogeneity of Odds Ratios" on page 542.

CMH1 < (*cmh-options*) >
requests the Cochran-Mantel-Haenszel correlation statistic. This option does not provide the CMH row mean scores (ANOVA) statistic or the general association statistic, which are provided by the CMH option. For tables larger than 2×2, the CMH1 option requires less memory than the CMH option, which can require an enormous amount of memory for large tables.

For 2×2 tables, the CMH1 option also provides the adjusted Mantel-Haenszel and logit estimates of the odds ratio and relative risks, together with their confidence limits. For stratified 2×2 tables, the CMH1 option provides the Breslow-Day test for homogeneity of odds ratios.

The *cmh-options* for CMH1 are the same as the *cmh-options* that are available with the CMH option. For more information, see the description of the CMH option.

CMH2 < (*cmh-options*) >
requests the Cochran-Mantel-Haenszel correlation statistic and the row mean scores (ANOVA) statistic. This option does not provide the CMH general association statistic, which is provided by the CMH option. For tables larger than 2×2, the CMH2 option requires less memory than the CMH option, which can require an enormous amount of memory for large tables.

For 2×2 tables, the CMH1 option also provides the adjusted Mantel-Haenszel and logit estimates of the odds ratio and relative risks, together with their confidence limits. For stratified 2×2 tables, the CMH1 option provides the Breslow-Day test for homogeneity of odds ratios.

The *cmh-options* for CMH2 are the same as the *cmh-options* that are available with the CMH option. For more information, see the description of the CMH option.

COMMONRISKDIFF < *options* >
requests the common (stratified) risk difference for multiway 2×2 tables, where the risk difference is the difference between the row 1 proportion and the row 2 proportion in a 2×2 table. By default, this option provides Mantel-Haenszel and summary score estimates of the common risk difference, together with their confidence limits. For more information, see the section "Common Risk Difference" on page 511.

You can specify the following *options* to request confidence limit types and tests for the common risk difference:

CL=*type* | (*types*)
requests confidence limits for the common risk difference. You can specify one or more *types* of confidence limits. When you specify only one *type*, you can omit the parentheses. You can specify CL=NONE to suppress the "Confidence Limits for the Common Risk Difference" table.

You can specify the confidence level in the ALPHA= option. By default, ALPHA=0.05, which produces 95% confidence limits for the common risk difference.

You can specify one or more of the following *types*:

K

KLINGENBERG
requests Klingenberg confidence limits for the Mantel-Haenszel common risk difference. For more information, see the section "Klingenberg Confidence Limits" on page 512.

MH
requests Mantel-Haenszel confidence limits, which are computed by using Mantel-Haenszel stratum weights and the Sato variance estimator (Sato 1989). For more information, see the section "Mantel-Haenszel Confidence Limits and Test" on page 511.

MN
requests Miettinen-Nurminen confidence limits for the common risk difference (Miettinen and Nurminen 1985).

MNMH
requests confidence limits that are computed by using the Miettinen-Nurminen method with Mantel-Haenszel weights (Lu 2008).

MR

MINRISK
requests minimum risk confidence limits, which are computed by using minimum risk weights. For more information, see the section "Minimum Risk Confidence Limits and Test" on page 513.

NEWCOMBE
requests stratified Newcombe confidence limits that use Mantel-Haenszel weights to combine the stratum components. For more information, see the section "Stratified Newcombe Confidence Limits" on page 515.

NEWCOMBEMR
requests stratified Newcombe confidence limits that use minimum risk weights to combine the stratum components. For more information, see the section "Stratified Newcombe Confidence Limits" on page 515.

NONE
suppresses the "Confidence Limits for the Common Risk Difference" table.

SCORE
requests summary score confidence limits. For more information, see the section "Summary Score Confidence Limits" on page 514.

COLUMN=1 | 2
specifies the table column for which to compute the common risk difference statistics.

By default, COLUMN=1 unless you specify the column for the risk difference plot or for the stratum-level risk difference statistics. In this case, when you omit the COMMONRISKDIFF(COLUMN=) option, PROC FREQTAB provides the common risk difference statistics for the same column that you specify for the plot or for the stratum-level statistics.

CORRECT=NO
removes the continuity correction in the minimum risk confidence limits and in the minimum risk test, which you can request by specifying the CL=MR and TEST=MR options, respectively. For more information, see the section "Minimum Risk Confidence Limits and Test" on page 513.

PRINTWTS < =*type* | (*types*) >
displays the stratum weights together with the stratum risk differences and frequencies. By default, this option displays the weight type or types for the confidence limits and tests that you request. Optionally, you can specify the weight type to display.

You can specify one or more of the following *types*:

MH
displays Mantel-Haenszel stratum weights. For more information, see the section "Mantel-Haenszel Confidence Limits and Test" on page 511.

MN
displays Miettinen-Nurminen stratum weights.

MR
displays minimum risk stratum weights. For more information, see the section "Minimum Risk Confidence Limits and Test" on page 513.

SCORE
displays summary score stratum weights. For more information, see the section "Summary Score Confidence Limits" on page 514.

TEST < =*type* | **(***types***) >**
requests common risk difference tests. You can specify one or more *types*. When you specify only one *type*, you can omit the parentheses. If you do not specify *types*, this option provides tests that correspond to the confidence limit *types* that you specify in the CL= option.

You can specify one or more of the following *types*:

MH
requests a Mantel-Haenszel test, which is computed by using Mantel-Haenszel stratum weights and the Sato variance estimator (Sato 1989). For more information, see the section "Mantel-Haenszel Confidence Limits and Test" on page 511.

MR < (VAR=SAMPLE) >

MINRISK < (VAR=SAMPLE) >
requests the minimum risk test, which is computed by using minimum risk weights. If you specify VAR=SAMPLE, PROC FREQTAB uses the sample (observed) variance estimate instead of a null variance estimate to compute the minimum risk test statistic. For more information, see the section "Minimum Risk Confidence Limits and Test" on page 513.

SCORE
requests the summary score test. For more information, see the section "Summary Score Confidence Limits" on page 514.

CQ

COCHQ
requests Cochran's Q test of marginal homogeneity, which can be computed for multiway tables in which each variable has two levels ($2 \times 2 \times \cdots \times 2$ tables). For more information, see the section "Cochran's Q Test" on page 535.

The AGREE option provides Cochran's Q test together with several other measures of agreement. You can use the CQ option to compute Cochran's Q test without the other measures of agreement.

CROSSLIST <(*options*)>

displays crosstabulation tables by using an ODS column format instead of the default crosstabulation cell format. In CROSSLIST tables, the rows correspond to the crosstabulation table cells, and the columns correspond to descriptive statistics such as frequencies and percentages. For more information about the contents of CROSSLIST tables, see the section "Two-Way and Multiway Tables" on page 556.

By default, CROSSLIST tables display all levels of the column variable within each level of the row variable, including any levels that have frequencies of 0. By default, multiway CROSSLIST tables display all levels of the row variable within each stratum, including any row levels that have frequencies of 0 in the stratum. To suppress variable levels that have frequencies of 0, you can specify the NOSPARSE option.

You cannot specify both the LIST option and the CROSSLIST option in the same TABLES statement.

You can specify the following *options*:

CELLCHI2

displays cell chi-squares in the CROSSLIST table. A cell chi-square is the table cell's contribution to the Pearson chi-square statistic. The cell chi-square is computed as $(frequency - expected)^2/expected$, where *frequency* is the table cell frequency (count) and *expected* is the expected cell frequency, which is computed under the null hypothesis that the row and column variables are independent. For more information, see the section "Pearson Chi-Square Test for Two-Way Tables" on page 477.

DEVIATION

displays deviations in the CROSSLIST table. A deviation is the difference between the observed table cell frequency and the expected frequency (*frequency* – *expected*). The expected frequencies are computed under the null hypothesis that the row and column variables are independent. For more information, see the section "Pearson Chi-Square Test for Two-Way Tables" on page 477. You can display the expected frequencies in the CROSSLIST table by specifying the CROSSLIST(EXPECTED) option.

EXPECTED

displays expected frequencies in the CROSSLIST table. Expected cell frequencies are computed as the product of the corresponding row totals and column totals divided by the total frequency of the two-way table. These are the expected frequencies under the null hypothesis that the row and column variables are independent. For more information, see the section "Pearson Chi-Square Test for Two-Way Tables" on page 477.

FORMAT=*format-name*

specifies the format for frequencies, expected frequencies, and deviations in the CROSSLIST table.

You can specify any standard SAS numeric format, or you can specify a numeric format that is defined by the FORMAT procedure. The format length must not exceed 24. By default, PROC FREQTAB uses the BEST8. format to display frequencies in the CROSSLIST table.

To change formats in any table that PROC FREQTAB displays, you can use PROC TEMPLATE. For more information, see the chapter "The TEMPLATE Procedure" in the *SAS Output Delivery System: User's Guide*.

FORMATP=*format-name*
specifies the format for percentages in the CROSSLIST table.

You can specify any standard SAS numeric format, or you can specify a numeric format that is defined by the FORMAT procedure. The format length must not exceed 24. By default, PROC FREQTAB uses the format 6.2 to display percentages in the CROSSLIST table.

To change formats in any table that PROC FREQTAB displays, you can use PROC TEMPLATE. For more information, see the chapter "The TEMPLATE Procedure" in the *SAS Output Delivery System: User's Guide*.

NOCOL
suppresses the display of column percentages in the CROSSLIST table.

NOFREQ
suppresses the display of frequencies in the CROSSLIST table.

NOPERCENT
suppresses the display of table percentages (the Percent column) in the CROSSLIST table. To suppress the display of row or column percentages, you can specify the CROSSLIST(NOROW) or CROSSLIST(NOCOL) option, respectively.

NOROW
suppresses the display of row percentages in the CROSSLIST table.

PEARSONRES
displays Pearson residuals in the CROSSLIST table. The Pearson residual is the square root of the table cell's contribution to the Pearson chi-square statistic. The Pearson residual is computed as $(frequency - expected)/\sqrt{expected}$, where *frequency* is the table cell frequency (count) and *expected* is the expected table cell frequency, which is computed under the null hypothesis that the row and column variables are independent. For more information, see the section "Pearson Chi-Square Test for Two-Way Tables" on page 477.

You can display the expected values, deviations, and cell chi-squares in the CROSSLIST table by specifying the CROSSLIST(EXPECTED), CROSSLIST(DEVIATION), and CROSSLIST(CELLCHI2) options, respectively.

STDRES
displays standardized residuals in the CROSSLIST table. The standardized residual is the ratio of (*frequency* – *expected*) to its standard error, where *frequency* is the table cell frequency (count) and *expected* is the expected table cell frequency, which is computed under the null hypothesis that the row and column variables are independent. For more information, see the section "Standardized Residuals" on page 478.

You can display the expected values and deviations in the CROSSLIST table by specifying the CROSSLIST(EXPECTED) and CROSSLIST(DEVIATION) options, respectively.

TOTPCT

displays percentages of the total multiway table frequency for multiway tables (n-way tables where $n > 2$). By default, the CROSSLIST table displays percentages of the two-way table (stratum) frequency but does not display percentages of the total multiway table frequency. For more information, see the section "Two-Way and Multiway Tables" on page 556.

CUMCOL

displays cumulative column percentages in the crosstabulation table. This option applies to two-way and multiway tables that are displayed in the default crosstabulation cell format.

DEVIATION

displays deviations in the crosstabulation table. A deviation is the difference between the observed table cell frequency and the expected frequency (*frequency – expected*). The expected frequencies are computed under the null hypothesis that the row and column variables are independent. For more information, see the section "Pearson Chi-Square Test for Two-Way Tables" on page 477. You can display the expected values by specifying the EXPECTED option.

This option applies to two-way and multiway tables that are displayed in the default crosstabulation cell format or in CROSSLIST format. To display deviations in one-way frequency tables, you can specify the ONEWAY(DEVIATION) option.

EXPECTED

displays expected frequencies in the crosstabulation table. Expected table cell frequencies are computed as the product of the corresponding row totals and column totals divided by the total frequency of the two-way table. These are the expected frequencies under the null hypothesis that the row and column variables are independent. For more information, see the section "Pearson Chi-Square Test for Two-Way Tables" on page 477.

This option applies to two-way and multiway tables that are displayed in the default crosstabulation cell format or in CROSSLIST format. To display expected frequencies in one-way frequency tables, you can specify the ONEWAY(EXPECTED) option.

FISHER

requests Fisher's exact test for tables that are larger than 2×2. (For 2×2 tables, the CHISQ option provides Fisher's exact test.) This test is also known as the Freeman-Halton test. See the sections "Fisher's Exact Test" on page 480 and "Exact Statistics" on page 547 for more information.

If you omit the CHISQ option in the TABLES statement, the FISHER option invokes CHISQ. You can also request Fisher's exact test by specifying the FISHER option in the EXACT statement.

NOTE: PROC FREQTAB computes exact tests by using fast and efficient algorithms that are superior to direct enumeration. Exact tests are appropriate when a data set is small, sparse, skewed, or heavily tied. For some large problems, computation of exact tests might require a substantial amount of time and memory. Consider using asymptotic tests for such problems. Alternatively, when asymptotic methods might not be sufficient for such large problems, consider using Monte Carlo estimation of exact p-values. You can request Monte Carlo estimation by specifying the MC *computation-option* in the EXACT statement. See the section "Computational Resources" on page 549 for more information.

FORMAT=*format-name*
specifies the format for frequencies, expected frequencies, and deviations in crosstabulation tables.

You can specify any standard SAS numeric format, or you can specify a numeric format that is defined by the FORMAT procedure. The format length must not exceed 24.

This option applies to crosstabulation tables that are displayed in default crosstabulation cell form, CROSSLIST form, or LIST form. You can use the ONEWAY(FORMAT=) option to specify the format for frequencies in one-way tables.

To change display formats in any table that PROC FREQTAB produces, you can use PROC TEMPLATE. For more information, see the chapter "The TEMPLATE Procedure" in the *SAS Output Delivery System: User's Guide*.

FORMATP=*format-name*
specifies the format for percentages in crosstabulation tables.

You can specify any standard SAS numeric format, or you can specify a numeric format that is defined by the FORMAT procedure. The format length must not exceed 24.

This option applies to crosstabulation tables that are displayed in default crosstabulation cell form, CROSSLIST form, or LIST form. You can use the ONEWAY(FORMATP=) option to specify the format for percentages in one-way frequency tables.

To change display formats in any table that PROC FREQTAB produces, you can use PROC TEMPLATE. For more information, see the chapter "The TEMPLATE Procedure" in the *SAS Output Delivery System: User's Guide*.

GAILSIMON < (COLUMN=1 | 2) >
GS < (COLUMN=1 | 2) >
requests the Gail-Simon test for qualitative interaction, which applies to stratified 2×2 tables. For more information, see the section "Gail-Simon Test for Qualitative Interactions" on page 546.

The COLUMN= option specifies the column of the risk differences to use to compute the Gail-Simon test. By default, PROC FREQTAB uses column 1 risk differences. If you specify COLUMN=2, PROC FREQTAB uses column 2 risk differences.

JT
requests the Jonckheere-Terpstra test. For more information, see the section "Jonckheere-Terpstra Test" on page 527. To request exact *p*-values for the Jonckheere-Terpstra test, specify the JT option in the EXACT statement. See the section "Exact Statistics" on page 547 for more information.

LIST < (*options*) >
displays two-way and multiway tables by using a list format instead of the default crosstabulation cell format. This option displays an entire multiway table in a single table instead of separate two-way (stratum) tables. In list format, each row of the table corresponds to a single crosstabulation table cell. For more information, see the section "Two-Way and Multiway Tables" on page 556.

By default, a table in list format does not display cells for which the frequency is 0 unless you specify the ZEROS option in the WEIGHT statement and do not specify the NOSPARSE option in the TABLES statement.

The LIST option is not available in the same TABLES statement together with statistic options. When you specify statistic options in a TABLES statement, you can display the crosstabulation tables by

using the default format or the CROSSLIST format. However, you can specify the LIST option and statistic options in different TABLES statements in the same invocation of PROC FREQTAB.

You can specify the following *options*:

FORMAT=*format-name*
specifies the format for frequencies and cumulative frequencies in the LIST crosstabulation table.

You can specify any standard SAS numeric format, or you can specify a numeric format that is defined by the FORMAT procedure. The format length must not exceed 24. By default, PROC FREQTAB uses the BEST8. format to display frequencies in the LIST crosstabulation table.

To change display formats in any table that PROC FREQTAB produces, you can use PROC TEMPLATE. For more information, see the chapter "The TEMPLATE Procedure" in the *SAS Output Delivery System: User's Guide*.

FORMATP=*format-name*
specifies the format for percentages and cumulative percentages in the LIST crosstabulation table.

You can specify any standard SAS numeric format, or you can specify a numeric format that is defined by the FORMAT procedure. The format length must not exceed 24. By default, PROC FREQTAB uses the format 6.2 to display percentages in the LIST table.

To change display formats in any table that PROC FREQTAB produces, you can use PROC TEMPLATE. For more information, see the chapter "The TEMPLATE Procedure" in the *SAS Output Delivery System: User's Guide*.

NOCUM
suppresses the display of cumulative frequencies and cumulative percentages in the LIST crosstabulation table.

NOFREQ
suppresses the display of frequencies and cumulative frequencies in the LIST crosstabulation table.

NOPERCENT
suppresses the display of percentages and cumulative percentages in the LIST crosstabulation table.

MAXLEVELS=*n*
specifies the maximum number of variable levels to display in one-way frequency tables. The value of *n* must be a positive integer. PROC FREQTAB displays the first *n* variable levels, matching the order in which the levels appear in the one-way frequency table. (The ORDER= option controls the order of the variable levels. By default, ORDER=INTERNAL, which orders the variable levels by unformatted value.)

The MAXLEVELS= option also applies to one-way frequency plots, which you can request by specifying the PLOTS=FREQPLOT option when ODS Graphics is enabled.

If you specify the MISSPRINT option to display missing levels in frequency tables, MAXLEVELS=*n* displays the first *n* nonmissing levels.

The MAXLEVELS= option does not apply to the OUT= output data set, which includes all variable levels. The MAXLEVELS= option does not affect the computation of percentages, statistics, or tests for the one-way table; these values are based on the complete table.

MEASURES <(CL)>

requests measures of association and their asymptotic standard errors. This option provides the following measures: gamma, Kendall's tau-*b*, Stuart's tau-*c*, Somers' $D(C|R)$, Somers' $D(R|C)$, Pearson and Spearman correlation coefficients, lambda (symmetric and asymmetric), and uncertainty coefficients (symmetric and asymmetric). If you specify the CL option in parentheses after the MEASURES option, PROC FREQTAB provides confidence limits for the measures of association. For more information, see the section "Measures of Association" on page 482.

For 2×2 tables, the MEASURES option also provides the odds ratio, column 1 relative risk, column 2 relative risk, and their asymptotic Wald confidence limits. You can request the odds ratio and relative risks separately (without the other measures of association) by specifying the RELRISK option. You can request confidence limits for the odds ratio by specifying the OR(CL=) option.

You can use the TEST statement to request asymptotic tests for the following measures of association: gamma, Kendall's tau-*b*, Stuart's tau-*c*, Somers' $D(C|R)$, Somers' $D(R|C)$, and Pearson and Spearman correlation coefficients. You can use the EXACT statement to request exact confidence limits for the odds ratio, exact unconditional confidence limits for the relative risks, and exact tests for the following measures of association: Kendall's tau-*b*, Stuart's tau-*c*, Somers' $D(C|R)$ and $D(R|C)$, and Pearson and Spearman correlation coefficients. For more information, see the descriptions of the TEST and EXACT statements and the section "Exact Statistics" on page 547.

NOCOL

suppresses the display of column percentages in crosstabulation tables. A table cell's column percentage is computed as the cell frequency divided by the corresponding column frequency.

NOCUM

suppresses the display of cumulative frequencies and percentages in one-way frequency tables and in list-format crosstabulation tables (which you can request by specifying the LIST option).

NOFREQ

suppresses the display of table cell frequencies in crosstabulation tables. This option also suppresses row total frequencies.

In list-format crosstabulation tables (which you can request by specifying the LIST option), the NOFREQ option suppresses the display of frequencies and cumulative frequencies. To suppress display of frequencies in one-way frequency tables, you can specify the ONEWAY(NOFREQ) option.

NOPERCENT

suppresses the display of overall percentages in crosstabulation tables. These percentages include table cell, row, and column percentages of the total two-way table frequency. To suppress display of cell percentages of row or column totals, you can specify the NOROW or NOCOL option, respectively.

For one-way frequency tables and list-format crosstabulation tables, the NOPERCENT option suppresses the display of percentages and cumulative percentages.

NOPRINT

suppresses the display of frequency and crosstabulation tables but displays all requested tests and statistics. To suppress the display of all output, including tests and statistics, use the NOPRINT option in the PROC FREQTAB statement.

NOROW
suppresses the display of row percentages in crosstabulation tables. A table cell's row percentage is computed as the cell frequency divided by the corresponding row frequency.

NOSPARSE
suppresses the display of zero-frequency table cells in LIST and CROSSLIST tables. This option also excludes zero-frequency table cells from OUT= output data sets.

When you specify the ZEROS option in the WEIGHT statement, PROC FREQTAB includes observations that have weights of 0 in the analysis. By default, zero-frequency table cells are displayed in the LIST table and included in the OUT= data set. You can use the NOSPARSE option to exclude the zero-frequency table cells.

When you specify the CROSSLIST option, by default the CROSSLIST table displays all levels of the column variable within each level of the row variable (including any levels that have frequencies of 0). By default for multiway CROSSLIST tables, the CROSSLIST table displays all levels of the row variable within each stratum of the table (including any row levels that have frequencies of 0 in the stratum). To suppress variable levels in the CROSSLIST table that have frequencies of 0, you can specify the NOSPARSE option.

NOWARN
suppresses the log warning message for the validity of the asymptotic Pearson chi-square test. By default, PROC FREQTAB provides a validity warning for the asymptotic Pearson chi-square test when more than 20% of the table cells have expected frequencies that are less than 5. This warning message appears in the log if you specify the NOPRINT option in the PROC FREQTAB statement,

The NOWARN option is equivalent to the CHISQ(WARN=NOLOG) option. You can also use the CHISQ(WARN=) option to suppress the warning message in the display and to request a warning variable in the chi-square ODS output data set or in the OUTPUT data set.

ONEWAY (*options*)
controls the statistics to display in one-way frequency tables. For more information about the contents of one-way frequency tables, see the section "One-Way Frequency Tables" on page 554.

You can specify the following *options*:

CELLCHI2
displays cell chi-squares in the one-way frequency table. A cell chi-square is the table cell's contribution to the Pearson chi-square statistic. The cell chi-square is computed as $(frequency - expected)^2/expected$, where *frequency* is the table cell (level) frequency and *expected* is the expected frequency. For more information, see the section "Chi-Square Test for One-Way Tables" on page 477.

DEVIATION
displays deviations in the one-way frequency table. A deviation is the difference between the observed table cell (level) frequency and the expected frequency (*frequency – expected*), where the expected frequencies are the null hypothesis frequencies for the chi-square goodness-of-fit test.

By default, the expected frequency for each class level is the total frequency divided by the number of levels. Alternatively, you can provide null frequencies or null proportions by specifying the CHISQ(TESTF=) or CHISQ(TESTP=) option, respectively. For more information, see the section "Chi-Square Test for One-Way Tables" on page 477.

EXPECTED
displays expected frequencies in the one-way frequency table, where the expected frequencies are the null hypothesis frequencies for the chi-square goodness-of-fit test.

By default, the expected frequency for each class level is the total frequency divided by the number of levels. Alternatively, you can provide null frequencies or null proportions by specifying the CHISQ(TESTF=) or CHISQ(TESTP=) option, respectively. For more information, see the section "Chi-Square Test for One-Way Tables" on page 477.

When you specify the CHISQ(TESTF=) option, the one-way frequency table displays the specified null hypothesis frequencies by default, and the EXPECTED option has no effect.

FORMAT=*format-name*
specifies the format for frequencies, expected frequencies, and deviations in the one-way frequency table.

You can specify any standard SAS numeric format, or you can specify a numeric format that is defined by the FORMAT procedure. The format length must not exceed 24. By default, PROC FREQTAB uses the BEST8. format to display frequencies in the one-way frequency table.

To change display formats in any table that PROC FREQTAB produces, you can use PROC TEMPLATE. For more information, see the chapter "The TEMPLATE Procedure" in the *SAS Output Delivery System: User's Guide*.

FORMATP=*format-name*
specifies the format for percentages in the one-way frequency table.

You can specify any standard SAS numeric format, or you can specify a numeric format that is defined by the FORMAT procedure. The format length must not exceed 24. By default, PROC FREQTAB uses the format 6.2 to display percentages in the one-way frequency table.

To change display formats in any table that PROC FREQTAB produces, you can use PROC TEMPLATE. For more information, see the chapter "The TEMPLATE Procedure" in the *SAS Output Delivery System: User's Guide*.

MAXLEVELS=*n*
specifies the maximum number of variable levels to display in the one-way frequency table. The value of *n* must be a positive integer. PROC FREQTAB displays the first *n* variable levels, matching the order in which the levels appear in the one-way frequency table. (The ORDER= option controls the order of the variable levels. By default, ORDER=INTERNAL, which orders the variable levels by unformatted values.)

The MAXLEVELS= option also applies to one-way frequency plots, which you can request by specifying the PLOTS=FREQPLOT option when ODS Graphics is enabled.

If you specify the MISSPRINT option to display missing levels in frequency tables, MAXLEVELS=*n* displays the first *n* nonmissing levels.

The MAXLEVELS= option does not apply to the OUT= output data set, which includes all variable levels. The MAXLEVELS= option does not affect the computation of percentages, statistics, or tests for the one-way table; these values are based on the complete table.

NOCUM
suppresses the display of cumulative frequencies and percentages in one-way frequency tables.

NOFREQ
suppresses the display of frequencies and cumulative frequencies in one-way frequency tables.

NOPERCENT
suppresses the display of percentages and cumulative percentages in one-way frequency tables.

RESIDUAL
displays Pearson residuals in the one-way frequency table. The Pearson residual is the square root of the table cell's contribution to the Pearson chi-square statistic. The Pearson residual is computed as $(frequency - expected)/\sqrt{expected}$, where *frequency* is the table cell frequency (count) and *expected* is the expected table cell frequency.

OR < (CL=*type* | (*types*) >
ODDSRATIO < (CL=*type* | (*types*) >
requests the odds ratio and confidence limits for 2×2 tables. For more information, see the section "Odds Ratio" on page 516.

You can specify one or more *types* of confidence limits. When you specify only one confidence limit *type*, you can omit the parentheses around the request. PROC FREQTAB displays the confidence limits in the "Confidence Limits for the Odds Ratio" table.

Specifying the OR option without the CL= option is equivalent to specifying the RELRISK option, which produces the "Odds Ratio and Relative Risks" table. For more information, see the description of the RELRISK option. When you specify the OR(CL=) option, PROC FREQTAB does not produce the "Odds Ratio and Relative Risks" table unless you also specify the RELRISK or MEASURES option.

The ALPHA= option determines the confidence level; by default, ALPHA=0.05, which produces 95% confidence limits for the odds ratio.

You can specify the following *types*:

EXACT
displays exact confidence limits for the odds ratio in the "Confidence Limits for the Odds Ratio" table. (By default, PROC FREQTAB displays the exact confidence limits in a separate table.) You must also request computation of the exact confidence limits by specifying the OR option in the EXACT statement. For more information, see the subsection "Exact Confidence Limits" in the section "Confidence Limits for the Odds Ratio" on page 516.

LR
LIKELIHOODRATIO
requests likelihood ratio confidence limits for the odds ratio. For more information, see the subsection "Likelihood Ratio Confidence Limits" in the section "Confidence Limits for the Odds Ratio" on page 516.

MIDP
requests exact mid-*p* confidence limits for the odds ratio. For more information, see the subsection "Exact Mid-*p* Confidence Limits" in the section "Confidence Limits for the Odds Ratio" on page 516.

SCORE <(CORRECT=NO)>
requests score confidence limits for the odds ratio. For more information, see the subsection "Score Confidence Limits" in the section "Confidence Limits for the Odds Ratio" on page 516. If you specify CORRECT=NO, PROC FREQTAB provides the uncorrected form of the score confidence limits.

WALD
requests asymptotic Wald confidence limits, which are based on a log transformation of the odds ratio. For more information, see the subsection "Wald Confidence Limits" in the section "Confidence Limits for the Odds Ratio" on page 516.

WALDMODIFIED
requests Wald modified confidence limits for the odds ratio. For more information, see the subsection "Wald Modified Confidence Limits" in the section "Confidence Limits for the Odds Ratio" on page 516.

OUT=*data-table*
names an output data table that contains frequency or crosstabulation table counts and percentages. If more than one table request appears in the TABLES statement, the contents of the OUT= data table correspond to the last table request in the TABLES statement. The OUT= data table variable COUNT contains the frequencies and the variable PERCENT contains the percentages. For more information, see the section "Contents of the TABLES Statement Output Data Set" on page 552. You can specify the following options to include additional information in the OUT= data table: OUTCUM, OUTEXPECT, and OUTPCT.

OUTCUM
includes cumulative frequencies and cumulative percentages in the OUT= data set. The variable CUM_FREQ contains the cumulative frequencies, and the variable CUM_PCT contains the cumulative percentages. For more information, see the section "Contents of the TABLES Statement Output Data Set" on page 552. This option is available for one-way frequency tables and for tables that you display in list format (which you can request by specifying the LIST option).

OUTEXPECT
includes expected cell frequencies in the OUT= data set for crosstabulation tables. The variable EXPECTED contains the expected cell frequencies. For more information, see the section "Contents of the TABLES Statement Output Data Set" on page 552. This option has no effect for one-way tables or for tables that you display in list format (which you can request by specifying the LIST option).

OUTPCT
includes the following additional variables in the OUT= data set for crosstabulation tables:

PCT_COL	percentage of column frequency
PCT_ROW	percentage of row frequency
PCT_TABL	percentage of stratum (two-way table) frequency, for n-way tables where $n > 2$

For more information, see the section "Contents of the TABLES Statement Output Data Set" on page 552. This option has no effect for one-way tables or for tables that you display in list format (which you can request by specifying the LIST option).

PLCORR < (*options*) >

POLYCHORIC < (*options*) >

requests the polychoric correlation coefficient and its asymptotic standard error. For 2×2 tables, this statistic is more commonly known as the tetrachoric correlation coefficient and is labeled as such in the displayed output. For more information, see the section "Polychoric Correlation" on page 488.

If you also specify the CL or MEASURES(CL) option, PROC FREQTAB provides confidence limits for the polychoric correlation. If you specify the PLCORR option in the TEST statement, the procedure provides Wald and likelihood ratio tests for the polychoric correlation. The PLCORR option invokes the MEASURES option.

You can specify the following *options*:

ADJUST

replaces a 2×2 table cell frequency of 0 with 0.5 before computing the tetrachoric correlation (Brown and Benedetti 1977a, p. 353). To maintain the row and column marginal frequencies, adjacent cell frequencies are decreased by 0.5 and the opposite cell frequency is increased by 0.5.

This option is available for 2×2 tables and is applied only when a single cell frequency is 0. It has no effect when both off-diagonal cell frequencies are 0 (and therefore the correlation is 1) or when both diagonal cell frequencies are 1 (and therefore the correlation is –1).

CONVERGE=*value*

specifies the convergence criterion. The *value* must be a positive number. By default, CONVERGE=0.0001. Iterative computation of the polychoric correlation stops when the convergence measure falls below *value* or when the number of iterations exceeds the MAXITER= *number*, whichever happens first. For parameter values that are less than 0.01, PROC FREQTAB evaluates convergence by using the absolute difference instead of the relative difference. For more information, see the section "Polychoric Correlation" on page 488.

MAXITER=*number*

specifies the maximum *number* of iterations. The value of *number* must be a positive integer. By default, MAXITER=50. Iterative computation of the polychoric correlation stops when the number of iterations exceeds the maximum *number* or when the convergence measure falls below the CONVERGE= *value*, whichever happens first. For more information, see the section "Polychoric Correlation" on page 488.

PLOTS < (*global-plot-options*) > < =*plot-request* < (*plot-options*) > >

PLOTS < (*global-plot-options*) > < =(*plot-request* < (*plot-options*) > < . . . *plot-request* < (*plot-options*) > >) >

controls the plots that are produced through ODS Graphics. *Plot-requests* identify the plots, and *plot-options* control the appearance and content of the plots. You can specify *plot-options* in parentheses after a *plot-request*. A *global-plot-option* applies to all plots for which it is available unless it is altered by a specific *plot-option*. You can specify *global-plot-options* in parentheses after the PLOTS option.

When you specify only one *plot-request*, you can omit the parentheses around the request. For example:

```
plots=all
plots=freqplot
plots=(freqplot oddsratioplot)
plots(only)=(cumfreqplot deviationplot)
```

ODS Graphics must be enabled before plots can be requested. For example:

```
ods graphics on;
proc freqtab;
   tables treatment*response / chisq plots=freqplot;
   weight wt;
run;
ods graphics off;
```

If ODS Graphics is enabled but you do not specify the PLOTS= option, PROC FREQTAB produces all plots that are associated with the analyses that you request, with the exception of the frequency, cumulative frequency, and mosaic plots. To produce a frequency plot or cumulative frequency plot when ODS Graphics is enabled, you must specify the FREQPLOT or CUMFREQPLOT *plot-request*, respectively, in the PLOTS= option, or you must specify the PLOTS=ALL option. To produce a mosaic plot when ODS Graphics is enabled, you must specify the MOSAICPLOT *plot-request* in the PLOTS= option, or you must specify the PLOTS=ALL option.

PROC FREQTAB produces the remaining plots (listed in Table 11.10) by default when you request the corresponding TABLES statement options. You can suppress default plots and request specific plots by using the PLOTS(ONLY)= option; PLOTS(ONLY)=(*plot-requests*) produces only the plots that are specified as *plot-requests*. You can suppress all plots by specifying the PLOTS=NONE option. The PLOTS option has no effect when you specify the NOPRINT option in the PROC FREQTAB statement.

Plot Requests

Table 11.10 lists the available *plot-requests* together with their required TABLES statement options. Descriptions of the *plot-requests* follow the table in alphabetical order.

Table 11.10 Plot Requests

Plot Request	Description	Required TABLES Statement Option
AGREEPLOT	Agreement plot	AGREE ($r \times r$ table)
ALL	All plots	None
CUMFREQPLOT	Cumulative frequency plot	One-way table request
DEVIATIONPLOT	Deviation plot	CHISQ (one-way table)
FREQPLOT	Frequency plot	Any table request
KAPPAPLOT	Kappa plot	AGREE ($h \times r \times r$ table)
MOSAICPLOT	Mosaic plot	Two-way or multiway table request
NONE	No plots	None
ODDSRATIOPLOT	Odds ratio plot	MEASURES, OR, or RELRISK ($h \times 2 \times 2$ table)
RELRISKPLOT	Relative risk plot	MEASURES or RELRISK ($h \times 2 \times 2$ table)

Table 11.10 *continued*

Plot Request	Description	Required TABLES Statement Option
RISKDIFFPLOT	Risk difference plot	RISKDIFF ($h \times 2 \times 2$ table)
WTKAPPAPLOT	Weighted kappa plot	AGREE ($h \times r \times r$ table, $r > 2$)

You can specify the following *plot-requests*:

AGREEPLOT < (*plot-options*) >
requests an agreement plot (Bangdiwala and Bryan 1987), An agreement plot displays the strength of agreement in a two-way table, where the row and column variables represent two independent ratings of n subjects. For information about agreement plots, see Bangdiwala (1988), Bangdiwala et al. (2008), and Friendly (2000, Section 3.7.2).

To produce an agreement plot, you must also specify the AGREE option in the TABLES statement. Agreement statistics and plots are available for two-way square tables, where the number of rows equals the number of columns.

Table 11.11 lists the *plot-options* that are available for agreement plots. For descriptions of the *plot-options*, see the subsection "Plot Options" in this section.

Table 11.11 Plot Options for AGREEPLOT

Plot Option	Description	Values
LEGEND=	Legend	NO and YES*
PARTIAL=	Partial agreement	NO and YES*
SHOWSCALE=	Frequency scale	NO and YES*
STATS	Statistics	None

*Default

If you specify the STATS *plot-option*, the agreement plot displays the values of the kappa coefficient, the weighted kappa coefficient, the B_n measure (Bangdiwala and Bryan 1987), and the sample size. PROC FREQTAB stores these statistics in an ODS table named BnMeasure, which is not displayed. For more information, see the section "ODS Table Names" on page 565.

ALL
requests all plots that are associated with the specified analyses. Table 11.10 lists the available *plot-requests* and the corresponding analysis options. If you specify the PLOTS=ALL option, PROC FREQTAB produces the frequency, cumulative frequency, and mosaic plots that are associated with the tables that you request. (These plots are not produced by default when ODS Graphics is enabled.)

CUMFREQPLOT < (*plot-options*) >
requests a plot of cumulative frequencies. Cumulative frequency plots are available for one-way frequency tables.

To produce a cumulative frequency plot, you must specify the CUMFREQPLOT *plot-request* in the PLOTS= option, or you must specify the PLOTS=ALL option. PROC FREQTAB does not produce cumulative frequency plots by default when ODS Graphics is enabled.

Table 11.12 lists the *plot-options* that are available for cumulative frequency plots. For descriptions of the *plot-options*, see the subsection "Plot Options" in this section.

Table 11.12 Plot Options for CUMFREQPLOT

Plot Option	Description	Values
ORIENT=	Orientation	HORIZONTAL and VERTICAL*
SCALE=	Scale	FREQ* and PERCENT
TYPE=	Type	BARCHART* and DOTPLOT

*Default

DEVIATIONPLOT < (*plot-options*) >

requests a plot of relative deviations from expected frequencies. Deviation plots are available for chi-square analysis of one-way frequency tables. To produce a deviation plot, you must also specify the CHISQ option in the TABLES statement for a one-way frequency table.

Table 11.13 lists the *plot-options* that are available for deviation plots.

Table 11.13 Plot Options for DEVIATIONPLOT

Plot Option	Description	Values
NOSTAT	No statistic	None
ORIENT=	Orientation	HORIZONTAL and VERTICAL*
PLOTVAR=	Plot variable	CELLCHI2, DEVIATION*, and RESIDUAL
SCALE=	Scale	ABS, NONE*, and PERCENT
TYPE=	Type	BARCHART* and DOTPLOT

*Default

For descriptions of the NOSTAT, ORIENT=, and TYPE= *plot-options*, see the subsection "Plot Options" in this section.

You can specify the following *plot-options*:

PLOTVAR=CELLCHI2 | DEVIATION | RESIDUAL

specifies the deviation statistic to display in the deviation plot. By default, PLOTVAR=DEVIATION, which displays the relative deviations. For each class level, the relative deviation is computed as the deviation divided by the expected frequency under the null hypothesis ((*frequency* – *expected*)/*expected*).

PLOTVAR=CELLCHI2 displays the cell chi-square contributions, which are computed as $(frequency - expected)^2/expected$. For more information, see the ONEWAY(CELLCHI2) option.

PLOTVAR=RESIDUAL displays the Pearson residuals, which are computed as $(frequency - expected)/\sqrt{expected}$. For more information, see the ONEWAY(RESIDUAL) option.

SCALE=ABS | NONE | PERCENT

specifies the scale of the deviation statistic to display. By default, SCALE=NONE, which displays the unscaled deviations. SCALE=ABS displays the absolute values of the deviation statistics (relative deviations or residuals). SCALE=ABS has no effect for the cell chi-squares, which are nonnegative. SCALE=PERCENT displays the percentages of the total of the absolute deviations.

The SCALE=PERCENT *global-plot-option* invokes the DEVIATIONPLOT(SCALE=PERCENT) *plot-option*. You can alter this by specifying the individual DEVIATIONPLOT(SCALE=) *plot-option*.

FREQPLOT < (*plot-options*) >

requests a frequency plot. Frequency plots are available for frequency and crosstabulation tables. For multiway crosstabulation tables, PROC FREQTAB provides a two-way frequency plot for each stratum (two-way table).

To produce a frequency plot, you must specify the FREQPLOT *plot-request* in the PLOTS= option, or you must specify the PLOTS=ALL option. PROC FREQTAB does not produce frequency plots by default when ODS Graphics is enabled.

Table 11.14 lists the *plot-options* that are available for frequency plots. For descriptions of the *plot-options*, see the subsection "Plot Options" in this section.

Table 11.14 Plot Options for FREQPLOT

Plot Option	Description	Values
GROUPBY=**	Primary group	COLUMN* and ROW
NPANELPOS=**	Sections per panel	Number (4*)
ORIENT=	Orientation	HORIZONTAL and VERTICAL*
SCALE=	Scale	FREQ*, GROUPPERCENT**, LOG, PERCENT, and SQRT
TWOWAY=**	Two-way layout	CLUSTER, GROUPHORIZONTAL, GROUPVERTICAL*, and STACKED
TYPE=	Type	BARCHART* and DOTPLOT

*Default

**For two-way tables

You can specify the following *plot-options* for all frequency plots: ORIENT=, SCALE=, and TYPE=. You can specify the following *plot-options* for frequency plots of two-way (and multiway) tables: GROUPBY=, NPANELPOS=, and TWOWAY=. The NPANELPOS= *plot-option* is not available with the TWOWAY=CLUSTER or TWOWAY=STACKED layout, which is always displayed in a single panel.

By default, PROC FREQTAB displays frequency plots as bar charts. To display frequency plots as dot plots, specify TYPE=DOTPLOT. To plot percentages instead of frequencies, specify SCALE=PERCENT. For two-way tables, there are four frequency plot layouts available, which you can request by specifying the TWOWAY= *plot-option*. For more information, see the subsection "Plot Options" in this section.

By default, graph cells in a two-way layout are first grouped by column variable levels; row variable levels are then displayed within the column variable levels. To group first by row variable levels, specify GROUPBY=ROW.

KAPPAPLOT < (*plot-options*) >
requests a plot of kappa statistics along with confidence limits. Kappa plots are available for multiway square tables and display the kappa statistic (with confidence limits) for each two-way table (stratum). Kappa plots also display the overall kappa statistic unless you specify the COMMON=NO *plot-option*. To produce a kappa plot, you must specify the AGREE option in the TABLES statement to compute kappa statistics.

Table 11.15 lists the *plot-options* that are available for kappa plots. For descriptions of the *plot-options*, see the subsection "Plot Options" in this section.

Table 11.15 Plot Options for KAPPAPLOT and WTKAPPAPLOT

Plot Option	Description	Values
CLDISPLAY=	Error bar type	BAR, LINE, LINEARROW, SERIF*, and SERIFARROW
COMMON=	Overall kappa	NO and YES*
NPANELPOS=	Statistics per graphic	Number (all*)
ORDER=	Order of two-way levels	ASCENDING and DESCENDING
RANGE=	Range to display	Values and CLIP
STATS	Statistic values	None

*Default

MOSAICPLOT < (*plot-options*) >
requests a mosaic plot. Mosaic plots are available for two-way and multiway crosstabulation tables; for multiway tables, PROC FREQTAB provides a mosaic plot for each two-way table (stratum).

To produce a mosaic plot, you must specify the MOSAICPLOT *plot-request* in the PLOTS= option, or you must specify the PLOTS=ALL option. PROC FREQTAB does not produce mosaic plots by default when ODS Graphics is enabled.

Mosaic plots display tiles that correspond to the crosstabulation table cells. The areas of the tiles are proportional to the frequencies of the table cells. The column variable is displayed on the X axis, and the tile widths are proportional to the relative frequencies of the column variable levels. The row variable is displayed on the Y axis, and the tile heights are proportional to the relative frequencies of the row levels within column levels. For more information, see Friendly (2000).

By default, the colors of the tiles correspond to the row variable levels. If you specify the COLORSTAT= *plot-option*, the tiles are colored according to the values of the Pearson or standardized residuals.

You can specify the following *plot-options*:

COLORSTAT < =PEARSONRES | STDRES >
colors the mosaic plot tiles according to the values of residuals. If you specify COLORSTAT=PEARSONRES, the tiles are colored according to the Pearson residuals of the corresponding table cells. For more information, see the section "Pearson Chi-Square Test for Two-Way Tables" on page 477. If you specify COLORSTAT=STDRES, the tiles are colored according to the standardized residuals of the corresponding table cells. For more information, see the section "Standardized Residuals" on page 478. You can display the Pearson or standardized residuals in the CROSSLIST table by specifying the CROSSLIST(PEARSONRES) or CROSSLIST(STDRES) option, respectively.

SQUARE
produces a square mosaic plot, where the height of the Y axis equals the width of the X axis. In a square mosaic plot, the scale of the relative frequencies is the same on both axes. By default, PROC FREQTAB produces a rectangular mosaic plot.

NONE
suppresses all plots.

ODDSRATIOPLOT < (*plot-options*) >
requests a plot of odds ratios along with confidence limits. Odds ratio plots are available for multiway 2×2 tables and display the odds ratio (with confidence limits) for each 2×2 table (stratum). To produce an odds ratio plot, you must also specify the MEASURES, OR, or RELRISK option in the TABLES statement to compute the odds ratios.

Table 11.16 lists the *plot-options* that are available for odds ratio plots. For descriptions of the *plot-options*, see the subsection "Plot Options" in this section.

Table 11.16 Plot Options for ODDSRATIOPLOT, RELRISKPLOT, and RISKDIFFPLOT

Plot Option	Description	Values
CL=	Confidence limit type	Type
CLDISPLAY=	Error bar type	BAR, LINE, LINEARROW, SERIF*, and SERIFARROW
COLUMN=**	Risk column	1* and 2
COMMON=	Common value	NO and YES*
LOGBASE=***	Axis scale	2, E, and 10
NPANELPOS=	Statistics per graphic	Number (all*)
ORDER=	Order of two-way levels	ASCENDING and DESCENDING
RANGE=	Range to display	Values and CLIP
STATS	Statistic values	None

*Default

**Available for RELRISKPLOT and RISKDIFFPLOT

***Available for ODDSRATIOPLOT and RELRISKPLOT

You can specify one of the following confidence limit types for the odds ratio plot: exact (CL=EXACT), likelihood ratio (CL=LR), exact mid-p (CL=MIDP), score (CL=SCORE), Wald (CL=WALD), or Wald modified (CL=WALDMODIFIED). By default, the odds ratio plot displays

Wald confidence limits. For more information, see the descriptions of the CL= *plot-option* and the OR(CL=) option.

To display exact confidence limits in the odds ratio plot, you must also request their computation by specifying the OR option in the EXACT statement.

When CL=WALD or CL=EXACT, the odds ratio plot displays the common odds ratio by default when it is available. To compute the common odds ratio along with Wald confidence limits, specify the CMH option in the TABLES statement. To compute the common odds ratio along with exact confidence limits, specify the COMOR option in the EXACT statement. To suppress display of the common odds ratio, specify COMMON=NO.

RELRISKPLOT < (*plot-options*) >

requests a plot of relative risks along with confidence limits. Relative risk plots are available for multiway 2×2 tables and display the relative risk (with confidence limits) for each 2×2 table (stratum). To produce a relative risk plot, you must also specify the MEASURES or RELRISK option in the TABLES statement to compute relative risks.

Table 11.16 lists the *plot-options* that are available for relative risk plots. For descriptions of the *plot-options*, see the subsection "Plot Options" in this section.

You can specify one of the following confidence limit types for the relative risk plot: exact (CL=EXACT), likelihood ratio (CL=LR), score (CL=SCORE), Wald (CL=WALD), or Wald modified (CL=WALDMODIFIED). By default, the relative risk plot displays Wald confidence limits. For more information, see the descriptions of the CL= *plot-option* and the RELRISK(CL=) option.

To display exact confidence limits in the relative risk plot, you must also request their computation by specifying the RELRISK option in the EXACT statement. The risk column that you specify for the confidence limits must match the risk column that you specify for the plot.

The relative risk plot displays the common relative risk by default when you specify CL=WALD and the CMH option in the TABLES statement. To suppress display of the common relative risk, specify COMMON=NO.

In addition to the *plot-options* in Table 11.16, you can specify the following *plot-option*:

FOOTNOTE=NO

suppresses the footnote that identifies the column for which the relative risk is computed.

RISKDIFFPLOT < (*plot-options*) >

requests a plot of risk (proportion) differences along with confidence limits for multiway 2×2 tables. The risk difference plot displays the risk difference (with confidence limits) for each 2×2 table (stratum). Optionally, the plot also displays the common risk difference.

To produce a risk difference plot, you must also specify the RISKDIFF option in the TABLES statement to compute risk differences.

Table 11.16 lists the *plot-options* that are available for risk difference plots. For descriptions of the *plot-options*, see the subsection "Plot Options" in this section.

You can specify the confidence limit type for the stratum risk differences by using the CL= *plot-option*. You can specify one of the following confidence limit types: Agresti-Caffo (CL=AC),

exact (CL=EXACT), Hauck-Anderson (CL=HA), Miettinen-Nurminen (score) (CL=MN), Newcombe (CL=NEWCOMBE), and Wald (CL=WALD). By default, the plot displays Wald confidence limits for the stratum risk differences. For more information, see the descriptions of the CL= *plot-option* and the RISKDIFF(CL=) option.

To display exact confidence limits in the risk difference plot, you must also request their computation by specifying the RISKDIFF option in the EXACT statement. The risk column that you specify for the confidence limits must match the risk column that you specify for the plot.

By default, the risk difference plot displays the common risk difference when you specify the RISKDIFF(COMMON) or COMMONRISKDIFF option unless you specify the CL=EXACT *plot-option*. To suppress display of the common risk difference, specify COMMON=NO.

In addition to the *plot-options* in Table 11.16, you can specify the following *plot-options*:

CLNOTE=NO
suppresses the note that identifies the confidence limit type.

COMMON=*type*
specifies the *type* of confidence limits to display for the common risk difference.

The default common confidence limit *type* depends on the stratum confidence limit *type*. By default, COMMON=MN if CL=MN and COMMON=NEWCOMBE if CL=NEWCOMBE. Otherwise, COMMON=MH by default.

You can specify one of the following *types*:

K

KLINGENBERG
displays Klingenberg confidence limits. For more information, see the COMMONRISKDIFF(CL=K) option and the section "Klingenberg Confidence Limits" on page 512.

MH
displays Mantel-Haenszel confidence limits. For more information, see the COMMONRISKDIFF(CL=MH) option and the section "Mantel-Haenszel Confidence Limits and Test" on page 511.

MN
displays Miettinen-Nurminen confidence limits. For more information, see the COMMONRISKDIFF(CL=MN) option.

MNMH
displays confidence limits that are computed by using the Miettinen-Nurminen method with Mantel-Haenszel weights. For more information, see the COMMONRISKDIFF(CL=MNMH) option.

MR

MINRISK
displays minimum risk confidence limits. For more information, see the COMMONRISKDIFF(CL=MR) option and the section "Minimum Risk Confidence Limits and Test" on page 513.

NEWCOMBE
displays stratified Newcombe confidence limits that use Mantel-Haenszel weights to combine the stratum components. For more information, see the COMMONRISKDIFF(CL=NEWCOMBE) option and the section "Stratified Newcombe Confidence Limits" on page 515.

NEWCOMBEMR
displays stratified Newcombe confidence limits that use minimum risk weights to combine the stratum components. For more information, see the COMMONRISKDIFF(CL=NEWCOMBEMR) option and the section "Stratified Newcombe Confidence Limits" on page 515.

NONE
suppresses the common risk difference in the risk difference plot.

SCORE
displays summary score confidence limits. For more information, see the COMMONRISKDIFF(CL=SCORE) option and the section "Summary Score Confidence Limits" on page 514.

FOOTNOTE=NO
suppresses the footnote that identifies the column for which the risk difference is computed.

WTKAPPAPLOT <(*plot-options*)>
requests a plot of weighted kappa coefficients along with confidence limits. Weighted kappa plots are available for multiway square tables and display the weighted kappa coefficient (with confidence limits) for each two-way table (stratum). Weighted kappa plots also display the overall weighted kappa coefficient unless you specify the COMMON=NO *plot-option*.

To produce a weighted kappa plot, you must specify the AGREE option in the TABLES statement to compute weighted kappa coefficients, and the table dimension must be greater than 1.

Table 11.15 lists the *plot-options* that are available for weighted kappa plots. For descriptions of the *plot-options*, see the subsection "Plot Options" in this section.

Global Plot Options

A *global-plot-option* applies to all plots for which the option is available unless it is altered by an individual *plot-option*. You can specify *global-plot-options* in parentheses after the PLOTS option. For example:

```
plots(order=ascending stats)=(riskdiffplot oddsratioplot)
plots(only)=freqplot
```

The following *plot-options* are available as *global-plot-options*: CLDISPLAY=, COLUMN=, COMMON=, EXACT, LOGBASE=, NPANELPOS=, ORDER=, ORIENT=, RANGE=, SCALE=, STATS, and TYPE=. For descriptions of these *plot-options*, see the subsection "Plot Options" in this section.

In addition to these *plot-options*, you can specify the following *global-plot-option*:

ONLY
suppresses the default plots and requests only the plots that are specified as *plot-requests*.

Plot Options

You can specify the following *plot-options* in parentheses after a *plot-request*:

CL=*type*
specifies the *type* of confidence limits to display. You can specify the CL= *plot-option* when you specify any of the following *plot-requests*: ODDSRATIOPLOT, RELRISKPLOT, and RISKDIFFPLOT.

For odds ratio plots (ODDSRATIOPLOT), the available confidence limit types include the following: exact (CL=EXACT), likelihood ratio (CL=LR), exact mid-*p* (CL=MIDP), score (CL=SCORE), Wald (CL=WALD), and Wald modified (CL=WALDMODIFIED). For more information, see the description of the OR(CL=) option and the section "Confidence Limits for the Odds Ratio" on page 516. By default, CL=WALD. When you specify CL=EXACT to display exact confidence limits, you must also request computation of exact confidence limits by specifying the OR option in the EXACT statement.

For relative risk plots (RELRISKPLOT), the available confidence limit types include the following: exact (CL=EXACT), likelihood ratio (CL=LR), score (CL=SCORE), Wald (CL=WALD), and Wald modified (CL=WALDMODIFIED). For more information, see the description of the RELRISK(CL=) option and the section "Confidence Limits for the Relative Risk" on page 519. By default, CL=WALD. When you specify CL=EXACT to display exact confidence limits, you must also request computation of exact confidence limits by specifying the RELRISK option in the EXACT statement.

For risk difference plots (RISKDIFFPLOT), the available confidence limit types include the following: Agresti-Caffo (CL=AC), exact (CL=EXACT), Hauck-Anderson (CL=HA), Miettinen-Nurminen (score) (CL=MN), Newcombe (CL=NEWCOMBE), and Wald (CL=WALD). For more information, see the description of the RISKDIFF(CL=) option and the section "Confidence Limits for the Risk Difference" on page 502. By default, CL=WALD. When you specify CL=EXACT to display exact confidence limits in the plot, you must also request computation of exact confidence limits by specifying the RISKDIFF option in the EXACT statement.

CLDISPLAY=BAR < *width* **> | LINE | LINEARROW | SERIF | SERIFARROW**
controls the appearance of the confidence limit error bars. You can specify the CLDISPLAY= *plot-option* when you specify the following *plot-requests*: KAPPAPLOT, ODDSRATIOPLOT, RELRISKPLOT, RISKDIFFPLOT, and WTKAPPAPLOT.

By default, CLDISPLAY=SERIF, which displays the confidence limits as lines with serifs. CLDISPLAY=LINE displays the confidence limits as plain lines without serifs. The CLDISPLAY=SERIFARROW and CLDISPLAY=LINEARROW *plot-options* display arrowheads on any error bars that are clipped by the RANGE= *plot-option*; if an entire error bar is cut from the plot, the plot displays an arrowhead that points toward the statistic.

CLDISPLAY=BAR displays the confidence limits as bars. By default, the width of the bars equals the size of the marker for the estimate. You can control the width of the bars and the size of the marker by specifying the value of *width* as a percentage of the distance between bars, $0 < \textit{width} \leq 1$. The bar might disappear when the value of *width* is very small.

COLUMN=1 | 2

specifies the table column for which to compute the risks (proportions) for the relative risk plot (RELRISKPLOT) and the risk difference plot (RISKDIFFPLOT). If you specify COLUMN=1, the plot displays the column 1 relative risks or risk differences; if you specify COLUMN=2, the plot displays the column 2 relative risks or risk differences.

If you omit this option for the relative risk plot, the plot uses the table column that you specify for the relative risk statistics in the RELRISK(COLUMN=) option. If you omit both of these COLUMN= options, then by default, COLUMN=1 for the relative risk plot.

If you omit the COLUMN= option for the risk difference plot, the plot uses the table column that you specify for the risk difference statistics in the RISKDIFF(COLUMN=) option. If you omit both of these COLUMN= options, then by default, COLUMN=1 for the risk difference plot.

COMMON=NO | YES

controls the display of the common (overall) statistic in plots that display stratum (two-way table) statistics for multiway tables. You can specify the COMMON= *plot-option* when you specify the following *plot-requests*: KAPPAPLOT, ODDSRATIOPLOT, RELRISKPLOT, RISKDIFFPLOT, and WTKAPPAPLOT.

COMMON=NO suppresses display of the common statistic and its confidence limits. By default, COMMON=YES, which displays the common statistic and its confidence limits when these values are available. For more information, see the descriptions of the *plot-requests*.

EXACT

requests display of exact confidence limits instead of asymptotic confidence limits. You can specify the EXACT *plot-option* when you specify the following *plot-requests*: ODDSRATIOPLOT, RELRISKPLOT, and RISKDIFFPLOT. The EXACT *plot-option* is equivalent to the CL=EXACT *plot-option*.

When you specify the EXACT *plot-option*, you must also request computation of exact confidence limits by specifying the appropriate *statistic-option* in the EXACT statement.

GROUPBY=COLUMN | ROW

specifies the primary grouping for two-way frequency plots, which you can request by specifying the FREQPLOT *plot=request*. By default, GROUPBY=COLUMN, which groups graph cells first by column variable and displays row variable levels within column variable levels. You can specify GROUPBY=ROW to group first by row variable. In two-way and multiway table requests, the column variable is the last variable specified and forms the columns of the crosstabulation table. The row variable is the next-to-last variable specified and forms the rows of the table.

By default for a bar chart that is displayed in the TWOWAY=STACKED layout, bars correspond to the column variable levels, and row levels are displayed (stacked) within each column bar. By default for a bar chart that is displayed in the TWOWAY=CLUSTER layout, bars are first grouped by column variable levels, and row levels are displayed as adjacent bars within each column-level group. You can reverse the default row and column variable grouping by specifying GROUPBY=ROW.

LOGBASE=2 | E | 10
applies to the odds ratio plot (ODDSRATIOPLOT) and the relative risk plot (RELRISKPLOT). This *plot-option* displays the odds ratio or relative risk axis on the log scale that you specify.

LEGEND=NO | YES
applies to the agreement plot (AGREEPLOT). LEGEND=NO suppresses the legend that identifies the areas of exact and partial agreement. By default, LEGEND=YES.

NOSTAT
applies to the deviation plot (DEVIATIONPLOT). NOSTAT suppresses the chi-square *p*-value that deviation plot displays by default.

NPANELPOS=*n*
divides the plot into multiple panels that display at most |*n*| statistics or sections.

If *n* is positive, the number of statistics or sections per panel is balanced; if *n* is negative, the number of statistics per panel is not balanced. For example, suppose you want to display 21 odds ratios. NPANELPOS=20 displays two panels, the first with 11 odds ratios and the second with 10 odds ratios; NPANELPOS=–20 displays 20 odds ratios in the first panel but only 1 odds ratio in the second panel. This *plot-option* is available for all plots except mosaic plots and one-way weighted frequency plots.

For two-way frequency plots (FREQPLOT), NPANELPOS=*n* requests that panels display at most |*n*| sections, where sections correspond to row or column variable levels, depending on the type of plot and the grouping. By default, *n*=4 and each panel includes at most four sections. This *plot-option* applies to two-way plots that are displayed in the TWOWAY=GROUPVERTICAL or TWOWAY=GROUPHORIZONTAL layout. The NPANELPOS= *plot-option* does not apply to the TWOWAY=CLUSTER and TWOWAY=STACKED layouts, which are always displayed in a single panel.

For plots that display statistics along with confidence limits, NPANELPOS=*n* requests that panels display at most |*n*| statistics. By default, *n*=0 and all statistics are displayed in a single panel. This *plot-option* applies to the following plots: KAPPAPLOT, ODDSRATIOPLOT, RELRISKPLOT, RISKDIFFPLOT, and WTKAPPAPLOT.

ORDER=ASCENDING | DESCENDING
displays the two-way table (strata) statistics in order of the statistic value. You can specify the ORDER= *plot-option* when you specify the following *plot-requests*: KAPPAPLOT, ODDSRATIOPLOT, RELRISKPLOT, RISKDIFFPLOT, and WTKAPPAPLOT.

If you specify ORDER=ASCENDING or ORDER=DESCENDING, the plot displays the statistics in ascending or descending order, respectively. By default, the order of the statistics in the plot matches the order that the two-way table strata appear in the multiway table display.

ORIENT=HORIZONTAL | VERTICAL
controls the orientation of the plot. You can specify the ORIENT= *plot-option* when you specify the following *plot-requests*: CUMFREQPLOT, DEVIATIONPLOT, and FREQPLOT.

ORIENT=HORIZONTAL places the variable levels on the Y axis and the frequencies, percentages, or statistic values on the X axis. ORIENT=VERTICAL places the variable levels on the X axis. The default orientation is ORIENT=VERTICAL for bar charts (TYPE=BARCHART) and ORIENT=HORIZONTAL for dot plots (TYPE=DOTPLOT).

PARTIAL=NO | YES

controls the display of partial agreement in the agreement plot (AGREEPLOT). PARTIAL=NO suppresses the display of partial agreement. When you specify PARTIAL=NO, the agreement plot displays only exact agreement. Exact agreement includes the diagonal cells of the square table, where the row and column variable levels are the same. Partial agreement includes the adjacent off-diagonal table cells, where the row and column values are within one level of exact agreement. By default, PARTIAL=YES.

RANGE=(< *min*> < **,** *max*> **)| CLIP**

specifies the range of values to display. You can specify the RANGE= *plot-option* when you specify the following *plot-requests*: KAPPAPLOT, ODDSRATIOPLOT, RELRISKPLOT, RISKDIFFPLOT, and WTKAPPAPLOT.

If you specify RANGE=CLIP, the confidence limits are clipped and the display range is determined by the minimum and maximum values of the statistics. By default, the display range includes all confidence limits.

SCALE=FREQ | GROUPPERCENT | LOG | PERCENT | SQRT

specifies the scale of the frequencies to display. This *plot-option* is available for frequency plots (FREQPLOT) and cumulative frequency plots (CUMFREQPLOT).

By default, SCALE=FREQ, which displays unscaled frequencies. SCALE=PERCENT displays percentages (relative frequencies) of the total frequency. SCALE=LOG displays log (base 10) frequencies. SCALE=SQRT displays square roots of the frequencies, producing a plot known as a *rootogram*.

SCALE=GROUPPERCENT is available for two-way frequency plots. This option displays the row or column percentages instead of the overall percentages (of the table frequency). By default (or when you specify the GROUPBY=COLUMN *plot-option*), SCALE=GROUPPERCENT displays the column percentages. If you specify the GROUPBY=ROW *plot-option*, the primary grouping of graph cells is by row variable level and the plot displays row percentages. For more information, see the description of the GROUPBY= *plot-option*.

SHOWSCALE=NO | YES

controls the display of the cumulative frequency scale on the right side of the agreement plot (AGREEPLOT). SHOWSCALE=NO suppresses the display of the scale. By default, SHOWSCALE=YES.

STATS

displays statistic values in the plot. For the following *plot-requests*, the STATS *plot-option* displays the statistics and their confidence limits on the right side of the plot: KAPPAPLOT, ODDSRATIOPLOT, RELRISKPLOT, RISKDIFFPLOT, and WTKAPPAPLOT.

For the agreement plot (AGREEPLOT), the STATS *plot-option* displays the values of the kappa statistic, the weighted kappa statistic, the B_n measure (Bangdiwala and Bryan 1987), and the sample size. PROC FREQTAB stores these statistics in an ODS table named BnMeasure, which is not displayed. For more information, see the section "ODS Table Names" on page 565.

If you do not request the STATS *plot-option*, these plots do not display the statistic values.

TWOWAY=CLUSTER | GROUPHORIZONTAL | GROUPVERTICAL | STACKED

specifies the layout for two-way frequency plots.

All TWOWAY= layouts are available for bar charts (TYPE=BARCHART). All TWOWAY= layouts except TWOWAY=CLUSTER are available for dot plots (TYPE=DOTPLOT). The ORIENT= and GROUPBY= *plot-options* are available for all TWOWAY= layouts.

The default two-way layout is TWOWAY=GROUPVERTICAL, which produces a grouped plot that has a vertical common baseline. By default for bar charts (TYPE=BARCHART, ORIENT=VERTICAL), the X axis displays column variable levels, and the Y axis displays frequencies. The plot includes a vertical (Y-axis) block for each row variable level. The relative positions of the graph cells in this plot layout are the same as the relative positions of the table cells in the crosstabulation table. You can reverse the default row and column grouping by specifying the GROUPBY=ROW *plot-option*.

The TWOWAY=GROUPHORIZONTAL layout produces a grouped plot that has a horizontal common baseline. By default (GROUPBY=COLUMN), the plot displays a block on the X axis for each column variable level. Within each column-level block, the plot displays row variable levels.

The TWOWAY=STACKED layout produces stacked displays of frequencies. By default (GROUPBY=COLUMN) in a stacked bar chart, the bars correspond to column variable levels, and row levels are stacked within each column level. By default in a stacked dot plot, the dotted lines correspond to column levels, and cell frequencies are plotted as data dots on the corresponding column line. The dot color identifies the row level.

The TWOWAY=CLUSTER layout, which is available only for bar charts, displays groups of adjacent bars. By default, the primary grouping is by column variable level, and row levels are displayed within each column level.

You can reverse the default row and column grouping in any layout by specifying the GROUPBY=ROW *plot-option*. By default, GROUPBY=COLUMN, which groups first by column variable.

TYPE=BARCHART | DOTPLOT

specifies the plot type (format) of the frequency (FREQPLOT), cumulative frequency (CUMFREQPLOT), and deviation plots (DEVIATIONPLOT). TYPE=BARCHART produces a bar chart and TYPE=DOTPLOT produces a dot plot. By default, TYPE=BARCHART.

PRINTKWTS

displays the agreement weights that PROC FREQTAB uses to compute the weighted kappa coefficient. Agreement weights reflect the relative agreement between pairs of variable levels. By default, PROC FREQTAB uses the Cicchetti-Allison form of agreement weights. If you specify the AGREE(WT=FC) option, the procedure uses the Fleiss-Cohen form of agreement weights. For more information, see the section "Weighted Kappa Coefficient" on page 532.

This option has no effect unless you also specify the AGREE option to compute the weighted kappa coefficient. The PRINTKWTS option is equivalent to the AGREE(PRINTKWTS) option.

RELRISK <(*relrisk-options*)>

requests relative risk measures and their confidence limits for 2 × 2 tables. These measures include the odds ratio, the column 1 relative risk, and the column 2 relative risk. For more information, see the section "Odds Ratio and Relative Risks" on page 516. By default, PROC FREQTAB displays the relative risk measures and their asymptotic Wald confidence limits in the "Odds Ratio and Relative Risks" table. You can also obtain this table by specifying the MEASURES option, which produces other measures of association in addition to the relative risks.

You can specify *relrisk-options* in parentheses after the RELRISK option to request tests and additional confidence limits for the column 1 or column 2 relative risk. Table 11.17 summarizes the *relrisk-options*.

When you request tests or additional confidence limit types for the relative risk, PROC FREQTAB does not display the "Odds Ratio and Relative Risks" table unless you also specify the PRINTALL *relrisk-option*.

Table 11.17 RELRISK (Relative Risk) Options

Option	Description
COLUMN=1 | 2	Specifies the risk column
PRINTALL	Displays "Odds Ratio and Relative Risks" table
Request Confidence Limits	
CL=EXACT	Displays exact confidence limits
CL=LR	Requests likelihood ratio confidence limits
CL=SCORE	Requests score confidence limits
CL=WALD	Requests Wald confidence limits
CL=WALDMODIFIED	Requests Wald modified confidence limits
Request Tests	
EQUAL(NULL=)	Requests an equality test
EQUIV | EQUIVALENCE	Requests an equivalence test
MARGIN=	Specifies the test margin
METHOD=	Specifies the test method
NONINF | NONINFERIORITY	Requests a noninferiority test
SUP | SUPERIORITY	Requests a superiority test

You can specify the following *relrisk-options*:

CL=*type* | (*types*)

specifies confidence limit types for the relative risk. You can specify one or more *types* of confidence limits. When you specify only one *type*, you can omit the parentheses around the request. When you specify the CL= *relrisk-option*, PROC FREQTAB displays the confidence limits in the "Confidence Limits for the Relative Risk" table.

The ALPHA= option determines the level of the confidence limits that the CL= *relrisk-option* provides. By default, ALPHA=0.05, which produces 95% confidence limits for the relative risk.

You can specify the following *types*:

EXACT
displays exact unconditional confidence limits for the relative risk in the "Confidence Limits for the Relative Risk" table. (By default, PROC FREQTAB displays the exact confidence limits in a separate table.) You must also request computation of the exact confidence limits by specifying the RELRISK option in the EXACT statement. For more information, see the subsection "Exact Unconditional Confidence Limits" in the section "Confidence Limits for the Relative Risk" on page 519.

LR
LIKELIHOOD RATIO
requests likelihood ratio confidence limits for the relative risk. For more information, see the subsection "Likelihood Ratio Confidence Limits" in the section "Confidence Limits for the Relative Risk" on page 519.

SCORE < (CORRECT=NO) >
requests score confidence limits for the relative risk. For more information, see the subsection "Score Confidence Limits" in the section "Confidence Limits for the Relative Risk" on page 519. If you specify CORRECT=NO, PROC FREQTAB provides the uncorrected form of the confidence limits.

WALD
requests asymptotic Wald confidence limits, which are based on a log transformation of the relative risk. For more information, see the subsection "Wald Confidence Limits" in the section "Confidence Limits for the Relative Risk" on page 519.

WALDMODIFIED
requests Wald modified confidence limits for the relative risk. For more information, see the subsection "Wald Modified Confidence Limits" in the section "Confidence Limits for the Relative Risk" on page 519.

COLUMN=1 | 2
specifies the table column for which to compute the relative risk confidence limits (which you request by specifying the CL= *relrisk-option*) and the relative risk tests (EQUAL, EQUIV, NONINF, and SUP).

This option has no effect on the "Odds Ratio and Relative Risks" table, which displays both column 1 and column 2 relative risks.

By default, COLUMN=1 unless you specify the column for the relative risk plot by using the RELRISKPLOT(COLUMN=) option. When you specify the column for the plot (and omit the RELRISK(COLUMN=) option), PROC FREQTAB uses the same column for both the plot and the relative risk statistics.

EQUAL < (NULL=*value*)>
requests an equality test for the relative risk. For more information, see the subsection "Equality Test" in the section "Relative Risk Tests" on page 522.

You can specify the null hypothesis *value* of the relative risk in the NULL= option. The null *value* must be a positive number. By default, NULL=1. You can specify the equality test method in the METHOD= *relrisk-option*. By default, PROC FREQTAB produces a Wald test (METHOD=WALD).

EQUIV

EQUIVALENCE

requests an equivalence test for the relative risk. For more information, see the subsection "Equivalence Test" in the section "Relative Risk Tests" on page 522. You can specify the test method in the METHOD= *relrisk-option*, and you can specify the test margins in the MARGIN= *relrisk-option*. By default, METHOD=WALD and MARGIN=(0.8,1.25).

MARGIN=*value* | **(***lower***,** *upper***)**

specifies the margin for the noninferiority, superiority, and equivalence tests, which you request by specifying the NONINF, SUP, and EQUIV *relrisk-options*, respectively. By default, MARGIN=0.8 for noninferiority tests, MARGIN=1.25 for superiority tests, and MARGIN=(0.8,1.25) for equivalence tests.

For noninferiority and superiority tests, specify a single *value* in the MARGIN= option. The *value* must be a positive number. For a noninferiority test, the *value* should be less than 1; for a superiority test, the *value* should be greater than 1.

For an equivalence test, you can specify a single MARGIN= *value*, or you can specify both *lower* and *upper* values. All values must be positive numbers. If you specify a single *value*, PROC FREQTAB uses *value* as the lower margin and the inverse of *value* as the upper margin. If you specify both *lower* and *upper* values, the value of *lower* must be less than the value of *upper*.

METHOD=*method*

specifies the method to be used for the equality, equivalence, noninferiority, and superiority tests, which you request by specifying the EQUAL, EQUIV, NONINF, and SUP *relrisk-options*, respectively. By default, METHOD=WALD.

You can specify one of the following *methods*:

FM

SCORE

requests Farrington-Manning (score) tests for the equality, equivalence, noninferiority, and superiority analyses of the relative risk. For more information, see the subsection "Farrington-Manning (Score) Test" in the section "Relative Risk Tests" on page 522.

LR

LIKELIHOODRATIO

requests likelihood ratio tests for the equality, equivalence, noninferiority, and superiority analyses of the relative risk. For more information, see the subsection "Likelihood Ratio Test" in the section "Relative Risk Tests" on page 522.

WALD

requests Wald tests for the equality, equivalence, noninferiority, and superiority analyses of the relative risk. For more information, see the subsection "Wald Test" in the section "Relative Risk Tests" on page 522.

WALDMODIFIED
requests Wald modified tests for the equality, equivalence, noninferiority, and superiority analyses of the relative risk. For more information, see the subsection "Wald Modified Test" in the section "Relative Risk Tests" on page 522.

NONINF
NONINFERIORITY
requests a noninferiority test for the relative risk. For more information, see the subsection "Noninferiority Test" in the section "Relative Risk Tests" on page 522. You can specify the test method in the METHOD= *relrisk-option*, and you can specify the margin in the MARGIN= *relrisk-option*. By default, METHOD=WALD and MARGIN=0.8.

PRINTALL
displays the "Odds Ratio and Relative Risks" table when you request tests or additional confidence limits by specifying *relrisk-options*. By default, PROC FREQTAB does not display this table when you request tests or additional confidence limits for the relative risk.

SUP
SUPERIORITY
requests a superiority test for the relative risk. For more information, see the subsection "Superiority Test" in the section "Relative Risk Tests" on page 522. You can specify the test method in the METHOD= *relrisk-option*, and you can specify the margin in the MARGIN= *relrisk-option*. By default, METHOD=WALD and MARGIN=1.25.

RISKDIFF < (*riskdiff-options*) >
requests risks (binomial proportions) and risk differences for 2 × 2 tables. By default, this option provides the row 1 risk, row 2 risk, total (overall) risk, and risk difference (row 1 – row 2), together with their asymptotic standard errors and Wald confidence limits; by default, this option also provides exact (Clopper-Pearson) confidence limits for the row 1, row 2, and total risks. You can request exact unconditional confidence limits for the risk difference by specifying the RISKDIFF option in the EXACT statement. PROC FREQTAB displays these results in the column 1 and column 2 "Risk Estimates" tables (which you can suppress by specifying the NORISKS *riskdiff-option*).

You can specify *riskdiff-options* in parentheses after the RISKDIFF option to request tests and additional confidence limits for the risk difference, in addition to estimates of the common risk difference for multiway 2 × 2 tables. Table 11.18 summarizes the *riskdiff-options*.

The CL= *riskdiff-option* requests confidence limits for the risk difference. Available confidence limit types include Agresti-Caffo, exact unconditional, Hauck-Anderson, Miettinen-Nurminen (score), Newcombe, and Wald. Continuity-corrected Newcombe and Wald confidence limits are also available. You can request more than one type of confidence limits in the same analysis. PROC FREQTAB displays the confidence limits in the "Confidence Limits for the Risk Difference" table.

The CL=EXACT *riskdiff-option* displays exact unconditional confidence limits in the "Confidence Limits for the Risk Difference" table. When you specify CL=EXACT, you must also request computation of the exact confidence limits by specifying the RISKDIFF option in the EXACT statement.

The EQUAL, EQUIV, NONINF, and SUP *riskdiff-options* request tests of equality, equivalence, noninferiority, and superiority, respectively, for the risk difference. Available test methods include Farrington-Manning (score), Hauck-Anderson, and Wald. Newcombe (hybrid-score) confidence limits are available for the equivalence, noninferiority, and superiority analyses.

As part of the noninferiority, superiority, and equivalence analyses, PROC FREQTAB provides null-based equivalence limits that have a confidence coefficient of $100(1-2\alpha)\%$ (Schuirmann 1999). The ALPHA= option determines the confidence level; by default, ALPHA=0.05, which produces 90% equivalence limits for these analyses. For more information, see the sections "Noninferiority Tests" on page 507 and "Equivalence Test" on page 510.

Table 11.18 RISKDIFF (Proportion Difference) Options

Option	Description
COLUMN=1 | 2	Specifies the risk column
COMMON	Requests common risk difference
CORRECT	Requests continuity correction
NORISKS	Suppresses default risk tables
Request Confidence Limits	
CL=AC	Requests Agresti-Caffo confidence limits
CL=EXACT	Displays exact confidence limits
CL=HA	Requests Hauck-Anderson confidence limits
CL=MN | SCORE	Requests Miettinen-Nurminen confidence limits
CL=NEWCOMBE	Requests Newcombe confidence limits
CL=WALD	Requests Wald confidence limits
Request Tests	
EQUAL(NULL=)	Requests an equality test
EQUIV | EQUIVALENCE	Requests an equivalence test
MARGIN=	Specifies the test margin
METHOD=	Specifies the test method
NONINF | NONINFERIORITY	Requests a noninferiority test
SUP | SUPERIORITY	Requests a superiority test
VAR=SAMPLE | NULL	Specifies the test variance

You can specify the following *riskdiff-options*:

CL=*type* **|** **(***types***)**
requests confidence limits for the risk difference. You can specify one or more *types* of confidence limits. When you specify only one *type*, you can omit the parentheses around the request. PROC FREQTAB displays the confidence limits in the "Confidence Limits for the Risk Difference" table.

The ALPHA= option determines the level of the confidence limits. By default, ALPHA=0.05, which produces 95% confidence limits for the risk difference.

You can specify the CL= *riskdiff-option* with or without requests for risk difference tests. The confidence limits that CL= produces do not depend on the tests that you request and do not use the value of the test margin (which you can specify in the MARGIN= *riskdiff-option*).

You can specify the following *types*:

AC

AGRESTICAFFO

requests Agresti-Caffo confidence limits for the risk difference. For more information, see the subsection "Agresti-Caffo Confidence Limits" in the section "Confidence Limits for the Risk Difference" on page 502.

EXACT

displays exact unconditional confidence limits for the risk difference in the "Confidence Limits for the Risk Difference" table. You must also request computation of the exact confidence limits by specifying the RISKDIFF option in the EXACT statement.

By default, PROC FREQTAB computes the exact confidence limits by inverting two separate one-sided exact tests that are based on the score statistic. For more information, see the RISKDIFF option in the EXACT statement and the subsection "Exact Unconditional Confidence Limits" in the section "Confidence Limits for the Risk Difference" on page 502.

By default, PROC FREQTAB also displays these exact confidence limits in the "Risk Estimates" table. You can suppress this table by specifying the NORISKS *riskdiff-option*.

HA

requests Hauck-Anderson confidence limits for the risk difference. For more information, see the subsection "Hauck-Anderson Confidence Limits" in the section "Confidence Limits for the Risk Difference" on page 502.

MN < (CORRECT=NO | MEE) >

SCORE < (CORRECT=NO | MEE) >

requests Miettinen-Nurminen (score) confidence limits for the risk difference. For more information, see the subsection "Miettinen-Nurminen (Score) Confidence Limits" in the section "Confidence Limits for the Risk Difference" on page 502. By default, the Miettinen-Nurminen confidence limits include a bias correction factor (Miettinen and Nurminen 1985; Newcombe and Nurminen 2011). If you specify CL=MN(CORRECT=NO), PROC FREQTAB provides the uncorrected form of the confidence limits (Mee 1984).

NEWCOMBE < (CORRECT) >

requests Newcombe hybrid-score confidence limits for the risk difference. If you specify CL=NEWCOMBE(CORRECT) or the CORRECT *riskdiff-option*, the Newcombe confidence limits include a continuity correction. For more information, see the subsection "Newcombe Confidence Limits" in the section "Confidence Limits for the Risk Difference" on page 502.

WALD < (CORRECT) >

requests Wald confidence limits for the risk difference. If you specify CL=WALD(CORRECT) or the CORRECT *riskdiff-option*, the Wald confidence limits include a continuity correction. For more information, see the subsection "Wald Confidence Limits" in the section "Confidence Limits for the Risk Difference" on page 502.

COLUMN=1 | 2 | BOTH

specifies the table column for which to compute the risk difference confidence limits (which you request by specifying the CL= *riskdiff-option*), the risk difference tests (EQUAL, EQUIV, NONINF, and SUP), and the common risk difference statistics (COMMON). COLUMN=BOTH does not apply to the common risk difference statistics.

By default, COLUMN=1 unless you specify the column for the risk difference plot by using the RISKDIFFPLOT(COLUMN=) option. When you specify the column for the plot (and omit the RISKDIFF(COLUMN=) option), PROC FREQTAB uses the same column for both the plot and the risk difference statistics.

This option has no effect on the "Risk Estimates" table, which is produced for both column 1 and column 2. You can suppress the "Risk Estimates" table by specifying the NORISKS *riskdiff-option*.

COMMON

requests estimates of the common (overall) risk difference for multiway 2×2 tables. This option provides Mantel-Haenszel and summary score estimates for the common risk difference, together with their confidence limits. If you specify the RISKDIFF(CL=NEWCOMBE) option, the RISKDIFF(COMMON) option also provides Newcombe confidence limits for the common risk difference. For more information, see the section "Common Risk Difference" on page 511.

You can use the COMMONRISKDIFF option to request additional confidence limits and tests for the common risk difference.

If you do not specify the COLUMN= *riskdiff-option*, PROC FREQTAB provides the common risk difference for column 1 by default. If you specify COLUMN=2, PROC FREQTAB provides the common risk difference for column 2. COLUMN=BOTH does not apply to the common risk difference.

CORRECT

includes a continuity correction in the Wald confidence limits, Wald tests, and Newcombe confidence limits. For more information, see the section "Risks and Risk Differences" on page 501.

EQUAL < (NULL=*value*)>

requests an equality test for the risk difference. For more information, see the section "Equality Tests" on page 507.

You can specify the null hypothesis *value* of the risk difference in the NULL= option. By default, NULL=0. You can specify the null *value* in proportion form as a number between –1 and 1, or you can specify the null *value* in percentage form as a number between –100 and 100. When the *value* is between –100 and –1 or between 1 and 100, PROC FREQTAB converts the number to a proportion. PROC FREQTAB treats the values –1 and 1 as percentages.

You can specify the equality test method by using the METHOD= *riskdiff-option*. By default, PROC FREQTAB produces a Wald test (METHOD=WALD). By default, PROC FREQTAB uses the sample variance to compute the Wald test statistic; if you specify the VAR=NULL *riskdiff-option*, PROC FREQTAB uses the null (test-based) variance.

EQUIV

EQUIVALENCE

requests an equivalence test for the risk difference. For more information, see the section "Equivalence Test" on page 510. You can specify the test method in the METHOD= *riskdiff-option*, and you can specify the margins in the MARGIN= *riskdiff-option*. By default, METHOD=WALD and MARGIN=0.2.

MARGIN=*value* | **(***lower***,** *upper***)**

specifies the margin for the noninferiority, superiority, and equivalence tests, which you request by specifying the NONINF, SUP, and EQUIV *riskdiff-options*, respectively. By default, MARGIN=0.2.

For noninferiority and superiority tests, specify a single *value* in the MARGIN= option. The *value* must be a positive number. You can specify *value* as a number between 0 and 1. Or you can specify *value* in percentage form as a number between 1 and 100, and PROC FREQTAB converts that number to a proportion. PROC FREQTAB treats the value 1 as 1%.

For an equivalence test, you can specify a single MARGIN= *value*, or you can specify both *lower* and *upper* values. If you specify a single *value*, it must be a positive number, as described previously. If you specify a single *value* for an equivalence test, PROC FREQTAB uses –*value* as the lower margin and *value* as the upper margin for the test. If you specify both *lower* and *upper* values for an equivalence test, you can specify them in proportion form as numbers between –1 and 1. Or you can specify them in percentage form as numbers between –100 and 100, and PROC FREQTAB converts the numbers to proportions. The value of *lower* must be less than the value of *upper*.

METHOD=*method*

specifies the method to be used for the equality, equivalence, noninferiority, and superiority tests, which you request by specifying the EQUAL, EQUIV, NONINF, and SUP *riskdiff-options*, respectively. By default, METHOD=WALD.

You can specify the following *methods*:

FM

SCORE

requests Farrington-Manning (score) tests for the equality, equivalence, noninferiority, and superiority analyses. For more information, see the subsection "Farrington-Manning (Score) Test" in the section "Noninferiority Tests" on page 507.

HA

requests Hauck-Anderson tests for the equality, equivalence, noninferiority, and superiority analyses. For more information, see the subsection "Hauck-Anderson Test" in the section "Noninferiority Tests" on page 507.

NEWCOMBE

requests Newcombe (hybrid-score) confidence limits for the equivalence, noninferiority, and superiority analyses. If you specify the CORRECT *riskdiff-option*, the Newcombe confidence limits include a continuity correction. For more information, see the subsection "Newcombe Noninferiority Analysis" in the section "Noninferiority Tests" on page 507.

WALD
requests Wald tests for the equality, equivalence, noninferiority, and superiority analyses. By default, PROC FREQTAB uses the sample variance to compute these Wald test statistics; if you specify the VAR=NULL *riskdiff-option*, PROC FREQTAB uses the null (test-based) variance. If you specify the CORRECT *riskdiff-option*, the Wald tests and confidence limits include a continuity correction. For more information, see the subsection "Wald Test" in the section "Noninferiority Tests" on page 507.

NONINF

NONINFERIORITY
requests a noninferiority test for the risk difference. For more information, see the section "Noninferiority Tests" on page 507. You can specify the test method in the METHOD= *riskdiff-option*, and you can specify the margin in the MARGIN= *riskdiff-option*. By default, METHOD=WALD and MARGIN=0.2.

NORISKS
suppresses display of the "Risk Estimates" tables, which the RISKDIFF option produces by default for column 1 and column 2. The "Risk Estimates" tables contain the risks and risk differences, together with their asymptotic standard errors, Wald confidence limits, and exact confidence limits.

SUP

SUPERIORITY
requests a superiority test for the risk difference. For more information, see the section "Superiority Test" on page 509. You can specify the test method in the METHOD= *riskdiff-option*, and you can specify the margin in the MARGIN= *riskdiff-option*. By default, METHOD=WALD and MARGIN=0.2.

VAR=NULL | SAMPLE
specifies the type of variance to use in the Wald tests of equality, equivalence, noninferiority, and superiority. If you specify VAR=SAMPLE, PROC FREQTAB uses the sample variance. If you specify VAR=NULL, PROC FREQTAB uses a test-based variance that is computed by using the null hypothesis value of the risk difference. For more information, see the sections "Equality Tests" on page 507 and "Noninferiority Tests" on page 507. By default, VAR=SAMPLE.

SCORES=*type*
specifies the type of row and column scores that PROC FREQTAB uses to compute the following statistics: Mantel-Haenszel chi-square, Pearson correlation, Cochran-Armitage test for trend, weighted kappa coefficient, and Cochran-Mantel-Haenszel statistics. The value of *type* can be one of the following:

- **MODRIDIT**
- **RANK**
- **RIDIT**
- **TABLE**

See the section "Scores" on page 475 for descriptions of these score types.

If you do not specify the SCORES= option, PROC FREQTAB uses SCORES=TABLE by default. For character variables, the row and column TABLE scores are the row and column numbers. That is, the TABLE score is 1 for row 1, 2 for row 2, and so on. For numeric variables, the row and column TABLE scores equal the variable values. For more information, see the section "Scores" on page 475. Using MODRIDIT, RANK, or RIDIT scores yields nonparametric analyses.

You can use the SCOROUT option to display the row and column scores.

SCOROUT

displays the row and column scores that PROC FREQTAB uses to compute score-based tests and statistics. You can specify the score type by using the SCORES= option. For more information, see the section "Scores" on page 475.

The scores are computed and displayed only when PROC FREQTAB computes statistics for two-way tables. You can use ODS to store the scores in an output data set. See the section "ODS Table Names" on page 565 for more information.

SENSPEC <(*options*)>

requests estimates of sensitivity, specificity, accuracy, positive predictive value, and negative predictive value for 2×2 tables. The "Sensitivity and Specificity" table provides these estimates together with their standard errors and confidence limits. For more information, see the section "Sensitivity and Specificity" on page 500.

You can specify the confidence level in the ALPHA= option. By default, ALPHA=0.05, which produces 95% confidence limits.

You can specify the following *options*:

NOTE<=YES | NO>

controls the footnote that identifies the reference level (true positives) in the "Sensitivity and Specificity" table. NOTE=NO suppresses this footnote, and NOTE<=YES> displays it. By default, PROC FREQTAB displays the footnote only when you specify the reference level by using the REFCELL=, REFCOLUMN=, and/or REFROW= options.

REFCELL=*number*

specifies the 2×2 table cell to use as the true-positive classification (positive row variable level and positive column variable level) in the SENSPEC computations. For more information, see the section "Sensitivity and Specificity" on page 500.

You can specify the true-positive cell *number* as 1, 2, 3, or 4; these numbers correspond to the cells of the 2×2 crosstabulation table. By default, REFCELL=1, which uses table cell (1,1) as the true-positive cell (and the corresponding row 1 and column 1 as the positive row and column levels, respectively). REFCELL=2, 3, and 4 use table cells (1,2), (2,1), and (2,2), respectively, as the true-positive cells.

You cannot specify this option together with the REFROW= or REFCOLUMN= option. The true-positive cell *number* determines the corresponding positive row and column levels.

REFCOLUMN=*number* | '*level-value*'
specifies the column level to use as the positive column level in the SENSPEC computations. For more information, see the section "Sensitivity and Specificity" on page 500.

You can specify the positive column level *number* as 1 or 2, which is the order in which the level appears in the 2×2 crosstabulation table. Or you can specify the positive column *level-value*, which is the formatted value of the level. The *level-value* must be enclosed in single quotes. By default, REFCOLUMN=1.

REFROW=*number* | '*level-value*'
specifies the row level to use as the positive row level in the SENSPEC computations. For more information, see the section "Sensitivity and Specificity" on page 500.

You can specify the positive row level *number* as 1 or 2, which is the order in which the level appears in the 2×2 crosstabulation table. Or you can specify the positive row *level-value*, which is the formatted value of the level. The *level-value* must be enclosed in single quotes. By default, REFROW=1.

TOTPCT
displays percentages of the total multiway table frequency in multiway crosstabulation tables (n-way tables where $n > 2$). By default, crosstabulation tables display percentages of the two-way table (stratum) frequency but do not display percentages of the total multiway table frequency. For more information, see the section "Two-Way and Multiway Tables" on page 556.

By default, tables in list format (which you can request by specifying the LIST option) display the percentages of the total multiway table frequency. The variable PERCENT in the OUT= output data set also provides the percentages of the total multiway table frequency.

TREND
requests the Cochran-Armitage test for trend. The table must be $2 \times C$ or $R \times 2$ to compute the trend test. For more information, see the section "Cochran-Armitage Test for Trend" on page 526. To request exact p-values for the trend test, specify the TREND option in the EXACT statement. See the section "Exact Statistics" on page 547 for more information.

TEST Statement

TEST *test-options* **;**

The TEST statement requests asymptotic tests for measures of association and measures of agreement. The *test-options* identify which tests to compute. Table 11.19 lists the available *test-options*, together with their corresponding TABLES statement options. Descriptions of the *test-options* follow the table in alphabetical order.

For each measure of association or agreement that you request in the TEST statement, PROC FREQTAB provides an asymptotic test that the measure is 0. The procedure displays the asymptotic standard error under the null hypothesis, the test statistic, and the one-sided and two-sided p-values. PROC FREQTAB also provides confidence limits for the measure. The ALPHA= option in the TABLES statement determines the confidence level; by default, ALPHA=0.05, which provides 95% confidence limits. For more information, see the sections "Asymptotic Tests" on page 482 and "Confidence Limits" on page 482. For information about

the individual measures, see the sections "Measures of Association" on page 482 and "Tests and Measures of Agreement" on page 529.

You can also request exact tests for selected measures of association and agreement by using the EXACT statement. For more information, see the section "Exact Statistics" on page 547.

Using the TEST Statement with the TABLES Statement

You must use a TABLES statement with the TEST statement. If you use only one TABLES statement, you do not need to specify the same options in both the TABLES and TEST statements; when you specify an option in the TEST statement, PROC FREQTAB automatically invokes the corresponding TABLES statement option. However, when you use the TEST statement with multiple TABLES statements, you must specify options in the TABLES statements to request statistics; PROC FREQTAB then provides asymptotic tests for those statistics that you specify in the TEST statement.

Test Options

Table 11.19 summarizes the *test-options* that you can specify in the TEST statement.

Table 11.19 TEST Statement Options

Test Option	Asymptotic Tests	Required TABLES Statement Option
AGREE	Simple and weighted kappa coefficients	AGREE
GAMMA	Gamma	ALL or MEASURES
KAPPA	Simple kappa coefficient	AGREE
KENTB | TAUB	Kendall's tau-b	ALL or MEASURES
MEASURES	Gamma, Kendall's tau-b, Stuart's tau-c, Somers' $D(C\|R)$, Somers' $D(R\|C)$, Pearson and Spearman correlations	ALL or MEASURES
PCORR	Pearson correlation coefficient	ALL or MEASURES
PLCORR	Polychoric correlation	PLCORR
SCORR	Spearman correlation coefficient	ALL or MEASURES
SMDCR	Somers' $D(C\|R)$	ALL or MEASURES
SMDRC	Somers' $D(R\|C)$	ALL or MEASURES
STUTC | TAUC	Stuart's tau-c	ALL or MEASURES
WTKAPPA | WTKAP	Weighted kappa coefficient	AGREE

You can specify the following *test-options*:

AGREE

requests asymptotic tests for the simple kappa coefficient and the weighted kappa coefficient. For more information, see the sections "Simple Kappa Coefficient" on page 530 and "Weighted Kappa Coefficient" on page 532.

By default, these tests are based on null values of 0; you can specify nonzero null values for the simple kappa and weighted kappa tests by using the AGREE(NULLKAPPA=) and AGREE(NULLWTKAPPA=) options, respectively, in the TABLES statement.

The AGREE option in the TABLES statement provides estimates, standard errors, and confidence limits for kappa coefficients. You can request exact tests for kappa coefficients by using the EXACT statement.

Kappa coefficients are defined only for square tables, where the number of rows equals the number of columns. Kappa coefficients are not computed for tables that are not square. For 2×2 tables, the weighted kappa coefficient is identical to the simple kappa coefficient, and PROC FREQTAB presents only the simple kappa coefficient.

GAMMA

requests an asymptotic test for the gamma statistic. For more information, see the section "Gamma" on page 483. The MEASURES option in the TABLES statement provides the gamma statistic and its asymptotic standard error.

KAPPA

requests an asymptotic test for the simple kappa coefficient. For more information, see the section "Simple Kappa Coefficient" on page 530.

By default, the null value of kappa for this test is 0; you can specify a nonzero null value by using the AGREE(NULLKAPPA=) option in the TABLES statement.

The AGREE option in the TABLES statement provides the kappa statistic, its standard error, and its confidence limits. You can request an exact test for the simple kappa coefficient by specifying the KAPPA option in the EXACT statement.

Kappa coefficients are defined only for square tables, where the number of rows equals the number of columns. PROC FREQTAB does not compute kappa coefficients for tables that are not square.

KENTB

TAUB

requests an asymptotic test for Kendall's tau-*b*. For more information, see the section "Kendall's Tau-b" on page 484.

The MEASURES option in the TABLES statement provides Kendall's tau-*b* and its standard error. You can request an exact test for Kendall's tau-*b* by specifying the KENTB option in the EXACT statement.

MEASURES

requests asymptotic tests for the following measures of association: gamma, Kendall's tau-*b*, Pearson correlation coefficient, Somers' $D(C|R)$, Somers' $D(R|C)$, Spearman correlation coefficient, and Stuart's tau-*c*. For more information, see the section "Measures of Association" on page 482.

The MEASURES option in the TABLES statement provides measures of association and their asymptotic standard errors. You can request exact tests for selected measures by using the EXACT statement.

PCORR

requests an asymptotic test for the Pearson correlation coefficient. For more information, see the section "Pearson Correlation Coefficient" on page 485.

The MEASURES option in the TABLES statement provides the Pearson correlation and its standard error. You can request an exact test for the Pearson correlation by specifying the PCORR option in the EXACT statement.

PLCORR

requests Wald and likelihood ratio tests for the polychoric correlation coefficient. For more information, see the section "Polychoric Correlation" on page 488.

The PLCORR option in the TABLES statement provides the polychoric correlation and its standard error.

SCORR

requests an asymptotic test for the Spearman correlation coefficient. For more information, see the section "Spearman Rank Correlation Coefficient" on page 486.

The MEASURES option in the TABLES statement provides the Spearman correlation and its standard error. You can request an exact test for the Spearman correlation by specifying the SCORR option in the EXACT statement.

SMDCR

requests an asymptotic test for Somers' $D(C|R)$. For more information, see the section "Somers' D" on page 485.

The MEASURES option in the TABLES statement provides Somers' $D(C|R)$ and its standard error. You can request an exact test for Somers' $D(C|R)$ by specifying the SMDCR option in the EXACT statement.

SMDRC

requests an asymptotic test for Somers' $D(R|C)$. For more information, see the section "Somers' D" on page 485.

The MEASURES option in the TABLES statement provides Somers' $D(R|C)$ and its standard error. You can request an exact test for Somers' $D(R|C)$ by specifying the SMDRC option in the EXACT statement.

STUTC

TAUC

requests an asymptotic test for Stuart's tau-c. For more information, see the section "Stuart's Tau-c" on page 484.

The MEASURES option in the TABLES statement provides Stuart's tau-c and its standard error. You can request an exact test for Stuart's tau-c by specifying the STUTC option in the EXACT statement.

WTKAPPA

WTKAP

requests an asymptotic test for the weighted kappa coefficient. For more information, see the section "Weighted Kappa Coefficient" on page 532.

By default, the null value of weighted kappa for this test is 0; you can specify a nonzero null value by using the AGREE(NULLWTKAPPA=) option in the TABLES statement.

The AGREE option in the TABLES statement provides the weighted kappa coefficient, its standard error, and confidence limits. You can request an exact test for the weighted kappa by specifying the WTKAPPA option in the EXACT statement.

Kappa coefficients are defined only for square tables, where the number of rows equals the number of columns. PROC FREQTAB does not compute kappa coefficients for tables that are not square. For

2×2 tables, the weighted kappa coefficient is identical to the simple kappa coefficient, and PROC FREQTAB presents only the simple kappa coefficient.

WEIGHT Statement

WEIGHT *variable* < / *option* > **;**

The WEIGHT statement names a numeric variable that provides a weight for each observation in the input data table. The WEIGHT statement is most commonly used to input cell count data. See the section "Inputting Frequency Counts" on page 472 for more information. If you use a WEIGHT statement, PROC FREQTAB assumes that an observation represents *n* observations, where *n* is the value of *variable*. The value of the WEIGHT variable is not required to be an integer.

If the value of the WEIGHT variable is missing, PROC FREQTAB does not use that observation in the analysis. If the value of the WEIGHT variable is 0, PROC FREQTAB ignores the observation unless you specify the ZEROS option, which includes observations that have weights of 0. If you do not specify a WEIGHT statement, PROC FREQTAB assigns a weight of 1 to each observation. The sum of the WEIGHT variable values represents the total number of observations.

If any value of the WEIGHT variable is negative, PROC FREQTAB displays the frequencies computed from the weighted values but does not compute percentages and statistics. If you create an output data set by using the OUT= option in the TABLES statement, PROC FREQTAB assigns missing values to the PERCENT variable. PROC FREQTAB also assigns missing values to the variables that the OUTEXPECT and OUTPCT options provide. If any value of the WEIGHT variable is negative, you cannot create an output data set by using the OUTPUT statement because statistics are not computed when there are negative weights.

You can specify the following *option*:

ZEROS

includes observations that have weights of 0. By default, PROC FREQTAB ignores observations that have weights of 0.

If you specify the ZEROS option, frequency and crosstabulation tables display levels that contain only zero-weight observations. If you do not specify the ZEROS option, PROC FREQTAB does not process observations that have weights of 0 and therefore does not display levels that contain only zero-weight observations.

When you specify the ZEROS option, PROC FREQTAB includes zero-weight levels in chi-square tests and binomial computations for one-way tables. This makes it possible to compute binomial tests and estimates for a reference level that contains no observations with positive weights.

For two-way tables, the ZEROS option enables computation of kappa statistics when there are levels that contain no observations with positive weights. For more information, see the section "Tables with Zero-Weight Rows or Columns" on page 536.

Even when you specify the ZEROS option, PROC FREQTAB does not compute CHISQ or MEASURES statistics for two-way tables that contain a zero-weight row or column because most of these statistics are undefined in this case.

By default, the ZEROS option includes zero-weight table cells in the LIST table and the OUT= data set. To suppress zero-weight cells, you can specify the NOSPARSE option in the TABLES statement.

Details: FREQTAB Procedure

Inputting Frequency Counts

PROC FREQTAB can use either raw data or cell count data to produce frequency and crosstabulation tables. *Raw data*, also known as case-record data, report the data as one record for each subject or sample member. *Cell count data* report the data as a table, listing all possible combinations of data values along with the frequency counts. This way of presenting data often appears in published results.

The following DATA step statements store raw data in a data table:

```
data mylib.Raw;
   input Subject $ R C @@;
   datalines;
01 1 1  02 1 1  03 1 1  04 1 1  05 1 1
06 1 2  07 1 2  08 1 2  09 2 1  10 2 1
11 2 1  12 2 1  13 2 2  14 2 2  14 2 2
;
```

You can store the same data as cell counts by using the following DATA step statements:

```
data mylib.CellCounts;
   input R C Count @@;
   datalines;
1 1 5   1 2 3
2 1 4   2 2 3
;
```

The variable R contains the values for the rows, and the variable C contains the values for the columns. The variable Count contains the cell count for each row and column combination.

Both the mylib.Raw data table and the mylib.CellCounts data table produce identical frequency counts, two-way tables, and statistics. When you use the mylib.CellCounts data table, you must include a WEIGHT statement to specify that the variable Count contains cell counts. For example, the following PROC FREQTAB statements create a two-way crosstabulation table by using the mylib.CellCounts data table:

```
proc freqtab data=mylib.CellCounts;
   tables R*C;
   weight Count;
run;
```

Missing Values

If an observation has a missing value for the WEIGHT variable, PROC FREQTAB excludes that observation from the analysis.

If an observation has a missing value for a TABLES statement variable, by default PROC FREQTAB does not include that observation in the frequency or crosstabulation table (or in the frequency total, percentages, and statistics). PROC FREQTAB displays the frequency of missing values after the frequency or crosstabulation table.

PROC FREQTAB includes the frequency of missing values in the output data sets. The OUT= data set that you specify in the TABLES statement includes an observation that contains the frequency of missing values. The OUT= data set that you specify in the OUTPUT statement includes the frequency of missing values in the variable NMISS when you specify the NMISS option in the OUTPUT statement.

The following options change the way that PROC FREQTAB handles missing values of TABLES statement variables:

MISSPRINT displays missing value frequencies in frequency tables but does not include them in computing percentages or statistics. This option is available for one-way frequency tables and for tables in list format (which you can request by specifying the LIST option in the TABLES statement).

MISSING treats missing values as a valid nonmissing level for all TABLES statement variables. This option displays missing levels in frequency and crosstabulation tables and includes them in computing percentages and statistics.

This example shows the three ways that PROC FREQTAB can handle missing values of TABLES statement variables. The following DATA step statements create a data table that contains a missing value for the variable A:

```
data mylib.One;
   input A Freq;
   datalines;
1 2
2 2
. 2
;
```

The following PROC FREQTAB statements request a one-way frequency table for the variable A. The first request does not specify a missing value option. The second request specifies the MISSPRINT option in the PROC FREQTAB statement. The third request specifies the MISSING option in the PROC FREQTAB statement.

```
proc freqtab data=mylib.One;
   tables A;
   weight Freq;
   title 'Default';
run;
proc freqtab data=mylib.One missprint;
   tables A;
   weight Freq;
   title 'MISSPRINT Option';
```

```
run;
proc freqtab data=mylib.One missing;
   tables A;
   weight Freq;
   title 'MISSING Option';
run;
```

Figure 11.9 displays the frequency tables produced by this example. The first table shows PROC FREQTAB's default behavior for handling missing values. The frequency table does not include the missing level of the TABLES statement variable A. PROC FREQTAB displays the frequency of missing values after the table.

The second table, for which the MISSPRINT option is specified, displays the missing level of A but does not include its frequency in computing the total frequency and percentages.

The third table, for which the MISSING option is specified, treats the missing level as a valid nonmissing level. The frequency table displays the missing level of A and includes its frequency in computing the total frequency and percentages.

Figure 11.9 Missing Values in Frequency Tables

Default

The FREQTAB Procedure

A	Frequency	Percent	Cumulative Frequency	Cumulative Percent
1	2	50.00	2	50.00
2	2	50.00	4	100.00

Frequency Missing = 2

MISSPRINT Option

The FREQTAB Procedure

A	Frequency	Percent	Cumulative Frequency	Cumulative Percent
.	2	.	.	.
1	2	50.00	2	50.00
2	2	50.00	4	100.00

Frequency Missing = 2

MISSING Option

The FREQTAB Procedure

A	Frequency	Percent	Cumulative Frequency	Cumulative Percent
.	2	33.33	2	33.33
1	2	33.33	4	66.67
2	2	33.33	6	100.00

When a combination of variable levels in a two-way table is missing, PROC FREQTAB assigns 0 to the frequency count of the corresponding table cell. The default crosstabulation table and the CROSSLIST crosstabulation table display table cells that have frequencies of 0.

By default, the LIST crosstabulation table and the OUT= output data set do not include table cells that have frequencies of 0. If you specify the ZEROS option in the WEIGHT statement to include observations that have weights of 0, the LIST table and the OUT= output data set include zero-frequency table cells by default unless you specify the NOSPARSE option in the TABLES statement.

Statistical Computations

Definitions and Notation

A two-way table represents the crosstabulation of row variable X and column variable Y. Let the table row values or levels be denoted by $X_i, i = 1, 2, \ldots, R$, and the column values by $Y_j, j = 1, 2, \ldots, C$. Let n_{ij} denote the frequency of the table cell in the *i*th row and *j*th column and define the following notation:

$$n_{i\cdot} = \sum_j n_{ij} \quad \text{(row totals)}$$

$$n_{\cdot j} = \sum_i n_{ij} \quad \text{(column totals)}$$

$$n = \sum_i \sum_j n_{ij} \quad \text{(overall total)}$$

$$p_{ij} = n_{ij}/n \quad \text{(cell percentages)}$$

$$p_{i\cdot} = n_{i\cdot}/n \quad \text{(row percentages of total)}$$

$$p_{\cdot j} = n_{\cdot j}/n \quad \text{(column percentages of total)}$$

$$R_i = \text{score for row } i$$

$$C_j = \text{score for column } j$$

$$\bar{R} = \sum_i n_{i\cdot} R_i / n \quad \text{(average row score)}$$

$$\bar{C} = \sum_j n_{\cdot j} C_j / n \quad \text{(average column score)}$$

$$A_{ij} = \sum_{k>i} \sum_{l>j} n_{kl} + \sum_{k<i} \sum_{l<j} n_{kl}$$

$$D_{ij} = \sum_{k>i} \sum_{l<j} n_{kl} + \sum_{k<i} \sum_{l>j} n_{kl}$$

$$P = \sum_i \sum_j n_{ij} A_{ij} \quad \text{(twice the number of concordances)}$$

$$Q = \sum_i \sum_j n_{ij} D_{ij} \quad \text{(twice the number of discordances)}$$

Scores

PROC FREQTAB uses scores of the variable values to compute the Mantel-Haenszel chi-square, Pearson correlation, Cochran-Armitage test for trend, weighted kappa coefficient, and Cochran-Mantel-Haenszel statistics. The SCORES= option in the TABLES statement specifies the score type that PROC FREQTAB

uses. The available score types are TABLE, RANK, RIDIT, and MODRIDIT scores. The default score type is TABLE. Using MODRIDIT, RANK, or RIDIT scores yields nonparametric analyses.

For numeric variables, table scores are the values of the row and column levels. If the row or column variable is formatted, then the table score is the internal numeric value corresponding to that level. If two or more numeric values are classified into the same formatted level, then the internal numeric value for that level is the smallest of these values. For character variables, table scores are defined as the row numbers and column numbers (that is, 1 for the first row, 2 for the second row, and so on).

Rank scores, which you request with the SCORES=RANK option, are defined as

$$R_i^1 = \sum_{k<i} n_{k\cdot} + (n_{i\cdot} + 1)/2 \qquad i = 1, 2, \ldots, R$$
$$C_j^1 = \sum_{l<j} n_{\cdot l} + (n_{\cdot j} + 1)/2 \qquad j = 1, 2, \ldots, C$$

where R_i^1 is the rank score of row i, and C_j^1 is the rank score of column j. Note that rank scores yield midranks for tied values.

Ridit scores, which you request with the SCORES=RIDIT option, are defined as rank scores standardized by the sample size (Bross 1958; Mack and Skillings 1980). Ridit scores are derived from the rank scores as

$$R_i^2 = R_i^1/n \qquad i = 1, 2, \ldots, R$$
$$C_j^2 = C_j^1/n \qquad j = 1, 2, \ldots, C$$

Modified ridit scores (SCORES=MODRIDIT) represent the expected values of the order statistics of the uniform distribution on (0,1) (Van Elteren 1960; Lehmann and D'Abrera 2006). Modified ridit scores are derived from rank scores as

$$R_i^3 = R_i^1/(n+1) \qquad i = 1, 2, \ldots, R$$
$$C_j^3 = C_j^1/(n+1) \qquad j = 1, 2, \ldots, C$$

Chi-Square Tests and Statistics

The CHISQ option provides chi-square tests of homogeneity or independence and measures of association that are based on the chi-square statistic. When you specify the CHISQ option in the TABLES statement, PROC FREQTAB computes the following chi-square tests for each two-way table: Pearson chi-square, likelihood ratio chi-square, and Mantel-Haenszel chi-square tests. PROC FREQTAB provides the following measures of association that are based on the Pearson chi-square statistic: phi coefficient, contingency coefficient, and Cramér's V. For 2×2 tables, the CHISQ option also provides Fisher's exact test and the continuity-adjusted chi-square statistic. You can request Fisher's exact test for general $R \times C$ tables by specifying the FISHER option in the TABLES or EXACT statement.

If you specify the CHISQ option for one-way tables, PROC FREQTAB provides a one-way Pearson chi-square goodness-of-fit test. If you specify the CHISQ(LRCHI) option for one-way tables, PROC FREQTAB also provides a one-way likelihood ratio chi-square test. The other tests and statistics that the CHISQ option produces are available only for two-way tables.

For two-way tables, the null hypothesis for the chi-square tests is no association between the row variable and the column variable. When the sample size n is large, the test statistics have asymptotic chi-square

distributions under the null hypothesis. When the sample size is not large, or when the data set is sparse or heavily tied, exact tests might be more appropriate than asymptotic tests. PROC FREQTAB provides exact *p*-values for the Pearson chi-square, likelihood ratio chi-square, and Mantel-Haenszel chi-square tests, in addition to Fisher's exact test. For one-way tables, PROC FREQTAB provides exact *p*-values for the Pearson and likelihood ratio chi-square goodness-of-fit tests. You can request these exact tests by specifying the corresponding options in the EXACT statement. See the section "Exact Statistics" on page 547 for more information.

The Mantel-Haenszel chi-square statistic is appropriate only when both variables lie on an ordinal scale. The other chi-square tests and statistics in this section are appropriate for either nominal or ordinal variables. The following sections give the formulas that PROC FREQTAB uses to compute the chi-square tests and statistics. For more information about these statistics, see Agresti (2007) and Stokes, Davis, and Koch (2012), and the other references cited.

Chi-Square Test for One-Way Tables

For one-way frequency tables, the CHISQ option in the TABLES statement provides a chi-square goodness-of-fit test. Let C denote the number of classes, or levels, in the one-way table. Let f_i denote the frequency of class i (or the number of observations in class i) for $i = 1, 2, \ldots, C$. Then PROC FREQTAB computes the one-way chi-square statistic as

$$Q_P = \sum_{i=1}^{C} (f_i - e_i)^2 / e_i$$

where e_i is the expected frequency for class i under the null hypothesis.

In the test for equal proportions, which is the default for the CHISQ option, the null hypothesis specifies equal proportions of the total sample size for each class. Under this null hypothesis, the expected frequency for each class equals the total sample size divided by the number of classes,

$$e_i = n \,/\, C \quad \text{for} \quad i = 1, 2, \ldots, C$$

In the test for specified frequencies, which PROC FREQTAB computes when you input null hypothesis frequencies by using the TESTF= option, the expected frequencies are the TESTF= values that you specify. In the test for specified proportions, which PROC FREQTAB computes when you input null hypothesis proportions by using the TESTP= option, the expected frequencies are determined from the specified TESTP= proportions p_i as

$$e_i = p_i \times n \quad \text{for} \quad i = 1, 2, \ldots, C$$

Under the null hypothesis (of equal proportions, specified frequencies, or specified proportions), Q_P has an asymptotic chi-square distribution with C–1 degrees of freedom.

In addition to the asymptotic test, you can request an exact one-way chi-square test by specifying the CHISQ option in the EXACT statement. See the section "Exact Statistics" on page 547 for more information.

Pearson Chi-Square Test for Two-Way Tables

The Pearson chi-square for two-way tables involves the differences between the observed and expected frequencies, where the expected frequencies are computed under the null hypothesis of independence. The Pearson chi-square statistic is computed as

$$Q_P = \sum_{i} \sum_{j} (n_{ij} - e_{ij})^2 / e_{ij}$$

where n_{ij} is the observed frequency in table cell (i, j) and e_{ij} is the expected frequency in table cell (i, j). The expected frequency is computed under the null hypothesis that the row and column variables are independent,

$$e_{ij} = (n_{i\cdot} \times n_{\cdot j}) \; / \; n$$

When the row and column variables are independent, Q_P has an asymptotic chi-square distribution with $(R-1)(C-1)$ degrees of freedom. For large values of Q_P, this test rejects the null hypothesis in favor of the alternative hypothesis of general association.

In addition to the asymptotic test, you can request an exact Pearson chi-square test by specifying the PCHI or CHISQ option in the EXACT statement. See the section "Exact Statistics" on page 547 for more information.

For 2×2 tables, the Pearson chi-square is also appropriate for testing the equality of two binomial proportions. For $R \times 2$ and $2 \times C$ tables, the Pearson chi-square tests the homogeneity of proportions. For more information, see Fienberg (1980).

Standardized Residuals

When you specify the CROSSLIST(STDRES) option in the TABLES statement for two-way or multiway tables, PROC FREQTAB displays the standardized residuals in the CROSSLIST table.

The standardized residual of a crosstabulation table cell is the ratio of (*frequency* – *expected*) to its standard error, where *frequency* is the table cell frequency and *expected* is the estimated expected cell frequency. The expected frequency is computed under the null hypothesis that the row and column variables are independent. See the section "Pearson Chi-Square Test for Two-Way Tables" on page 477 for more information.

PROC FREQTAB computes the standardized residual of table cell (i, j) as

$$(n_{ij} - e_{ij}) \; / \; \sqrt{e_{ij}(1 - p_{i\cdot})(1 - p_{\cdot j})}$$

where n_{ij} is the observed frequency of table cell (i, j), e_{ij} is the expected frequency of the table cell, $p_{i\cdot}$ is the proportion in row i $(n_{i\cdot}/n)$, and $p_{\cdot j}$ is the proportion in column j $(n_{\cdot j}/n)$. The expected frequency of table cell (i, j) is computed as

$$e_{ij} = (n_{i\cdot} \times n_{\cdot j}) \; / \; n$$

Under the null hypothesis of independence, each standardized residual has an asymptotic standard normal distribution. See section 2.4.5 of Agresti (2007) for more information.

Likelihood Ratio Chi-Square Test for One-Way Tables

For one-way frequency tables, the CHISQ(LRCHI) option in the TABLES statement provides a likelihood ratio chi-square goodness-of-fit test. By default, the likelihood ratio test is based on the null hypothesis of equal proportions in the C classes (levels) of the one-way table. If you specify null hypothesis proportions or frequencies by using the CHISQ(TESTP=) or CHISQ(TESTF=) option, respectively, the likelihood ratio test is based on the null hypothesis values that you specify.

PROC FREQTAB computes the one-way likelihood ratio test as

$$G^2 = 2 \sum_{i=1}^{C} f_i \log(f_i / e_i)$$

where f_i is the observed frequency of class i, and e_i is the expected frequency of class i under the null hypothesis.

For the null hypothesis of equal proportions, the expected frequency of each class is the total sample size divided by the number of classes,

$$e_i = n \,/\, C \quad \text{for} \quad i = 1, 2, \ldots, C$$

If you provide null hypothesis frequencies by specifying the CHISQ(TESTF=) option in the TABLES statement, the expected frequencies are the TESTF= values that you specify. If you provide null hypothesis proportions by specifying the CHISQ(TESTP=) option in the TABLES statement, PROC FREQTAB computes the expected frequencies as

$$e_i = p_i \times n \quad \text{for} \quad i = 1, 2, \ldots, C$$

where the proportions p_i are the TESTP= values that you specify.

Under the null hypothesis (of equal proportions, specified frequencies, or specified proportions), the likelihood ratio statistic G^2 has an asymptotic chi-square distribution with C–1 degrees of freedom.

In addition to the asymptotic test, you can request an exact one-way likelihood ratio chi-square test by specifying the LRCHI option in the EXACT statement. See the section "Exact Statistics" on page 547 for more information.

Likelihood Ratio Chi-Square Test

The likelihood ratio chi-square involves the ratios between the observed and expected frequencies. The likelihood ratio chi-square statistic is computed as

$$G^2 = 2 \sum_i \sum_j n_{ij} \log\left(n_{ij}/e_{ij}\right)$$

where n_{ij} is the observed frequency in table cell (i, j) and e_{ij} is the expected frequency for table cell (i, j).

When the row and column variables are independent, G^2 has an asymptotic chi-square distribution with $(R–1)(C–1)$ degrees of freedom.

In addition to the asymptotic test, you can request an exact likelihood ratio chi-square test by specifying the LRCHI or CHISQ option in the EXACT statement. See the section "Exact Statistics" on page 547 for more information.

Continuity-Adjusted Chi-Square Test

The continuity-adjusted chi-square for 2×2 tables is similar to the Pearson chi-square, but it is adjusted for the continuity of the chi-square distribution. The continuity-adjusted chi-square is most useful for small sample sizes. The use of the continuity adjustment is somewhat controversial; this chi-square test is more conservative (and more like Fisher's exact test) when the sample size is small. As the sample size increases, the continuity-adjusted chi-square becomes more like the Pearson chi-square.

The continuity-adjusted chi-square statistic is computed as

$$Q_C = \sum_i \sum_j \left(\max(0, |n_{ij} - e_{ij}| - 0.5) \right)^2 \,/\, e_{ij}$$

Under the null hypothesis of independence, Q_C has an asymptotic chi-square distribution with $(R–1)(C–1)$ degrees of freedom.

Mantel-Haenszel Chi-Square Test

The Mantel-Haenszel chi-square statistic tests the alternative hypothesis that there is a linear association between the row variable and the column variable. Both variables must lie on an ordinal scale. The Mantel-Haenszel chi-square statistic is computed as

$$Q_{\mathrm{MH}} = (n-1)r^2$$

where r is the Pearson correlation between the row variable and the column variable. For a description of the Pearson correlation, see the "Pearson Correlation Coefficient" on page 485. The Pearson correlation and thus the Mantel-Haenszel chi-square statistic use the scores that you specify in the SCORES= option in the TABLES statement. See Mantel and Haenszel (1959) and Landis, Heyman, and Koch (1978) for more information.

Under the null hypothesis of no association, Q_{MH} has an asymptotic chi-square distribution with 1 degree of freedom.

In addition to the asymptotic test, you can request an exact Mantel-Haenszel chi-square test by specifying the MHCHI or CHISQ option in the EXACT statement. See the section "Exact Statistics" on page 547 for more information.

Fisher's Exact Test

Fisher's exact test is another test of association between the row and column variables. This test assumes that the row and column totals are fixed and uses the hypergeometric distribution to compute probabilities of possible tables conditional on the observed row and column totals. Fisher's exact test does not depend on any large-sample distribution assumptions, and so it is appropriate even for small sample sizes and for sparse tables.

2 × 2 Tables For 2 × 2 tables, PROC FREQTAB gives the following information for Fisher's exact test: table probability, two-sided p-value, left-sided p-value, and right-sided p-value. The table probability is the hypergeometric probability of the observed table, and is in fact the value of the test statistic for Fisher's exact test.

Where p is the hypergeometric probability of a specific table with the observed row and column totals, Fisher's exact p-values are computed by summing probabilities p over defined sets of tables,

$$\mathrm{Prob} = \sum_{A} p$$

The two-sided p-value is the sum of all possible table probabilities (conditional on the observed row and column totals) that are less than or equal to the observed table probability. For the two-sided p-value, the set A includes all possible tables with hypergeometric probabilities less than or equal to the probability of the observed table. A small two-sided p-value supports the alternative hypothesis of association between the row and column variables.

For 2 × 2 tables, one-sided p-values for Fisher's exact test are defined in terms of the frequency of the cell in the first row and first column of the table, the (1,1) cell. Denoting the observed (1,1) cell frequency by n_{11}, the left-sided p-value for Fisher's exact test is the probability that the (1,1) cell frequency is less than or equal to n_{11}. For the left-sided p-value, the set A includes those tables with a (1,1) cell frequency less than or equal to n_{11}. A small left-sided p-value supports the alternative hypothesis that the probability of an observation being in the first cell is actually less than expected under the null hypothesis of independent row and column variables.

Similarly, for a right-sided alternative hypothesis, A is the set of tables where the frequency of the (1,1) cell is greater than or equal to that in the observed table. A small right-sided p-value supports the alternative that the probability of the first cell is actually greater than that expected under the null hypothesis.

Because the (1,1) cell frequency completely determines the 2×2 table when the marginal row and column sums are fixed, these one-sided alternatives can be stated equivalently in terms of other cell probabilities or ratios of cell probabilities. The left-sided alternative is equivalent to an odds ratio less than 1, where the odds ratio is $(n_{11}n_{22}/n_{12}n_{21})$. The left-sided alternative is also equivalent to the column 1 risk for row 1 being less than the column 1 risk for row 2, $p_{1|1} < p_{1|2}$. Similarly, the right-sided alternative is equivalent to the column 1 risk for row 1 being greater than the column 1 risk for row 2, $p_{1|1} > p_{1|2}$. For more information, see Agresti (2007).

R × C Tables Fisher's exact test was extended to general $R \times C$ tables by Freeman and Halton (1951), and this test is also known as the Freeman-Halton test. For $R \times C$ tables, the two-sided p-value definition is the same as for 2×2 tables. The set A contains all tables with p less than or equal to the probability of the observed table. A small p-value supports the alternative hypothesis of association between the row and column variables. For $R \times C$ tables, Fisher's exact test is inherently two-sided. The alternative hypothesis is defined only in terms of general, and not linear, association. Therefore, Fisher's exact test does not have right-sided or left-sided p-values for general $R \times C$ tables.

For $R \times C$ tables, PROC FREQTAB computes Fisher's exact test by using the network algorithm of Mehta and Patel (1983), which provides a faster and more efficient solution than direct enumeration. See the section "Exact Statistics" on page 547 for more details.

Phi Coefficient

The phi coefficient is a measure of association derived from the Pearson chi-square. The range of the phi coefficient is $-1 \leq \phi \leq 1$ for 2×2 tables. For tables larger than 2×2, the range is $0 \leq \phi \leq \min(\sqrt{R-1}, \sqrt{C-1})$ (Liebetrau 1983). The phi coefficient is computed as

$$\phi = (n_{11}n_{22} - n_{12}n_{21}) \,/\, \sqrt{n_{1\cdot}n_{2\cdot}n_{\cdot 1}n_{\cdot 2}} \quad \text{for } 2 \times 2 \text{ tables}$$

$$\phi = \sqrt{Q_P/n} \quad \text{otherwise}$$

See Fleiss, Levin, and Paik (2003, pp. 98–99) for more information.

Contingency Coefficient

The contingency coefficient is a measure of association derived from the Pearson chi-square. The range of the contingency coefficient is $0 \leq P \leq \sqrt{(m-1)/m}$, where $m = \min(R, C)$ (Liebetrau 1983). The contingency coefficient is computed as

$$P = \sqrt{Q_P \,/\, (Q_P + n)}$$

See Kendall and Stuart (1979, pp. 587–588) for more information.

Cramér's V

Cramér's V is a measure of association derived from the Pearson chi-square. It is designed so that the attainable upper bound is always 1. The range of Cramér's V is $-1 \leq V \leq 1$ for 2×2 tables; for tables larger than 2×2, the range is $0 \leq V \leq 1$. Cramér's V is computed as

$$V = \phi \quad \text{for } 2 \times 2 \text{ tables}$$

$$V = \sqrt{\frac{Q_P/n}{\min(R-1, C-1)}} \quad \text{otherwise}$$

See Kendall and Stuart (1979, p. 588) for more information.

Measures of Association

When you specify the MEASURES option in the TABLES statement, PROC FREQTAB computes several statistics that describe the association between the row and column variables of the contingency table. The following are measures of ordinal association that consider whether the column variable Y tends to increase as the row variable X increases: gamma, Kendall's tau-*b*, Stuart's tau-*c*, and Somers' *D*. These measures are appropriate for ordinal variables, and they classify pairs of observations as *concordant* or *discordant*. A pair is concordant if the observation with the larger value of X also has the larger value of Y. A pair is discordant if the observation with the larger value of X has the smaller value of Y. See Agresti (2007) and the other references cited for the individual measures of association.

The Pearson correlation coefficient and the Spearman rank correlation coefficient are also appropriate for ordinal variables. The Pearson correlation describes the strength of the linear association between the row and column variables, and it is computed by using the row and column scores specified by the SCORES= option in the TABLES statement. The Spearman correlation is computed with rank scores. The polychoric correlation (requested by the PLCORR option) also requires ordinal variables and assumes that the variables have an underlying bivariate normal distribution. The following measures of association do not require ordinal variables and are appropriate for nominal variables: lambda asymmetric, lambda symmetric, and the uncertainty coefficients.

PROC FREQTAB computes estimates of the measures according to the formulas given in the following sections. For each measure, PROC FREQTAB computes an asymptotic standard error (ASE), which is the square root of the asymptotic variance denoted by Var in the following sections.

Confidence Limits

If you specify the CL option in the TABLES statement, PROC FREQTAB computes asymptotic confidence limits for all MEASURES statistics. The confidence coefficient is determined according to the value of the ALPHA= option, which, by default, is 0.05 and produces 95% confidence limits.

The confidence limits are computed as

$$\text{Est} \pm (z_{\alpha/2} \times \text{ASE})$$

where Est is the estimate of the measure, $z_{\alpha/2}$ is the $100(1-\alpha/2)$th percentile of the standard normal distribution, and ASE is the asymptotic standard error of the estimate.

Asymptotic Tests

For each measure that you specify in the TEST statement, PROC FREQTAB computes an asymptotic test of the null hypothesis that the measure is 0. Asymptotic tests are available for the following measures of association: gamma, Kendall's tau-*b*, Stuart's tau-*c*, Somers' $D(C|R)$, Somers' $D(R|C)$, the Pearson correlation coefficient, and the Spearman rank correlation coefficient. To compute an asymptotic test, PROC FREQTAB uses a standardized test statistic *z*, which has an asymptotic standard normal distribution under the null hypothesis. The test statistic is computed as

$$z = \text{Est} \; / \; \sqrt{\text{Var}_0(\text{Est})}$$

where Est is the estimate of the measure and $\mathrm{Var}_0(\mathrm{Est})$ is the variance of the estimate under the null hypothesis. Formulas for $\mathrm{Var}_0(\mathrm{Est})$ for the individual measures of association are given in the following sections.

Note that the ratio of Est to $\sqrt{\mathrm{Var}_0(\mathrm{Est})}$ is the same for the following measures: gamma, Kendall's tau-*b*, Stuart's tau-*c*, Somers' $D(C|R)$, and Somers' $D(R|C)$. Therefore, the tests for these measures are identical. For example, the *p*-values for the test of $H_0\colon \mathrm{gamma} = 0$ equal the *p*-values for the test of $H_0\colon \mathrm{tau} - b = 0$.

PROC FREQTAB computes one-sided and two-sided *p*-values for each of these tests. When the test statistic z is greater than its null hypothesis expected value of 0, PROC FREQTAB displays the right-sided *p*-value, which is the probability of a larger value of the statistic occurring under the null hypothesis. A small right-sided *p*-value supports the alternative hypothesis that the true value of the measure is greater than 0. When the test statistic is less than or equal to 0, PROC FREQTAB displays the left-sided *p*-value, which is the probability of a smaller value of the statistic occurring under the null hypothesis. A small left-sided *p*-value supports the alternative hypothesis that the true value of the measure is less than 0. The one-sided *p*-value P_1 can be expressed as

$$P_1 = \begin{cases} \mathrm{Prob}(Z > z) & \text{if } z > 0 \\ \mathrm{Prob}(Z < z) & \text{if } z \leq 0 \end{cases}$$

where Z has a standard normal distribution. The two-sided *p*-value P_2 is computed as

$$P_2 = \mathrm{Prob}(|Z| > |z|)$$

Exact Tests

Exact tests are available for the following measures of association: Kendall's tau-*b*, Stuart's tau-*c*, Somers' $D(C|R)$ and $(R|C)$, the Pearson correlation coefficient, and the Spearman rank correlation coefficient. If you request an exact test for a measure of association in the EXACT statement, PROC FREQTAB computes the exact test of the hypothesis that the measure is 0. For more information, see the section "Exact Statistics" on page 547.

Gamma

The gamma (Γ) statistic is based only on the number of concordant and discordant pairs of observations. It ignores tied pairs (that is, pairs of observations that have equal values of X or equal values of Y). Gamma is appropriate only when both variables lie on an ordinal scale. The range of gamma is $-1 \leq \Gamma \leq 1$. If the row and column variables are independent, gamma tends to be close to 0. Gamma is computed as

$$G = (P - Q) \,/\, (P + Q)$$

and the asymptotic variance is

$$\mathrm{Var}(G) = \frac{16}{(P+Q)^4} \sum_i \sum_j n_{ij} (Q A_{ij} - P D_{ij})^2$$

For 2×2 tables, gamma is equivalent to Yule's Q. See Goodman and Kruskal (1979) and Agresti (2002) for more information.

The variance under the null hypothesis that gamma equals 0 is computed as

$$\mathrm{Var}_0(G) = \frac{4}{(P+Q)^2} \left(\sum_i \sum_j n_{ij} (A_{ij} - D_{ij})^2 - (P - Q)^2 / n \right)$$

For more information, see Brown and Benedetti (1977b).

Kendall's Tau-b

Kendall's tau-b (τ_b) is similar to gamma except that tau-b uses a correction for ties. Tau-b is appropriate only when both variables lie on an ordinal scale. The range of tau-b is $-1 \leq \tau_b \leq 1$. Kendall's tau-b is computed as

$$t_b = (P - Q) \,/\, \sqrt{w_r w_c}$$

and the asymptotic variance is

$$\mathrm{Var}(t_b) = \frac{1}{w^4}\left(\sum_i \sum_j n_{ij}(2wd_{ij} + t_b v_{ij})^2 - n^3 t_b^2 (w_r + w_c)^2\right)$$

where

$$\begin{aligned} w &= \sqrt{w_r w_c} \\ w_r &= n^2 - \sum_i n_{i.}^2 \\ w_c &= n^2 - \sum_j n_{.j}^2 \\ d_{ij} &= A_{ij} - D_{ij} \\ v_{ij} &= n_{i.} w_c + n_{.j} w_r \end{aligned}$$

See Kendall (1955) for more information.

The variance under the null hypothesis that tau-b equals 0 is computed as

$$\mathrm{Var}_0(t_b) = \frac{4}{w_r w_c}\left(\sum_i \sum_j n_{ij}(A_{ij} - D_{ij})^2 - (P - Q)^2/n\right)$$

For more information, see Brown and Benedetti (1977b).

PROC FREQTAB also provides an exact test for the Kendall's tau-b. You can request this test by specifying the KENTB option in the EXACT statement. See the section "Exact Statistics" on page 547 for more information.

Stuart's Tau-c

Stuart's tau-c (τ_c) makes an adjustment for table size in addition to a correction for ties. Tau-c is appropriate only when both variables lie on an ordinal scale. The range of tau-c is $-1 \leq \tau_c \leq 1$. Stuart's tau-c is computed as

$$t_c = m(P - Q) \,/\, n^2(m - 1)$$

and the asymptotic variance is

$$\mathrm{Var}(t_c) = \frac{4m^2}{(m-1)^2 n^4}\left(\sum_i \sum_j n_{ij} d_{ij}^2 - (P - Q)^2/n\right)$$

where $m = \min(R, C)$ and $d_{ij} = A_{ij} - D_{ij}$. The variance under the null hypothesis that tau-c equals 0 is the same as the asymptotic variance

$$\mathrm{Var}_0(t_c) = \mathrm{Var}(t_c)$$

For more information, see Brown and Benedetti (1977b).

PROC FREQTAB also provides an exact test for the Stuart's tau-c. You can request this test by specifying the STUTC option in the EXACT statement. See the section "Exact Statistics" on page 547 for more information.

Somers' D

Somers' $D(C|R)$ and Somers' $D(R|C)$ are asymmetric modifications of tau-b. $C|R$ indicates that the row variable X is regarded as the independent variable and the column variable Y is regarded as dependent. Similarly, $R|C$ indicates that the column variable Y is regarded as the independent variable and the row variable X is regarded as dependent. Somers' D differs from tau-b in that it uses a correction only for pairs that are tied on the independent variable. Somers' D is appropriate only when both variables lie on an ordinal scale. The range of Somers' D is $-1 \leq D \leq 1$. Somers' $D(C|R)$ is computed as

$$D(C|R) = (P - Q) \,/\, w_r$$

and its asymptotic variance is

$$\mathrm{Var}(D(C|R)) = \frac{4}{w_r^4} \sum_i \sum_j n_{ij} \left(w_r d_{ij} - (P - Q)(n - n_{i.}) \right)^2$$

where $d_{ij} = A_{ij} - D_{ij}$ and

$$w_r = n^2 - \sum_i n_{i.}^2$$

For more information, see Somers (1962); Goodman and Kruskal (1979); Liebetrau (1983).

The variance under the null hypothesis that $D(C|R)$ equals 0 is computed as

$$\mathrm{Var}_0(D(C|R)) = \frac{4}{w_r^2} \left(\sum_i \sum_j n_{ij} (A_{ij} - D_{ij})^2 - (P - Q)^2 / n \right)$$

For more information, see Brown and Benedetti (1977b).

Formulas for Somers' $D(R|C)$ are obtained by interchanging the indices.

PROC FREQTAB also provides exact tests for Somers' $D(C|R)$ and $(R|C)$. You can request these tests by specifying the SMDCR and SMDCR options in the EXACT statement. See the section "Exact Statistics" on page 547 for more information.

Pearson Correlation Coefficient

The Pearson correlation coefficient (ρ) is computed by using the scores specified in the SCORES= option. This measure is appropriate only when both variables lie on an ordinal scale. The range of the Pearson correlation is $-1 \leq \rho \leq 1$. The Pearson correlation coefficient is computed as

$$r = v/w = s_{rc} / \sqrt{s_r s_c}$$

and its asymptotic variance is

$$\mathrm{Var}(r) = \frac{1}{w^4} \sum_i \sum_j n_{ij} \left(w(R_i - \bar{R})(C_j - \bar{C}) - \frac{b_{ij} v}{2w} \right)^2$$

where R_i and C_j are the row and column scores and

$$\begin{aligned} s_r &= \sum_i \sum_j n_{ij} (R_i - \bar{R})^2 \\ s_c &= \sum_i \sum_j n_{ij} (C_j - \bar{C})^2 \\ s_{rc} &= \sum_i \sum_j n_{ij} (R_i - \bar{R})(C_j - \bar{C}) \end{aligned}$$

$$\begin{aligned} b_{ij} &= (R_i - \bar{R})^2 s_c + (C_j - \bar{C})^2 s_r \\ v &= s_{rc} \\ w &= \sqrt{s_r s_c} \end{aligned}$$

For more information, see Snedecor and Cochran (1989).

The SCORES= option in the TABLES statement determines the type of row and column scores used to compute the Pearson correlation (and other score-based statistics). The default is SCORES=TABLE. See the section "Scores" on page 475 for details about the available score types and how they are computed.

The variance under the null hypothesis that the correlation equals 0 is computed as

$$\mathrm{Var}_0(r) = \left(\sum_i \sum_j n_{ij} (R_i - \bar{R})^2 (C_j - \bar{C})^2 - ss_{rc}^2 / n \right) \; / \; ss_r \, ss_c$$

This expression for the variance is derived for multinomial sampling in a contingency table framework, and it differs from the form obtained under the assumption that both variables are continuous and normally distributed. For more information, see Brown and Benedetti (1977b).

PROC FREQTAB also provides an exact test for the Pearson correlation coefficient. You can request this test by specifying the PCORR option in the EXACT statement. See the section "Exact Statistics" on page 547 for more information.

Spearman Rank Correlation Coefficient

The Spearman correlation coefficient (ρ_s) is computed by using rank scores, which are defined in the section "Scores" on page 475. This measure is appropriate only when both variables lie on an ordinal scale. The range of the Spearman correlation is $-1 \leq \rho_s \leq 1$. The Spearman correlation coefficient is computed as

$$r_s = v \; / \; w$$

and its asymptotic variance is

$$\mathrm{Var}(r_s) = \frac{1}{n^2 w^4} \sum_i \sum_j n_{ij} (z_{ij} - \bar{z})^2$$

where R_i and C_j are the row and column rank scores and

$$\begin{aligned}
v &= \sum_i \sum_j n_{ij} R(i) C(j) \\
w &= \frac{1}{12} \sqrt{FG} \\
F &= n^3 - \sum_i n_{i\cdot}^3 \\
G &= n^3 - \sum_j n_{\cdot j}^3 \\
R(i) &= R_i - n/2 \\
C(j) &= C_j - n/2 \\
\bar{z} &= \frac{1}{n} \sum_i \sum_j n_{ij} z_{ij} \\
z_{ij} &= w v_{ij} - v w_{ij}
\end{aligned}$$

$$\begin{aligned}
v_{ij} &= n \left(R(i) C(j) + \frac{1}{2} \sum_l n_{il} C(l) + \frac{1}{2} \sum_k n_{kj} R(k) + \right. \\
&\qquad \left. \sum_l \sum_{k>i} n_{kl} C(l) + \sum_k \sum_{l>j} n_{kl} R(k) \right) \\
w_{ij} &= \frac{-n}{96w} \left(F n_{\cdot j}^2 + G n_{i\cdot}^2 \right)
\end{aligned}$$

For more information, see Snedecor and Cochran (1989).

The variance under the null hypothesis that the correlation equals 0 is computed as

$$\mathrm{Var}_0(r_s) = \frac{1}{n^2 w^2} \sum_i \sum_j n_{ij} (v_{ij} - \bar{v})^2$$

where

$$\bar{v} = \sum_i \sum_j n_{ij} v_{ij} / n$$

This expression for the variance is derived for multinomial sampling in a contingency table framework, and it differs from the form obtained under the assumption that both variables are continuous and normally distributed. For more information, see Brown and Benedetti (1977b).

PROC FREQTAB also provides an exact test for the Spearman correlation coefficient. You can request this test by specifying the SCORR option in the EXACT statement. For more information, see the section "Exact Statistics" on page 547.

Polychoric Correlation

When you specify the PLCORR option in the TABLES statement, PROC FREQTAB computes the polychoric correlation and its standard error. The polychoric correlation is based on the assumption that the two ordinal, categorical variables of the frequency table have an underlying bivariate normal distribution. The polychoric correlation coefficient is the maximum likelihood estimate of the product-moment correlation between the underlying normal variables. The range of the polychoric correlation is from –1 to 1. For 2×2 tables, the polychoric correlation is also known as the tetrachoric correlation (and it is labeled as such in the displayed output). See Drasgow (1986) for an overview of polychoric correlation coefficient.

Olsson (1979) gives the likelihood equations and the asymptotic standard errors for estimating the polychoric correlation. The underlying continuous variables relate to the observed crosstabulation table through thresholds, which define a range of numeric values that correspond to each categorical (table) level. PROC FREQTAB uses Olsson's maximum likelihood method for simultaneous estimation of the polychoric correlation and the thresholds. (Olsson also presents a two-step method that estimates the thresholds first.)

PROC FREQTAB iteratively solves the likelihood equations by using a Newton-Raphson algorithm. The initial estimates of the thresholds are computed from the inverse of the normal distribution function at the cumulative marginal proportions of the table. Iterative computation of the polychoric correlation stops when the convergence measure falls below the convergence criterion or when the maximum number of iterations is reached, whichever occurs first. For parameter values that are less than 0.01, the procedure evaluates convergence by using the absolute difference instead of the relative difference. The PLCORR(CONVERGE=) option specifies the convergence criterion, which is 0.0001 by default. The PLCORR(MAXITER=) option specifies the maximum number of iterations, which is 20 by default.

If you specify the CL option in the TABLES statement, PROC FREQTAB provides confidence limits for the polychoric correlation. The confidence limits are computed as

$$\hat{\rho} \pm (z_{\alpha/2} \times \mathrm{se}(\hat{\rho}))$$

where $\hat{\rho}$ is the estimate of the polychoric correlation, $z_{\alpha/2}$ is the $100(1-\alpha/2)$th percentile of the standard normal distribution, and $\mathrm{se}(\hat{\rho})$ is the standard error of the polychoric correlation estimate.

If you specify the PLCORR option in the TEST statement, PROC FREQTAB provides Wald and likelihood ratio tests of the null hypothesis that the polychoric correlation is 0. The Wald test statistic is computed as

$$z = \hat{\rho} \,/\, \mathrm{se}(\hat{\rho})$$

which has a standard normal distribution under the null hypothesis. PROC FREQTAB computes one-sided and two-sided p-values for the Wald test. When the test statistic z is greater than its null expected value of 0, PROC FREQTAB displays the right-sided p-value. When the test statistic is less than or equal to 0, PROC FREQTAB displays the left-sided p-value.

The likelihood ratio statistic for the polychoric correlation is computed as

$$G^2 = -2 \log(L_0/L_1)$$

where L_0 is the value of the likelihood function (Olsson 1979) when the polychoric correlation is 0, and L_1 is the value of the likelihood function at the maximum (where all parameters are replaced with their maximum likelihood estimates). Under the null hypothesis, the likelihood ratio statistic has an asymptotic chi-square distribution with 1 degree of freedom.

Lambda (Asymmetric)

Asymmetric lambda, $\lambda(C|R)$, is interpreted as the probable improvement in predicting the column variable Y given knowledge of the row variable X. The range of asymmetric lambda is $0 \leq \lambda(C|R) \leq 1$. Asymmetric lambda $(C|R)$ is computed as

$$\lambda(C|R) = \frac{\sum_i r_i - r}{n - r}$$

and its asymptotic variance is

$$\mathrm{Var}(\lambda(C|R)) = \frac{n - \sum_i r_i}{(n-r)^3} \left(\sum_i r_i + r - 2 \sum_i (r_i \mid l_i = l) \right)$$

where

$$\begin{aligned} r_i &= \max_j(n_{ij}) \\ r &= \max_j(n_{\cdot j}) \\ c_j &= \max_i(n_{ij}) \\ c &= \max_i(n_{i\cdot}) \end{aligned}$$

The values of l_i and l are determined as follows. Denote by l_i the unique value of j such that $r_i = n_{ij}$, and let l be the unique value of j such that $r = n_{\cdot j}$. Because of the uniqueness assumptions, ties in the frequencies or in the marginal totals must be broken in an arbitrary but consistent manner. In case of ties, l is defined as the smallest value of j such that $r = n_{\cdot j}$.

For those columns containing a cell (i, j) for which $n_{ij} = r_i = c_j$, cs_j records the row in which c_j is assumed to occur. Initially cs_j is set equal to –1 for all j. Beginning with i=1, if there is at least one value j such that $n_{ij} = r_i = c_j$, and if $cs_j = -1$, l_i is defined to be the smallest such value of j, and cs_j is set equal to i. Otherwise, if $n_{il} = r_i$, l_i is defined to be equal to l. If neither condition is true, l_i is taken to be the smallest value of j such that $n_{ij} = r_i$.

The formulas for lambda asymmetric $(R|C)$ can be obtained by interchanging the indices.

For more information, see Goodman and Kruskal (1979).

Lambda (Symmetric)

The nondirectional lambda is the average of the two asymmetric lambdas, $\lambda(C|R)$ and $\lambda(R|C)$. Its range is $0 \leq \lambda \leq 1$. Lambda symmetric is computed as

$$\lambda = \frac{\sum_i r_i + \sum_j c_j - r - c}{2n - r - c} = \frac{w - v}{w}$$

and its asymptotic variance is computed as

$$\mathrm{Var}(\lambda) = \frac{1}{w^4}\Big(wvy - 2w^2\big(n - \sum_i \sum_j (n_{ij} \mid j = l_i, i = k_j)\big) - 2v^2(n - n_{kl})\Big)$$

where

$$\begin{aligned}
r_i &= \max_j(n_{ij}) \\
r &= \max_j(n_{\cdot j}) \\
c_j &= \max_i(n_{ij}) \\
c &= \max_i(n_{i\cdot}) \\
w &= 2n - r - c \\
v &= 2n - \sum_i r_i - \sum_j c_j \\
x &= \sum_i (r_i \mid l_i = l) + \sum_j (c_j \mid k_j = k) + r_k + c_l \\
y &= 8n - w - v - 2x
\end{aligned}$$

The definitions of l_i and l are given in the previous section. The values k_j and k are defined in a similar way for lambda asymmetric $(R|C)$.

For more information, see Goodman and Kruskal (1979).

Uncertainty Coefficients (Asymmetric)

The uncertainty coefficient $U(C|R)$ measures the proportion of uncertainty (entropy) in the column variable Y that is explained by the row variable X. Its range is $0 \leq U(C|R) \leq 1$. The uncertainty coefficient is computed as

$$U(C|R) = (H(X) + H(Y) - H(XY)) \;/\; H(Y) = v/w$$

and its asymptotic variance is

$$\mathrm{Var}(U(C|R)) = \frac{1}{n^2 w^4} \sum_i \sum_j n_{ij}\Big(H(Y)\log\Big(\frac{n_{ij}}{n_{i\cdot}}\Big) + (H(X) - H(XY))\log\Big(\frac{n_{\cdot j}}{n}\Big)\Big)^2$$

where

$$\begin{aligned} v &= H(X) + H(Y) - H(XY) \\ w &= H(Y) \\ H(X) &= -\sum_i \left(\frac{n_{i\cdot}}{n}\right) \log\left(\frac{n_{i\cdot}}{n}\right) \\ H(Y) &= -\sum_j \left(\frac{n_{\cdot j}}{n}\right) \log\left(\frac{n_{\cdot j}}{n}\right) \\ H(XY) &= -\sum_i \sum_j \left(\frac{n_{ij}}{n}\right) \ln\left(\frac{n_{ij}}{n}\right) \end{aligned}$$

The formulas for the uncertainty coefficient $U(R|C)$ can be obtained by interchanging the indices.

For more information, see Theil (1972, pp. 115–120) and Goodman and Kruskal (1979).

Uncertainty Coefficient (Symmetric)

The uncertainty coefficient U is the symmetric version of the two asymmetric uncertainty coefficients. Its range is $0 \leq U \leq 1$. The uncertainty coefficient is computed as

$$U = 2\left(H(X) + H(Y) - H(XY)\right) \;/\; \left(H(X) + H(Y)\right)$$

and its asymptotic variance is

$$\mathrm{Var}(U) = 4 \sum_i \sum_j \frac{n_{ij}\left(H(XY)\log\left(\frac{n_{i\cdot}n_{\cdot j}}{n^2}\right) - \left(H(X)+H(Y)\right)\log\left(\frac{n_{ij}}{n}\right)\right)^2}{n^2\left(H(X)+H(Y)\right)^4}$$

where $H(X)$, $H(Y)$, and $H(XY)$ are defined in the previous section. For more information, see Goodman and Kruskal (1979).

Binomial Proportion

If you specify the BINOMIAL option in the TABLES statement, PROC FREQTAB computes the binomial proportion for one-way tables. By default, this is the proportion of observations in the first variable level that appears in the output. (You can use the LEVEL= option to specify a different level for the proportion.) The binomial proportion is computed as

$$\hat{p} = n_1 \;/\; n$$

where n_1 is the frequency of the first (or designated) level and n is the total frequency of the one-way table. The standard error of the binomial proportion is computed as

$$\mathrm{se}(\hat{p}) = \sqrt{\hat{p}\;(1-\hat{p}) \;/\; n}$$

Binomial Confidence Limits

PROC FREQTAB provides Wald and exact (Clopper-Pearson) confidence limits for the binomial proportion. You can also request the following binomial confidence limit types by specifying the BINOMIAL(CL=) option: Agresti-Coull, Blaker, Jeffreys, exact mid-p, likelihood ratio, logit, and Wilson (score). For more information, see Brown, Cai, and DasGupta (2001), Agresti and Coull (1998), and Newcombe (1998b), in addition to the references cited for each confidence limit type.

Wald Confidence Limits Wald asymptotic confidence limits are based on the normal approximation to the binomial distribution. PROC FREQTAB computes the Wald confidence limits for the binomial proportion as

$$\hat{p} \pm (z_{\alpha/2} \times \mathrm{se}(\hat{p}))$$

where $z_{\alpha/2}$ is the $100(1-\alpha/2)$th percentile of the standard normal distribution. The confidence level α is determined by the ALPHA= option; by default, ALPHA=0.05, which produces 95% confidence limits.

If you specify CL=WALD(CORRECT) or the CORRECT *binomial-option*, PROC FREQTAB includes a continuity correction of $1/2n$ in the Wald asymptotic confidence limits. The purpose of this correction is to adjust for the difference between the normal approximation and the discrete binomial distribution. See Fleiss, Levin, and Paik (2003) for more information. The continuity-corrected Wald confidence limits for the binomial proportion are computed as

$$\hat{p} \pm (z_{\alpha/2} \times \mathrm{se}(\hat{p}) + (1/2n))$$

Exact (Clopper-Pearson) Confidence Limits Exact (Clopper-Pearson) confidence limits for the binomial proportion are constructed by inverting the equal-tailed test based on the binomial distribution. This method is attributed to Clopper and Pearson (1934). The exact confidence limits P_L and P_U satisfy the following equations, for $n_1 = 1, 2, \ldots n-1$:

$$\sum_{x=n_1}^{n} \binom{n}{x} P_L{}^x (1-P_L)^{n-x} = \alpha/2$$

$$\sum_{x=0}^{n_1} \binom{n}{x} P_U{}^x (1-P_U)^{n-x} = \alpha/2$$

The lower confidence limit is 0 when $n_1 = 0$, and the upper confidence limit is 1 when $n_1 = n$.

PROC FREQTAB computes the exact (Clopper-Pearson) confidence limits by using the F distribution as

$$P_L = \left(1 + \frac{n - n_1 + 1}{n_1 \, F(\, \alpha/2,\, 2n_1,\, 2(n-n_1+1)\,)} \right)^{-1}$$

$$P_U = \left(1 + \frac{n - n_1}{(n_1+1) \, F(\, 1-\alpha/2,\, 2(n_1+1),\, 2(n-n_1)\,)} \right)^{-1}$$

where $F(\alpha/2, b, c)$ is the $(\alpha/2)$th percentile of the F distribution with b and c degrees of freedom. See Leemis and Trivedi (1996) for a derivation of this expression. Also see Collett (1991) for more information about exact binomial confidence limits.

Because this is a discrete problem, the confidence coefficient (coverage probability) of the exact (Clopper-Pearson) interval is not exactly $(1-\alpha)$ but is at least $(1-\alpha)$. Thus, this confidence interval is conservative. Unless the sample size is large, the actual coverage probability can be much larger than the target value. For more information about the performance of these confidence limits, see Agresti and Coull (1998), Brown, Cai, and DasGupta (2001), and Leemis and Trivedi (1996).

Agresti-Coull Confidence Limits If you specify the CL=AGRESTICOULL *binomial-option*, PROC FREQTAB computes Agresti-Coull confidence limits for the binomial proportion as

$$\tilde{p} \pm (z_{\alpha/2} \times \sqrt{\tilde{p}\,(1-\tilde{p})\,/\,\tilde{n}})$$

where

$$\begin{aligned} \tilde{n}_1 &= n_1 + z^2_{\alpha/2}/2 \\ \tilde{n} &= n + z^2_{\alpha/2} \\ \tilde{p} &= \tilde{n}_1\,/\,\tilde{n} \end{aligned}$$

The Agresti-Coull confidence interval has the same general form as the standard Wald interval but uses $\tilde{p}$ in place of $\hat{p}$. For $\alpha = 0.05$, the value of $z_{\alpha/2}$ is close to 2, and this interval is the "add 2 successes and 2 failures" adjusted Wald interval of Agresti and Coull (1998).

Blaker Confidence Limits If you specify the CL=BLAKER *binomial-option*, PROC FREQTAB computes Blaker confidence limits for the binomial proportion, which are constructed by inverting the two-sided exact Blaker test (Blaker 2000). The $100(1-\alpha)\%$ Blaker confidence interval consists of all values of the proportion p_0 for which the test statistic $B(p_0, n_1)$ falls in the acceptance region,

$$\{p_0 : B(p_0, n_1) > \alpha\}$$

where

$$B(p_0, n_1) = \text{Prob}(\, \gamma(p_0, X) \le \gamma(p_0, n_1) \mid p_0 \,)$$

$$\gamma(p_0, n_1) = \min(\, \text{Prob}(\, X \ge n_1 \mid p_0 \,),\ \text{Prob}(\, X \le n_1 \mid p_0 \,) \,)$$

and X is a binomial random variable. For more information, see Blaker (2000).

Jeffreys Confidence Limits If you specify the CL=JEFFREYS *binomial-option*, PROC FREQTAB computes Jeffreys confidence limits for the binomial proportion as

$$\big(\, \beta(\alpha/2,\ n_1 + 1/2,\ n - n_1 + 1/2),\ \ \beta(1-\alpha/2,\ n_1 + 1/2,\ n - n_1 + 1/2) \,\big)$$

where $\beta(\alpha, b, c)$ is the αth percentile of the beta distribution with shape parameters b and c. The lower confidence limit is set to 0 when $n_1 = 0$, and the upper confidence limit is set to 1 when $n_1 = n$. This is an equal-tailed interval based on the noninformative Jeffreys prior for a binomial proportion. For more information, see Brown, Cai, and DasGupta (2001). For information about using beta priors for inference on the binomial proportion, see Berger (1985).

When you specify CL=JEFFREYS(MODIFY), the procedure provides modified Jeffreys confidence limits (Brown, Cai, and DasGupta 2001, p. 113) to improve the coverage of the confidence limits for proportions near 0 or 1. When $n_1 = 0$, the modified version replaces the upper confidence limit with $p_l = 1 - (\alpha/2)^{1/n}$. When $n_1 = n$, the modified version replaces the lower confidence limit with $1 - p_l$. The modified version also sets the lower confidence limit to 0 when $n_1 = 1$ and sets the upper confidence limit to 1 when $n_1 = n - 1$. Otherwise (when $1 < n_1 < n - 1$), the Jeffreys confidence limits are not modified.

Likelihood Ratio Confidence Limits If you specify the CL=LIKELIHOODRATIO *binomial-option*, PROC FREQTAB computes likelihood ratio confidence limits for the binomial proportion by inverting the likelihood ratio test. The likelihood ratio test statistic for the null hypothesis that the proportion equals p_0 can be expressed as

$$L(p_0) \;=\; -2\,(n_1 \log(\hat{p}/p_0) \;+\; (n-n_1)\log((1-\hat{p})/(1-p_0)))$$

The $100(1-\alpha)\%$ likelihood ratio confidence interval consists of all values of p_0 for which the test statistic $L(p_0)$ falls in the acceptance region,

$$\{p_0 : L(p_0) < \chi^2_{1,\alpha}\}$$

where $\chi^2_{1,\alpha}$ is the $100(1-\alpha)$th percentile of the chi-square distribution with 1 degree of freedom. PROC FREQTAB finds the confidence limits by iterative computation. For more information, see Fleiss, Levin, and Paik (2003), Brown, Cai, and DasGupta (2001), Agresti (2013), and Newcombe (1998b).

Logit Confidence Limits If you specify the CL=LOGIT *binomial-option*, PROC FREQTAB computes logit confidence limits for the binomial proportion, which are based on the logit transformation $Y = \log(\hat{p}/(1-\hat{p}))$. Approximate confidence limits for Y are computed as

$$Y_L \;=\; \log(\hat{p}/(1-\hat{p})) \;-\; z_{\alpha/2}\sqrt{n/(n_1(n-n_1))}$$

$$Y_U \;=\; \log(\hat{p}/(1-\hat{p})) \;+\; z_{\alpha/2}\sqrt{n/(n_1(n-n_1))}$$

The confidence limits for Y are inverted to produce $100(1-\alpha)\%$ logit confidence limits P_L and P_U for the binomial proportion p as

$$P_L \;=\; \exp(Y_L/(1+\exp(Y_L))$$

$$P_U \;=\; \exp(Y_U/(1+\exp(Y_U))$$

For more information, see Brown, Cai, and DasGupta (2001) and Korn and Graubard (1998).

Mid-*p* Confidence Limits If you specify the CL=MIDP *binomial-option*, PROC FREQTAB computes exact mid-p confidence limits for the binomial proportion by inverting two one-sided binomial tests that include mid-p tail areas. The mid-p approach replaces the probability of the observed frequency with half of that probability in the Clopper-Pearson sum, which is described in the section "Exact (Clopper-Pearson) Confidence Limits" on page 492. The exact mid-p confidence limits P_L and P_U are the solutions to the equations

$$\sum_{x=n_1+1}^{n}\binom{n}{x}P_L^{\,x}(1-P_L)^{\,n-x} \;+\; \frac{1}{2}\binom{n}{n_1}P_L^{\,n_1}(1-P_L)^{\,n-n_1} \;=\; \alpha/2$$

$$\sum_{x=0}^{n_1-1}\binom{n}{x}P_U^{\,x}(1-P_U)^{\,n-x} \;+\; \frac{1}{2}\binom{n}{n_1}P_U^{\,n_1}(1-P_U)^{\,n-n_1} \;=\; \alpha/2$$

For more information, see Agresti and Gottard (2007), Agresti (2013), Newcombe (1998b), and Brown, Cai, and DasGupta (2001).

Wilson (Score) Confidence Limits If you specify the CL=WILSON *binomial-option*, PROC FREQTAB computes Wilson confidence limits for the binomial proportion. These are also known as score confidence limits (Wilson 1927). The confidence limits are based on inverting the normal test that uses the null proportion in the variance (the score test). Wilson confidence limits are the roots of

$$|p - \hat{p}| = z_{\alpha/2}\sqrt{p(1-p)/n}$$

and are computed as

$$\left(\hat{p} + z^2_{\alpha/2}/2n \pm z_{\alpha/2}\sqrt{\left(\hat{p}(1-\hat{p}) + z^2_{\alpha/2}/4n\right)/n}\right) / \left(1 + z^2_{\alpha/2}/n\right)$$

When you specify CL=WILSON(CORRECT) or the CORRECT *binomial-option*, PROC FREQTAB provides continuity-corrected Wilson confidence limits, which are computed as the roots of

$$|p - \hat{p}| - 1/2n = z_{\alpha/2}\sqrt{p(1-p)/n}$$

The Wilson interval has been shown to have better performance than the Wald interval and the exact (Clopper-Pearson) interval. For more information, see Agresti and Coull (1998), Brown, Cai, and DasGupta (2001), and Newcombe (1998b).

When you specify CL=WILSON(ADAPT), PROC FREQTAB provides adapted Wilson confidence limits (Agresti and Coull 1998, p. 125) to improve the coverage of the confidence limits for proportions near 0 or 1. When $n_1 = 1$, the adapted version replaces the lower confidence limit with $(-\log(1-\alpha)/n)$. When $n_1 = (n-1)$, the adapted version replaces the upper confidence limit with $(1 + \log(1-\alpha)/n)$.

When you specify CL=WILSON(MODIFY), PROC FREQTAB provides modified Wilson confidence limits (Brown, Cai, and DasGupta 2001, pp. 112–113) to improve the coverage of the confidence limits for proportions near 0 or 1. The modified version replaces the lower confidence limit when $n_1 = 1, \ldots, n_1^*$, where $n_1^* = 2$ for $n \leq 50$ and $n_1^* = 3$ otherwise. The modified lower confidence limit is computed as $\chi^2(2n_1, \alpha)/2n$, where $\chi^2(2n_1, \alpha)$ is the 100αth percentile of the chi-square distribution with $2n_1$ degrees of freedom. Similarly, the modified version replaces the upper confidence limit when $n_1 = n - n_1^*, \ldots, n-1$. The modified upper confidence limit is computed as $1 - \chi^2(2(n-n_1), \alpha)/2n$.

Binomial Tests

The BINOMIAL option provides an asymptotic equality test for the binomial proportion by default. You can also specify *binomial-options* to request tests of noninferiority, superiority, and equivalence for the binomial proportion. If you specify the BINOMIAL option in the EXACT statement, PROC FREQTAB also computes exact p-values for the tests that you request with the *binomial-options*.

Equality Test PROC FREQTAB computes an asymptotic test of the hypothesis that the binomial proportion equals p_0, where you can specify the value of p_0 with the P= *binomial-option*. If you do not specify a null value with P=, PROC FREQTAB uses $p_0 = 0.5$ by default. The binomial test statistic is computed as

$$z = (\hat{p} - p_0)/\text{se}$$

By default, the standard error is based on the null hypothesis proportion as

$$\text{se} = \sqrt{p_0(1-p_0)/n}$$

If you specify the VAR=SAMPLE *binomial-option*, the standard error is computed from the sample proportion as

$$\text{se} = \sqrt{\hat{p}(1-\hat{p})/n}$$

If you specify the CORRECT *binomial-option*, PROC FREQTAB includes a continuity correction in the asymptotic test statistic, towards adjusting for the difference between the normal approximation and the discrete binomial distribution. For more information, see Fleiss, Levin, and Paik (2003). The continuity correction of $(1/2n)$ is subtracted from the numerator of the test statistic if $(\hat{p} - p_0)$ is positive; otherwise, the continuity correction is added to the numerator.

PROC FREQTAB computes one-sided and two-sided p-values for this test. When the test statistic z is greater than 0 (its expected value under the null hypothesis), PROC FREQTAB computes the right-sided p-value, which is the probability of a larger value of the statistic occurring under the null hypothesis. A small right-sided p-value supports the alternative hypothesis that the true value of the proportion is greater than p_0. When the test statistic is less than or equal to 0, PROC FREQTAB computes the left-sided p-value, which is the probability of a smaller value of the statistic occurring under the null hypothesis. A small left-sided p-value supports the alternative hypothesis that the true value of the proportion is less than p_0. The one-sided p-value P_1 can be expressed as

$$P_1 = \begin{cases} \text{Prob}(Z > z) & \text{if } z > 0 \\ \text{Prob}(Z < z) & \text{if } z \leq 0 \end{cases}$$

where Z has a standard normal distribution. The two-sided p-value is computed as $P_2 = 2 \times P_1$.

If you specify the BINOMIAL option in the EXACT statement, PROC FREQTAB also computes an exact test of the null hypothesis H_0: $p = p_0$. To compute the exact test, PROC FREQTAB uses the binomial probability function,

$$\text{Prob}(X = x \mid p_0) = \binom{n}{x} {p_0}^x \, (1-p_0)^{(n-x)} \quad \text{for } x = 0, 1, 2, \ldots, n$$

where the variable X has a binomial distribution with parameters n and p_0. To compute the left-sided p-value, $\text{Prob}(X \leq n_1)$, PROC FREQTAB sums the binomial probabilities over x from 0 to n_1. To compute the right-sided p-value, $\text{Prob}(X \geq n_1)$, PROC FREQTAB sums the binomial probabilities over x from n_1 to n. The exact one-sided p-value is the minimum of the left-sided and right-sided p-values,

$$P_1 = \min\left(\text{Prob}(X \leq n_1 \mid p_0),\ \text{Prob}(X \geq n_1 \mid p_0) \right)$$

and the exact two-sided p-value is computed as $P_2 = 2 \times P_1$.

Noninferiority Test If you specify the NONINF *binomial-option*, PROC FREQTAB provides a noninferiority test for the binomial proportion. The null hypothesis for the noninferiority test is

$$H_0: p - p_0 \leq -\delta$$

versus the alternative

$$H_a: p - p_0 > -\delta$$

where δ is the noninferiority margin and p_0 is the null proportion. Rejection of the null hypothesis indicates that the binomial proportion is not inferior to the null value. See Chow, Shao, and Wang (2003) for more information.

You can specify the value of δ with the MARGIN= *binomial-option*, and you can specify p_0 with the P= *binomial-option*. By default, $\delta = 0.2$ and $p_0 = 0.5$.

PROC FREQTAB provides an asymptotic Wald test for noninferiority. The test statistic is computed as

$$z = (\hat{p} - p_0^*) \,/\, \mathrm{se}$$

where p_0^* is the noninferiority limit,

$$p_0^* = p_0 - \delta$$

By default, the standard error is computed from the sample proportion as

$$\mathrm{se} = \sqrt{\hat{p}(1-\hat{p})/n}$$

If you specify the VAR=NULL *binomial-option*, the standard error is based on the noninferiority limit (determined by the null proportion and the margin) as

$$\mathrm{se} = \sqrt{p_0^*(1-p_0^*)/n}$$

If you specify the CORRECT *binomial-option*, PROC FREQTAB includes a continuity correction in the asymptotic test statistic z. The continuity correction of $(1/2n)$ is subtracted from the numerator of the test statistic if $(\hat{p} - p_0^*)$ is positive; otherwise, the continuity correction is added to the numerator.

The p-value for the noninferiority test is

$$P_z = \mathrm{Prob}(Z > z)$$

where Z has a standard normal distribution.

As part of the noninferiority analysis, PROC FREQTAB provides asymptotic Wald confidence limits for the binomial proportion. These confidence limits are computed as described in the section "Wald Confidence Limits" on page 492 but use the same standard error (VAR=NULL or VAR=SAMPLE) as the noninferiority test statistic z. The confidence coefficient is $100(1-2\alpha)\%$ (Schuirmann 1999). By default, if you do not specify the ALPHA= option, the noninferiority confidence limits are 90% confidence limits. You can compare the confidence limits to the noninferiority limit, $p_0^* = p_0 - \delta$.

If you specify the BINOMIAL option in the EXACT statement, PROC FREQTAB provides an exact noninferiority test for the binomial proportion. The exact p-value is computed by using the binomial probability function with parameters p_0^* and n,

$$P_x = \sum_{k=n_1}^{k=n} \binom{n}{k} (p_0^*)^{\,k}\, (1-p_0^*)^{\,(n-k)}$$

For more information, see Chow, Shao, and Wang (2003, p. 116). If you request exact binomial statistics, PROC FREQTAB also includes exact (Clopper-Pearson) confidence limits for the binomial proportion in the equivalence analysis display. For more information, see the section "Exact (Clopper-Pearson) Confidence Limits" on page 492.

Superiority Test If you specify the SUP *binomial-option*, PROC FREQTAB provides a superiority test for the binomial proportion. The null hypothesis for the superiority test is

$$H_0: p - p_0 \leq \delta$$

versus the alternative

$$H_a: p - p_0 > \delta$$

where δ is the superiority margin and p_0 is the null proportion. Rejection of the null hypothesis indicates that the binomial proportion is superior to the null value. You can specify the value of δ with the MARGIN= *binomial-option*, and you can specify the value of p_0 with the P= *binomial-option*. By default, $\delta = 0.2$ and $p_0 = 0.5$.

The superiority analysis is identical to the noninferiority analysis but uses a positive value of the margin δ in the null hypothesis. The superiority limit equals $p_0 + \delta$. The superiority computations follow those in the section "Noninferiority Test" on page 496 but replace $-\delta$ with δ. See Chow, Shao, and Wang (2003) for more information.

Equivalence Test If you specify the EQUIV *binomial-option*, PROC FREQTAB provides an equivalence test for the binomial proportion. The null hypothesis for the equivalence test is

$$H_0: p - p_0 \leq \delta_L \quad \text{or} \quad p - p_0 \geq \delta_U$$

versus the alternative

$$H_a: \delta_L < p - p_0 < \delta_U$$

where δ_L is the lower margin, δ_U is the upper margin, and p_0 is the null proportion. Rejection of the null hypothesis indicates that the binomial proportion is equivalent to the null value. See Chow, Shao, and Wang (2003) for more information.

You can specify the value of the margins δ_L and δ_U with the MARGIN= *binomial-option*. If you do not specify MARGIN=, PROC FREQTAB uses lower and upper margins of –0.2 and 0.2 by default. If you specify a single margin value δ, PROC FREQTAB uses lower and upper margins of $-\delta$ and δ. You can specify the null proportion p_0 with the P= *binomial-option*. By default, $p_0 = 0.5$.

PROC FREQTAB computes two one-sided tests (TOST) for equivalence analysis (Schuirmann 1987). The TOST approach includes a right-sided test for the lower margin and a left-sided test for the upper margin. The overall p-value is taken to be the larger of the two p-values from the lower and upper tests.

For the lower margin, the asymptotic Wald test statistic is computed as

$$z_L = (\hat{p} - p_L^*) \,/\, \text{se}$$

where the lower equivalence limit is

$$p_L^* = p_0 + \delta_L$$

By default, the standard error is computed from the sample proportion as

$$\text{se} = \sqrt{\hat{p}(1-\hat{p})/n}$$

If you specify the VAR=NULL *binomial-option*, the standard error is based on the lower equivalence limit (determined by the null proportion and the lower margin) as

$$\text{se} = \sqrt{p_L^*(1 - p_L^*)/n}$$

If you specify the CORRECT *binomial-option*, PROC FREQTAB includes a continuity correction in the asymptotic test statistic z_L. The continuity correction of $(1/2n)$ is subtracted from the numerator of the test statistic $(\hat{p} - p_L^*)$ if the numerator is positive; otherwise, the continuity correction is added to the numerator.

The p-value for the lower margin test is

$$P_{z,L} = \text{Prob}(Z > z_L)$$

The asymptotic test for the upper margin is computed similarly. The Wald test statistic is

$$z_U = (\hat{p} - p_U^*) \,/\, \text{se}$$

where the upper equivalence limit is

$$p_U^* = p_0 + \delta_U$$

By default, the standard error is computed from the sample proportion. If you specify the VAR=NULL *binomial-option*, the standard error is based on the upper equivalence limit as

$$\text{se} = \sqrt{p_U^*(1 - p_U^*)/n}$$

If you specify the CORRECT *binomial-option*, PROC FREQTAB includes a continuity correction of $(1/2n)$ in the asymptotic test statistic z_U.

The p-value for the upper margin test is

$$P_{z,U} = \text{Prob}(Z < z_U)$$

Based on the two one-sided tests (TOST), the overall p-value for the test of equivalence equals the larger p-value from the lower and upper margin tests, which can be expressed as

$$P_z = \max(P_{z,L}\,,\ P_{z,U})$$

As part of the equivalence analysis, PROC FREQTAB provides asymptotic Wald confidence limits for the binomial proportion. These confidence limits are computed as described in the section "Wald Confidence Limits" on page 492, but use the same standard error (VAR=NULL or VAR=SAMPLE) as the equivalence test statistics and have a confidence coefficient of $100(1 - 2\alpha)\%$ (Schuirmann 1999). By default, if you do not specify the ALPHA= option, the equivalence confidence limits are 90% limits. If you specify VAR=NULL, separate standard errors are computed for the lower and upper margin tests, each based on the null proportion and the corresponding (lower or upper) margin. The confidence limits are computed by using the maximum of these two standard errors. You can compare the confidence limits to the equivalence limits, $(p_0 + \delta_L,\ p_0 + \delta_U)$.

If you specify the BINOMIAL option in the EXACT statement, PROC FREQTAB also provides an exact equivalence test by using two one-sided exact tests (TOST). The procedure computes lower and upper margin exact tests by using the binomial probability function as described in the section "Noninferiority Test" on page 496. The overall exact p-value for the equivalence test is taken to be the larger p-value from the lower and upper margin exact tests. If you request exact statistics, PROC FREQTAB also includes exact (Clopper-Pearson) confidence limits in the equivalence analysis display. The confidence coefficient is $100(1 - 2\alpha)\%$ (Schuirmann 1999). For more information, see the section "Exact (Clopper-Pearson) Confidence Limits" on page 492.

Sensitivity and Specificity

The SENSPEC option in the TABLES statement provides estimates of sensitivity, specificity, positive predictive value, and negative predictive value for 2×2 tables. These measures are conditional (row and column) proportions in the 2×2 crosstabulation table. In sensitivity analysis, the row variable might represent a positive or negative diagnostic test result, and the column variable might represent the presence or absence of a condition. For more information, see Fleiss, Levin, and Paik (2003). The SENSPEC option also provides an estimate of accuracy, which is the proportion of correct classifications.

By default, the SENSPEC computations use table cell (1,1) as the reference cell that represents the true positives (positive row value and positive column value). You can specify a different reference cell by using the SENSPEC REFCELL= suboption or the REFCOLUMN= and REFROW= suboptions. For example, REFCELL=4 specifies table cell (2,2) as the true-positive cell (and row 2 and column 2 as the positive row and column levels, respectively). The notation in this section assumes that table cell (1,1) is the reference cell.

Sensitivity is computed as the column proportion for table cell (1,1), which is the ratio of the frequency in table cell (1,1) to the total frequency in column 1 of the 2×2 table. Sensitivity is denoted by

$$\mathrm{SN} = n_{11} \,/\, n_{\cdot 1}$$

Specificity is computed as the column proportion for table cell (2,2), which is the ratio of the frequency in table cell (2,2) to the total frequency in column 2. Specificity is denoted by

$$\mathrm{SP} = n_{22} \,/\, n_{\cdot 2}$$

The positive predictive value is the row proportion for table cell (1,1), which is computed as

$$\mathrm{PPV} = n_{11} \,/\, n_{1\cdot}$$

The negative predictive value is the row proportion for table cell (2,2), which is computed as

$$\mathrm{NPV} = n_{22} \,/\, n_{2\cdot}$$

Accuracy (correct classification rate) is the overall proportion in table cells (1,1) and (2,2), which is computed as

$$\mathrm{A} = (n_{11} + n_{22}) \,/\, n$$

The "Sensitivity and Specificity" table provides the estimates together with their standard errors and Wald confidence limits. PROC FREQTAB computes the standard errors and Wald confidence limits for these proportions as described in the section "Risks and Risk Differences" on page 501. The value of the confidence coefficient α is determined by the ALPHA= option; by default, ALPHA=0.05, which produces 95% confidence limits.

Risks and Risk Differences

The RISKDIFF option in the TABLES statement provides estimates of risks (binomial proportions) and risk differences for 2×2 tables. This analysis might be appropriate when comparing the proportion of some characteristic for two groups, where row 1 and row 2 correspond to the two groups, and the columns correspond to two possible characteristics or outcomes. For example, the row variable might be a treatment or dose, and the column variable might be the response. For more information, see Collett (1991); Fleiss, Levin, and Paik (2003); Stokes, Davis, and Koch (2012).

Let the frequencies of the 2×2 table be represented as follows:

	Column 1	Column 2	Total
Row 1	n_{11}	n_{12}	$n_{1\cdot}$
Row 2	n_{21}	n_{22}	$n_{2\cdot}$
Total	$n_{\cdot 1}$	$n_{\cdot 2}$	n

By default when you specify the RISKDIFF option, PROC FREQTAB provides estimates of the row 1 risk (proportion), the row 2 risk, the overall risk, and the risk difference for column 1 and for column 2 of the 2×2 table. The risk difference is defined as the row 1 risk minus the row 2 risk. The risks are binomial proportions of their rows (row 1, row 2, or overall), and the computation of their standard errors and Wald confidence limits follow the binomial proportion computations, which are described in the section "Binomial Proportion" on page 491.

The column 1 risk for row 1 is the proportion of row 1 observations classified in column 1,

$$\hat{p}_1 = n_{11} \,/\, n_{1\cdot}$$

which estimates the conditional probability of the column 1 response, given the first level of the row variable. The column 1 risk for row 2 is the proportion of row 2 observations classified in column 1,

$$\hat{p}_2 = n_{21} \,/\, n_{2\cdot}$$

The overall column 1 risk is the proportion of all observations classified in column 1,

$$\hat{p} = n_{\cdot 1} \,/\, n$$

The column 1 risk difference compares the risks for the two rows, and it is computed as the column 1 risk for row 1 minus the column 1 risk for row 2,

$$\hat{d} = \hat{p}_1 - \hat{p}_2$$

The standard error of the column 1 risk for row i is computed as

$$\mathrm{se}(\hat{p}_i) = \sqrt{\hat{p}_i \,(1 - \hat{p}_i) \,/\, n_{i\cdot}}$$

The standard error of the overall column 1 risk is computed as

$$\mathrm{se}(\hat{p}) = \sqrt{\hat{p} \,(1 - \hat{p}) \,/\, n}$$

Where the two rows represent independent binomial samples, the standard error of the column 1 risk difference is computed as

$$\mathrm{se}(\hat{d}) = \sqrt{\hat{p}_1(1 - \hat{p}_1)/n_{1\cdot} \;+\; \hat{p}_2(1 - \hat{p}_2)/n_{2\cdot}}$$

The computations are similar for the column 2 risks and risk difference.

Confidence Limits

By default, the RISKDIFF option provides Wald asymptotic confidence limits for the risks (row 1, row 2, and overall) and the risk difference. By default, the RISKDIFF option also provides exact (Clopper-Pearson) confidence limits for the risks. You can suppress the display of this information by specifying the NORISKS *riskdiff-option*. You can specify *riskdiff-options* to request tests and other types of confidence limits for the risk difference. For more information, see the sections "Confidence Limits for the Risk Difference" on page 502 and "Risk Difference Tests" on page 506.

The risks are equivalent to the binomial proportions of their corresponding rows. This section describes the Wald confidence limits that are provided by default when you specify the RISKDIFF option. The BINOMIAL option provides additional confidence limit types and tests for risks (binomial proportions). For more information, see the sections "Binomial Confidence Limits" on page 492 and "Binomial Tests" on page 495.

The Wald confidence limits are based on the normal approximation to the binomial distribution. PROC FREQTAB computes the Wald confidence limits for the risks and risk differences as

$$\text{Est} \pm \left(z_{\alpha/2} \times \text{se}(\text{Est}) \right)$$

where Est is the estimate, $z_{\alpha/2}$ is the $100(1-\alpha/2)$th percentile of the standard normal distribution, and se(Est) is the standard error of the estimate. The confidence level α is determined by the value of the ALPHA= option; by default, ALPHA=0.05, which produces 95% confidence limits.

If you specify the CORRECT *riskdiff-option*, PROC FREQTAB includes continuity corrections in the Wald confidence limits for the risks and risk differences. The purpose of a continuity correction is to adjust for the difference between the normal approximation and the binomial distribution, which is discrete. See Fleiss, Levin, and Paik (2003) for more information. The continuity-corrected Wald confidence limits are computed as

$$\text{Est} \pm \left(z_{\alpha/2} \times \text{se}(\text{Est}) + c \right)$$

where c is the continuity correction. For the row 1 risk, $c = (1/2n_{1\cdot})$; for the row 2 risk, $c = (1/2n_{2\cdot})$; for the overall risk, $c = (1/2n)$; and for the risk difference, $c = ((1/n_{1\cdot} + 1/n_{2\cdot})/2)$. The column 1 and column 2 risks use the same continuity correction.

By default when you specify the RISKDIFF option, PROC FREQTAB also provides exact (Clopper-Pearson) confidence limits for the column 1, column 2, and overall risks. These confidence limits are constructed by inverting the equal-tailed test that is based on the binomial distribution. For more information, see the section "Exact (Clopper-Pearson) Confidence Limits" on page 492.

Confidence Limits for the Risk Difference PROC FREQTAB provides the following confidence limit types for the risk difference: Agresti-Caffo, exact unconditional, Hauck-Anderson, Miettinen-Nurminen (score), Newcombe (hybrid-score), and Wald confidence limits. Continuity-corrected forms of Newcombe and Wald confidence limits are also available.

The confidence coefficient for the confidence limits produced by the CL= *riskdiff-option* is $100(1-\alpha)\%$, where the value of α is determined by the ALPHA= option. By default, ALPHA=0.05, which produces 95% confidence limits. This differs from the test-based confidence limits that are provided with the equivalence, noninferiority, and superiority tests, which have a confidence coefficient of $100(1-2\alpha)\%$ (Schuirmann 1999). For more information, see the section "Risk Difference Tests" on page 506.

Agresti-Caffo Confidence Limits

Agresti-Caffo confidence limits for the risk difference are computed as

$$\tilde{d} \pm (z_{\alpha/2} \times \mathrm{se}(\tilde{d}))$$

where $\tilde{d} = \tilde{p}_1 - \tilde{p}_2$, $\tilde{p}_i = (n_{i1} + 1)/(n_{i\cdot} + 2)$,

$$\mathrm{se}(\tilde{d}) = \sqrt{\tilde{p}_1(1-\tilde{p}_2)/(n_{1\cdot}+2) + \tilde{p}_2(1-\tilde{p}_2)/(n_{2\cdot}+2)}$$

and $z_{\alpha/2}$ is the $100(1-\alpha/2)$th percentile of the standard normal distribution.

The Agresti-Caffo interval adjusts the Wald interval for the risk difference by adding a pseudo-observation of each type (success and failure) to each sample. See Agresti and Caffo (2000) and Agresti and Coull (1998) for more information.

Hauck-Anderson Confidence Limits

Hauck-Anderson confidence limits for the risk difference are computed as

$$\hat{d} \pm (c + z_{\alpha/2} \times \mathrm{se}(\hat{d}))$$

where $\hat{d} = \hat{p}_1 - \hat{p}_2$ and $z_{\alpha/2}$ is the $100(1-\alpha/2)$th percentile of the standard normal distribution. The standard error is computed from the sample proportions as

$$\mathrm{se}(\hat{d}) = \sqrt{\hat{p}_1(1-\hat{p}_1)/(n_{1\cdot}-1) + \hat{p}_2(1-\hat{p}_2)/(n_{2\cdot}-1)}$$

The Hauck-Anderson continuity correction c is computed as

$$c = 1 \,/\, \left(2 \min(n_{1\cdot}, n_{2\cdot})\right)$$

For more information, see Hauck and Anderson (1986).

The subsection "Hauck-Anderson Test" in the section "Noninferiority Tests" on page 507 describes the corresponding noninferiority test.

Miettinen-Nurminen (Score) Confidence Limits

Miettinen-Nurminen (score) confidence limits for the risk difference (Miettinen and Nurminen 1985) are computed by inverting score tests for the risk difference. A score-based test statistic for the null hypothesis that the risk difference equals δ can be expressed as

$$T(\delta) = (\hat{d} - \delta)/\sqrt{\widetilde{\mathrm{Var}}(\delta)}$$

where $\hat{d}$ is the observed value of the risk difference $(\hat{p}_1 - \hat{p}_2)$,

$$\widetilde{\mathrm{Var}}(\delta) = (n/(n-1)) \; (\tilde{p}_1(\delta)(1-\tilde{p}_1(\delta))/n_1 + \tilde{p}_2(\delta)(1-\tilde{p}_2(\delta))/n_2)$$

and $\tilde{p}_1(\delta)$ and $\tilde{p}_2(\delta)$ are the maximum likelihood estimates of the row 1 and row 2 risks (proportions) under the restriction that the risk difference is δ. For more information, see Miettinen and Nurminen (1985, pp. 215–216) and Miettinen (1985, chapter 12).

The $100(1-\alpha)\%$ confidence interval for the risk difference consists of all values of δ for which the score test statistic $T(\delta)$ falls in the acceptance region,

$$\{\delta : T(\delta) < z_{\alpha/2}\}$$

where $z_{\alpha/2}$ is the $100(1-\alpha/2)$th percentile of the standard normal distribution. PROC FREQTAB finds the confidence limits by iterative computation, which stops when the iteration increment falls below the convergence criterion or when the maximum number of iterations is reached, whichever occurs first. By default, the convergence criterion is 0.00000001 and the maximum number of iterations is 100.

By default, the Miettinen-Nurminen confidence limits include the bias correction factor $n/(n-1)$ in the computation of $\widetilde{\mathrm{Var}}(\delta)$ (Miettinen and Nurminen 1985, p. 216). For more information, see Newcombe and Nurminen (2011). If you specify the CL=MN(CORRECT=NO) *riskdiff-option*, PROC FREQTAB does not include the bias correction factor in this computation (Mee 1984). See also Agresti (2002, p. 77). The uncorrected confidence limits are labeled as "Miettinen-Nurminen-Mee" confidence limits in the displayed output.

The maximum likelihood estimates of p_1 and p_2, subject to the constraint that the risk difference is δ, are computed as

$$\tilde{p}_1 = 2u\cos(w) - b/3a \quad \text{and} \quad \tilde{p}_2 = \tilde{p}_1 - \delta$$

where

$$\begin{aligned}
w &= (\pi + \cos^{-1}(v/u^3))/3 \\
v &= b^3/(3a)^3 - bc/6a^2 + d/2a \\
u &= \mathrm{sign}(v)\sqrt{b^2/(3a)^2 - c/3a} \\
a &= 1+\theta \\
b &= -(1+\theta+\hat{p}_1+\theta\hat{p}_2+\delta(\theta+2)) \\
c &= \delta^2 + \delta(2\hat{p}_1+\theta+1) + \hat{p}_1 + \theta\hat{p}_2 \\
d &= -\hat{p}_1\delta(1+\delta) \\
\theta &= n_{2\cdot}/n_{1\cdot}
\end{aligned}$$

For more information, see Farrington and Manning (1990, p. 1453).

Newcombe Confidence Limits

Newcombe (hybrid-score) confidence limits for the risk difference are constructed from the Wilson score confidence limits for each of the two individual proportions. The confidence limits for the individual proportions are used in the standard error terms of the Wald confidence limits for the proportion difference. See Newcombe (1998a) and Barker et al. (2001) for more information.

Wilson score confidence limits for p_1 and p_2 are the roots of

$$|p_i - \hat{p}_i| = z_{\alpha/2}\sqrt{p_i(1-p_i)/n_{i\cdot}}$$

for $i = 1, 2$. The confidence limits are computed as

$$\left(\hat{p}_i + z^2_{\alpha/2}/2n_{i\cdot} \pm z_{\alpha/2}\sqrt{\left(\hat{p}_i(1-\hat{p}_i) + z^2_{\alpha/2}/4n_{i\cdot}\right)/n_{i\cdot}}\right) / \left(1 + z^2_{\alpha/2}/n_{i\cdot}\right)$$

For more information, see the section "Wilson (Score) Confidence Limits" on page 495.

Denote the lower and upper Wilson score confidence limits for p_1 as L_1 and U_1, and denote the lower and upper confidence limits for p_2 as L_2 and U_2. The Newcombe confidence limits for the proportion difference ($d = p_1 - p_2$) are computed as

$$d_L = (\hat{p}_1 - \hat{p}_2) - \sqrt{(\hat{p}_1 - L_1)^2 + (U_2 - \hat{p}_2)^2}$$

$$d_U = (\hat{p}_1 - \hat{p}_2) + \sqrt{(U_1 - \hat{p}_1)^2 + (\hat{p}_2 - L_2)^2}$$

If you specify the CORRECT *riskdiff-option*, PROC FREQTAB provides continuity-corrected Newcombe confidence limits. By including a continuity correction of $1/2n_{i\cdot}$, the Wilson score confidence limits for the individual proportions are computed as the roots of

$$|p_i - \hat{p}_i| - 1/2n_{i\cdot} = z_{\alpha/2}\sqrt{p_i(1-p_i)/n_{i\cdot}}$$

The continuity-corrected confidence limits for the individual proportions are then used to compute the proportion difference confidence limits d_L and d_U.

Wald Confidence Limits

Wald confidence limits for the risk difference are computed as

$$\hat{d} \pm (z_{\alpha/2} \times \mathrm{se}(\hat{d}))$$

where $\hat{d} = \hat{p}_1 - \hat{p}_2$, $z_{\alpha/2}$ is the $100(1-\alpha/2)$th percentile of the standard normal distribution. and the standard error is computed from the sample proportions as

$$\mathrm{se}(\hat{d}) = \sqrt{\hat{p}_1(1-\hat{p}_1)/n_{1\cdot} + \hat{p}_2(1-\hat{p}_2)/n_{2\cdot}}$$

If you specify the CORRECT *riskdiff-option*, the Wald confidence limits include a continuity correction cc,

$$\hat{d} \pm (c + z_{\alpha/2} \times \mathrm{se}(\hat{d}))$$

where $c = (1/n_{1\cdot} + 1/n_{2\cdot})/2$.

The subsection "Wald Test" in the section "Noninferiority Tests" on page 507 describes the corresponding noninferiority test.

Exact Unconditional Confidence Limits

If you specify the RISKDIFF option in the EXACT statement, PROC FREQTAB provides exact unconditional confidence limits for the risk difference ($d = p_1 - p_2$). The exact unconditional approach fixes the row margins of the 2×2 table and eliminates the nuisance parameter p_2 by using the maximum p-value (worst-case scenario) over all possible values of p_2 (Santner and Snell 1980). The conditional approach, which is described in the section "Exact Statistics" on page 547, does not apply to the risk difference because of the nuisance parameter (Agresti 1992).

By default, PROC FREQTAB computes the confidence limits by the tail method, which inverts two separate one-sided exact tests of the risk difference, where the tests are based on the score statistic (Chan and Zhang 1999). The size of each one-sided exact test is at most $\alpha/2$, and the confidence coefficient is at least

$(1-\alpha)$. If you specify the RISKDIFF(METHOD=NOSCORE) option in the EXACT statement, PROC FREQTAB computes the confidence limits by inverting two separate one-sided exact tests that are based on the unstandardized risk difference. If you specify the RISKDIFF(METHOD=SCORE2) option in the EXACT statement, PROC FREQTAB computes the confidence limits by inverting a single two-sided exact test that is based on the score statistic (Agresti and Min 2001).

The score statistic is a less discrete statistic than the unstandardized risk difference and produces less conservative confidence limits (Agresti and Min 2001). For more information, see Santner et al. (2007). The section "Miettinen-Nurminen (Score) Confidence Limits" describe computation of the risk difference score statistic. For more information, see Miettinen and Nurminen (1985) and Farrington and Manning (1990).

PROC FREQTAB computes the exact unconditional confidence limits as follows. The risk difference is defined as the difference between the row 1 and row 2 risks (proportions), $d = p_1 - p_2$, and n_1 and n_2 denote the row totals of the 2×2 table. The joint probability function for the table can be expressed in terms of the table cell frequencies, the risk difference, and the nuisance parameter p_2 as

$$f(n_{11}, n_{21}; n_1, n_2, d, p_2) = \binom{n_1}{n_{11}} (d + p_2)^{n_{11}} (1 - d - p_2)^{n_1 - n_{11}} \times \binom{n_2}{n_{21}} p_2^{n_{21}} (1 - p_2)^{n_2 - n_{21}}$$

For the tail method (which inverts two separate one-sided exact tests), the $100(1-\alpha/2)\%$ confidence limits for the risk difference are computed as

$$\begin{aligned} d_L &= \sup\,(d_* : P_U(d_*) > \alpha/2) \\ d_U &= \inf\,(d_* : P_L(d_*) > \alpha/2) \end{aligned}$$

where

$$\begin{aligned} P_U(d_*) &= \sup_{p_2} \Big(\sum_{A, T(a) \geq t_0} f(n_{11}, n_{21}; n_1, n_2, d_*, p_2) \Big) \\ P_L(d_*) &= \sup_{p_2} \Big(\sum_{A, T(a) \leq t_0} f(n_{11}, n_{21}; n_1, n_2, d_*, p_2) \Big) \end{aligned}$$

The set A includes all 2×2 tables in which the row sums are n_1 and n_2, $T(a)$ denotes the value of the test statistic for table a in A, and t_0 is the value of the test statistic for the observed table. The test statistic is either the score statistic (by default) or the unstandardized risk difference. To compute $P_U(d_*)$, the sum includes probabilities of those tables for which $(T(a) \geq t_0)$. For a fixed value of d_*, $P_U(d_*)$ is defined as the maximum sum over all possible values of p_2.

The two-sided score method evaluates the p-values $P_U(d_*)$ and $P_L(d_*)$ by comparing $|T(a)|$ to $|t_0|$. To compute the confidence limits d_L and d_u, the two-sided method compares the p-values to α. For more information, see Agresti and Min (2001) and Santner et al. (2007).

Risk Difference Tests

PROC FREQTAB provides tests of equality, noninferiority, superiority, and equivalence for the risk (proportion) difference. The following analysis methods are available: Wald (with and without continuity correction), Hauck-Anderson, Farrington-Manning (score), and Newcombe (with and without continuity correction). You can specify the method by using the METHOD= *riskdiff-option*; by default, PROC FREQTAB provides Wald tests.

Equality Tests The equality test for the risk difference tests the null hypothesis that the risk difference equals the null value. You can specify a null value by using the EQUAL(NULL=) *riskdiff-option*; by default, the null value is 0. This test can be expressed as $H_0: d = d_0$ versus the alternative $H_a: d \neq d_0$, where $d = p_1 - p_2$ denotes the risk difference (for column 1 or column 2) and d_0 denotes the null value.

The test statistic is computed as

$$z = (\hat{d} - d_0)/\mathrm{se}(\hat{d})$$

where the standard error $\mathrm{se}(\hat{d})$ is computed by using the method that you specify. Available methods for the equality test include Wald (with and without continuity correction), Hauck-Anderson, and Farrington-Manning (score). For a description of the standard error computation, see the subsections "Wald Test," "Hauck-Anderson Test," and "Farrington-Manning (Score) Test," respectively, in the section "Noninferiority Tests" on page 507.

PROC FREQTAB computes one-sided and two-sided p-values for equality tests. When the test statistic z is greater than 0, PROC FREQTAB displays the right-sided p-value, which is the probability of a larger value occurring under the null hypothesis. The one-sided p-value can be expressed as

$$P_1 = \begin{cases} \mathrm{Prob}(Z > z) & \text{if } z > 0 \\ \mathrm{Prob}(Z < z) & \text{if } z \leq 0 \end{cases}$$

where Z has a standard normal distribution. The two-sided p-value is computed as $P_2 = 2 \times P_1$.

Noninferiority Tests If you specify the NONINF *riskdiff-option*, PROC FREQTAB provides a noninferiority test for the risk difference, or the difference between two proportions. The null hypothesis for the noninferiority test is

$$H_0: p_1 - p_2 \leq -\delta$$

versus the alternative

$$H_a: p_1 - p_2 > -\delta$$

where δ is the noninferiority margin. Rejection of the null hypothesis indicates that the row 1 risk is not inferior to the row 2 risk. See Chow, Shao, and Wang (2003) for more information.

You can specify the value of δ with the MARGIN= *riskdiff-option*. By default, $\delta = 0.2$. You can specify the test method with the METHOD= *riskdiff-option*. The following methods are available for the risk difference noninferiority analysis: Wald (with and without continuity correction), Hauck-Anderson, Farrington-Manning (score), and Newcombe (with and without continuity correction). The Wald, Hauck-Anderson, and Farrington-Manning methods provide tests and corresponding test-based confidence limits; the Newcombe method provides only confidence limits. If you do not specify METHOD=, PROC FREQTAB uses the Wald test by default.

The confidence coefficient for the test-based confidence limits is $100(1 - 2\alpha)\%$ (Schuirmann 1999). By default, if you do not specify the ALPHA= option, these are 90% confidence limits. You can compare the confidence limits to the noninferiority limit, $-\delta$.

The following sections describe the noninferiority analysis methods for the risk difference.

Wald Test

If you specify the METHOD=WALD *riskdiff-option*, PROC FREQTAB provides an asymptotic Wald test of noninferiority for the risk difference. This is also the default method. The Wald test statistic is computed as

$$z = (\hat{d} + \delta) \,/\, \mathrm{se}(\hat{d})$$

where ($\hat{d} = \hat{p}_1 - \hat{p}_2$) estimates the risk difference and δ is the noninferiority margin.

By default, the standard error for the Wald test is computed from the sample proportions as

$$\mathrm{se}(\hat{d}) = \sqrt{\hat{p}_1(1-\hat{p}_1)/n_{1\cdot} \;+\; \hat{p}_2(1-\hat{p}_2)/n_{2\cdot}}$$

If you specify the VAR=NULL *riskdiff-option*, the standard error is based on the null hypothesis that the risk difference equals –δ (Dunnett and Gent 1977). The standard error is computed as

$$\mathrm{se}(\hat{d}) = \sqrt{\tilde{p}(1-\tilde{p})/n_{2\cdot} \;+\; (\tilde{p}-\delta)(1-\tilde{p}+\delta)/n_{1\cdot}}$$

where

$$\tilde{p} = (n_{11} + n_{21} + \delta n_{1\cdot})/n$$

If you specify the CORRECT *riskdiff-option*, the test statistic includes a continuity correction. The continuity correction is subtracted from the numerator of the test statistic if the numerator is greater than 0; otherwise, the continuity correction is added to the numerator. The value of the continuity correction is $(1/n_{1\cdot} + 1/n_{2\cdot})/2$.

The p-value for the Wald noninferiority test is $P_z = \mathrm{Prob}(Z > z)$, where Z has a standard normal distribution.

Hauck-Anderson Test

If you specify the METHOD=HA *riskdiff-option*, PROC FREQTAB provides the Hauck-Anderson test for noninferiority. The Hauck-Anderson test statistic is computed as

$$z = (\hat{d} + \delta \;\pm\; c) \,/\, \mathrm{se}(\hat{d})$$

where $\hat{d} = \hat{p}_1 - \hat{p}_2$ and the standard error is computed from the sample proportions as

$$\mathrm{se}(\hat{d}) = \sqrt{\hat{p}_1(1-\hat{p}_1)/(n_{1\cdot}-1) \;+\; \hat{p}_2(1-\hat{p}_2)/(n_{2\cdot}-1)}$$

The Hauck-Anderson continuity correction c is computed as

$$c = 1 \,/\, \left(2\, \min(n_{1\cdot},\, n_{2\cdot})\right)$$

The p-value for the Hauck-Anderson noninferiority test is $P_z = \mathrm{Prob}(Z > z)$, where Z has a standard normal distribution. For more information, see Hauck and Anderson (1986) and Schuirmann (1999).

Farrington-Manning (Score) Test

If you specify the METHOD=FM *riskdiff-option*, PROC FREQTAB provides the Farrington-Manning (score) test of noninferiority for the risk difference. A score test statistic for the null hypothesis that the risk difference equals –δ can be expressed as

$$z = (\hat{d} + \delta) \,/\, \mathrm{se}(\hat{d})$$

where $\hat{d}$ is the observed value of the risk difference $(\hat{p}_1 - \hat{p}_2)$,

$$\mathrm{se}(\hat{d}) = \sqrt{\tilde{p}_1(1-\tilde{p}_1)/n_{1\cdot} + \tilde{p}_2(1-\tilde{p}_2)/n_{2\cdot}}$$

and $\tilde{p}_1$ and $\tilde{p}_2$ are the maximum likelihood estimates of the row 1 and row 2 risks (proportions) under the restriction that the risk difference is $-\delta$. The p-value for the noninferiority test is $P_z = \mathrm{Prob}(Z > z)$, where Z has a standard normal distribution. For more information, see Miettinen and Nurminen (1985); Miettinen (1985); Farrington and Manning (1990); Dann and Koch (2005).

The maximum likelihood estimates of p_1 and p_1, subject to the constraint that the risk difference is $-\delta$, are computed as

$$\tilde{p}_1 = 2u\cos(w) - b/3a \quad \text{and} \quad \tilde{p}_2 = \tilde{p}_1 + \delta$$

where

$$\begin{aligned}
w &= (\pi + \cos^{-1}(v/u^3))/3 \\
v &= b^3/(3a)^3 - bc/6a^2 + d/2a \\
u &= \mathrm{sign}(v)\sqrt{b^2/(3a)^2 - c/3a} \\
a &= 1 + \theta \\
b &= -(1 + \theta + \hat{p}_1 + \theta\hat{p}_2 - \delta(\theta + 2)) \\
c &= \delta^2 - \delta(2\hat{p}_1 + \theta + 1) + \hat{p}_1 + \theta\hat{p}_2 \\
d &= \hat{p}_1\delta(1-\delta) \\
\theta &= n_{2\cdot}/n_{1\cdot}
\end{aligned}$$

For more information, see Farrington and Manning (1990, p. 1453).

Newcombe Noninferiority Analysis

If you specify the METHOD=NEWCOMBE *riskdiff-option*, PROC FREQTAB provides a noninferiority analysis that is based on Newcombe hybrid-score confidence limits for the risk difference. The confidence coefficient for the confidence limits is $100(1-2\alpha)\%$ (Schuirmann 1999). By default, if you do not specify the ALPHA= option, these are 90% confidence limits. You can compare the confidence limits with the noninferiority limit, $-\delta$. If you specify the CORRECT *riskdiff-option*, the confidence limits includes a continuity correction. See the subsection "Newcombe Confidence Limits" in the section "Confidence Limits for the Risk Difference" on page 502 for more information.

Superiority Test If you specify the SUP *riskdiff-option*, PROC FREQTAB provides a superiority test for the risk difference. The null hypothesis is

$$H_0: p_1 - p_2 \leq \delta$$

versus the alternative

$$H_a: p_1 - p_2 > \delta$$

where δ is the superiority margin. Rejection of the null hypothesis indicates that the row 1 proportion is superior to the row 2 proportion. You can specify the value of δ with the MARGIN= *riskdiff-option*. By default, $\delta = 0.2$.

The superiority analysis is identical to the noninferiority analysis but uses a positive value of the margin δ in the null hypothesis. The superiority computations follow those in the section "Noninferiority Tests" on page 507 by replacing $-\delta$ by δ. See Chow, Shao, and Wang (2003) for more information.

Equivalence Test If you specify the EQUIV *riskdiff-option*, PROC FREQTAB provides an equivalence test for the risk difference, or the difference between two proportions. The null hypothesis for the equivalence test is

$$H_0: p_1 - p_2 \leq -\delta_L \quad \text{or} \quad p_1 - p_2 \geq \delta_U$$

versus the alternative

$$H_a: \delta_L < p_1 - p_2 < \delta_U$$

where δ_L is the lower margin and δ_U is the upper margin. Rejection of the null hypothesis indicates that the two binomial proportions are equivalent. See Chow, Shao, and Wang (2003) for more information.

You can specify the value of the margins δ_L and δ_U with the MARGIN= *riskdiff-option*. If you do not specify MARGIN=, PROC FREQTAB uses lower and upper margins of –0.2 and 0.2 by default. If you specify a single margin value δ, PROC FREQTAB uses lower and upper margins of $-\delta$ and δ. You can specify the test method with the METHOD= *riskdiff-option*. The following methods are available for the risk difference equivalence analysis: Wald (with and without continuity correction), Hauck-Anderson, Farrington-Manning (score), and Newcombe (with and without continuity correction). The Wald, Hauck-Anderson, and Farrington-Manning methods provide tests and corresponding test-based confidence limits; the Newcombe method provides only confidence limits. If you do not specify METHOD=, PROC FREQTAB uses the Wald test by default.

PROC FREQTAB computes two one-sided tests (TOST) for equivalence analysis (Schuirmann 1987). The TOST approach includes a right-sided test for the lower margin δ_L and a left-sided test for the upper margin δ_U. The overall p-value is taken to be the larger of the two p-values from the lower and upper tests.

The section "Noninferiority Tests" on page 507 gives details about the Wald, Hauck-Anderson, Farrington-Manning (score), and Newcombe methods for the risk difference. The lower margin equivalence test statistic takes the same form as the noninferiority test statistic but uses the lower margin value δ_L in place of $-\delta$. The upper margin equivalence test statistic take the same form as the noninferiority test statistic but uses the upper margin value δ_U in place of $-\delta$.

The test-based confidence limits for the risk difference are computed according to the equivalence test method that you select. If you specify METHOD=WALD with VAR=NULL, or METHOD=FM, separate standard errors are computed for the lower and upper margin tests. In this case, the test-based confidence limits are computed by using the maximum of these two standard errors. These confidence limits have a confidence coefficient of $100(1 - 2\alpha)\%$ (Schuirmann 1999). By default, if you do not specify the ALPHA= option, these are 90% confidence limits. You can compare the test-based confidence limits to the equivalence limits, (δ_L, δ_U).

Barnard's Unconditional Exact Test

The BARNARD option in the EXACT statement provides an unconditional exact test for the risk (proportion) difference for 2×2 tables. The reference set for the unconditional exact test consists of all 2×2 tables that have the same row sums as the observed table (Barnard 1945, 1947, 1949). This differs from the reference set for exact conditional inference, which is restricted to the set of tables that have the same row sums and the same column sums as the observed table. See the sections "Fisher's Exact Test" on page 480 and "Exact Statistics" on page 547 for more information.

The test statistic is the standardized risk difference, which is computed as

$$T = d / \sqrt{p_{\cdot 1}(1 - p_{\cdot 1})(1/n_1 + 1/n_2)}$$

where the risk difference d is defined as the difference between the row 1 and row 2 risks (proportions), $d = (n_{11}/n_1 - n_{21}/n_2)$; n_1 and n_2 are the row 1 and row 2 totals, respectively; and $p_{.1}$ is the overall proportion in column 1, $(n_{11} + n_{21})/n$.

Under the null hypothesis that the risk difference is 0, the joint probability function for a table can be expressed in terms of the table cell frequencies, the row totals, and the unknown parameter π as

$$f(n_{11}, n_{21}; n_1, n_2, \pi) = \binom{n_1}{n_{11}} \binom{n_2}{n_{21}} \pi^{n_{11}+n_{21}} (1-\pi)^{n-n_{11}-n_{21}}$$

where π is the common value of the risk (proportion).

PROC FREQTAB sums the table probabilities over the reference set for those tables where the test statistic is greater than or equal to the observed value of the test statistic. This sum can be expressed as

$$\text{Prob}(\pi) = \sum_{A, T(a) \geq t_0} f(n_{11}, n_{21}; n_1, n_2, \pi)$$

where the set A contains all 2×2 tables with row sums equal to n_1 and n_2, and $T(a)$ denotes the value of the test statistic for table a in A. The sum includes probabilities of those tables for which $(T(a) \geq t_0)$, where t_0 is the value of the test statistic for the observed table.

The sum $\text{Prob}(\pi)$ depends on the unknown value of π. To compute the exact p-value, PROC FREQTAB eliminates the nuisance parameter π by taking the maximum value of $\text{Prob}(\pi)$ over all possible values of π,

$$\text{Prob} = \sup_{(0 \leq \pi \leq 1)} (\text{Prob}(\pi))$$

See Suissa and Shuster (1985) and Mehta and Senchaudhuri (2003).

Common Risk Difference

If you specify the COMMONRISKDIFF option in the TABLES statement, PROC FREQTAB provides estimates, confidence limits, and tests for the common (overall) risk difference for multiway 2×2 tables.

Mantel-Haenszel Confidence Limits and Test

PROC FREQTAB computes the Mantel-Haenszel estimate, confidence limits, and test for the common risk difference by using Mantel-Haenszel stratum weights (Mantel and Haenszel 1959) and the Sato variance estimator (Sato 1989). The Mantel-Haenszel estimate of the common risk difference is

$$\widehat{d}_{\text{MH}} = \sum_h \widehat{d}_h \, w_h$$

where $\widehat{d}_h$ is the risk difference in stratum h and

$$w_h = \frac{n_{h1\cdot} n_{h2\cdot}}{n_h} \Big/ \sum_i \frac{n_{i1\cdot} n_{i2\cdot}}{n_i}$$

is the Mantel-Haenszel weight of stratum h. The column 1 risk difference in stratum (2×2 table) h is computed as

$$\widehat{d}_h = \hat{p}_{h1} - \hat{p}_{h2} = (n_{h11}/n_{h1\cdot}) - (n_{h21}/n_{h2\cdot})$$

where $\hat{p}_{h1}$ is the proportion of row 1 observations that are classified in column 1 and $\hat{p}_{h2}$ is the proportion or row 2 observations that are classified in column 1. The column 2 risk is computed in the same way. For more information, see Agresti (2013, p. 231).

PROC FREQTAB computes the variance of $\widehat{d}_{\mathrm{MH}}$ (Sato 1989) as

$$\widehat{\sigma}^2(\widehat{d}_{\mathrm{MH}}) = \left(\widehat{d}_{\mathrm{MH}} \sum_h P_h + \sum_h Q_h\right) / \left(\sum_h n_{h1\cdot} n_{h2\cdot} / n_h\right)^2$$

where

$$P_h = \left(n_{h1\cdot}^2 n_{h21} - n_{h2\cdot}^2 n_{h11} + n_{h1\cdot} n_{h2\cdot}(n_{h2\cdot} - n_{h1\cdot})/2\right) / n_h^2$$

$$Q_h = \left(n_{h11}(n_{h2\cdot} - n_{h21}) + n_{h21}(n_{h1\cdot} - n_{h11})\right) / 2n_h$$

The $100(1-\alpha)\%$ confidence limits for the common risk difference are

$$\widehat{d}_{\mathrm{MH}} \pm \left(z_{\alpha/2} \times \widehat{\sigma}(\widehat{d}_{\mathrm{MH}})\right)$$

If you specify the COMMONRISKDIFF(TEST=MH) option, PROC FREQTAB provides a Mantel-Haenszel test of the null hypothesis that the common risk difference is 0, which is computed as $z_{\mathrm{MH}} = \widehat{d}_{\mathrm{MH}} / \widehat{\sigma}(\widehat{d}_{\mathrm{MH}})$. The two-sided p-value is $\mathrm{Prob}(|Z| > |z_{\mathrm{MH}}|)$, where Z has a standard normal distribution.

Klingenberg Confidence Limits

Klingenberg confidence limits (Klingenberg 2014) for the Mantel-Haenszel common risk difference are based on inverting a test of homogeneity that uses the null form of the Sato variance estimator (Sato 1989). For performance evaluation of Klingenberg confidence limits, see Fisher (2015) and Klingenberg (2014).

The $100(1-\alpha)\%$ Klingenberg confidence limits for the common risk difference are

$$\widehat{d}_{\mathrm{Mid}} \pm M_{\alpha/2}$$

where M (margin of error) is computed as

$$M_{\alpha/2} = \sqrt{\widehat{d}_{\mathrm{Mid}}^2 - \widehat{d}_{\mathrm{MH}}^2 + z_{\alpha/2}^2 \, (Q/W^2)}$$

and the confidence interval midpoint is computed as

$$\widehat{d}_{\mathrm{Mid}} = \widehat{d}_{\mathrm{MH}} + 0.5 \, z_{\alpha/2}^2 \, (P/W^2)$$

The values P, Q, and W are computed as

$$P = \sum_h P_h$$

$$Q = \sum_h Q_h$$

$$W = \sum_h n_{h1\cdot} \, n_{h2\cdot} \, / \, n_h$$

where h denotes the stratum, and P_h and Q_h are defined in the section "Mantel-Haenszel Confidence Limits and Test" on page 511.

Minimum Risk Confidence Limits and Test

PROC FREQTAB computes the minimum risk estimate, confidence limits, and test for the common risk difference by using the method of Mehrotra and Railkar (2000). The stratum estimates are weighted by minimum risk weights, which minimize the mean square error of the estimate of the common risk difference. Minimum risk weights are designed to improve precision and reduce bias (compared to other weighting strategies) and can minimize the power loss that can occur when underlying assumptions are not met. For more information, see Mehrotra (2001) and Dmitrienko et al. (2005, section 1.3.3).

The minimum risk estimate of the common risk difference is

$$\widehat{d}_{\mathrm{MR}} = \sum_h \widehat{d}_h \; w_h^*$$

where $\widehat{d}_h$ is the risk difference in stratum h and w_h^* is the minimum risk weight of stratum h (which is described in the section "Minimum Risk Weights" on page 514). The variance of $\widehat{d}_{\mathrm{MR}}$ is estimated by

$$\widehat{V}(\widehat{d}_{\mathrm{MR}}) = \sum_h w_h^{*2} \; \widehat{V}_h$$

where $\widehat{V}_h$ (the variance estimate of the stratum h risk difference) is computed as

$$\widehat{V}_h = \hat{p}_{h1}(1 - \hat{p}_{h1})/n_{h1\cdot} \; + \; \hat{p}_{h2}(1 - \hat{p}_{h2})/n_{h2\cdot}$$

The $100(1-\alpha)\%$ minimum risk confidence limits for the common risk difference are

$$\widehat{d}_{\mathrm{MR}} \; \pm \; \left(c \; + \; z_{\alpha/2} \sqrt{\widehat{V}(\widehat{d}_{\mathrm{MR}})} \right)$$

where the continuity correction is

$$c = 0.1875 \; / \; \sum_h (n_{h1\cdot} n_{h2\cdot} / n_h)$$

The continuity correction is applied only when $c < |\widehat{d}_{\mathrm{MR}}|$ (Fleiss, Levin, and Paik 2003). You can remove the continuity correction by specifying the COMMONRISKDIFF(CORRECT=NO) option.

By default, the minimum risk test is computed as

$$z_{\mathrm{MR}} = \left(\widehat{d}_{\mathrm{MR}} \pm c \right) \; / \; \sqrt{\widehat{V}_0(\widehat{d}_{\mathrm{MR}})}$$

The continuity correction c is subtracted from $\widehat{d}_{\mathrm{MR}}$ if $\widehat{d}_{\mathrm{MR}} > 0$ and added to $\widehat{d}_{\mathrm{MR}}$ if $\widehat{d}_{\mathrm{MR}} < 0$. The null variance of the common risk difference is estimated by

$$\widehat{V}_0(\widehat{d}_{\mathrm{MR}}) = \sum_h w_h^{*2} \; \widehat{V}_0(\widehat{d}_h)$$

where $\widehat{V}_0(\widehat{d}_h)$ (an estimate of the variance of the stratum h risk difference under the null hypothesis) is

$$\widehat{V}_0(\widehat{d}_h) = \bar{p}_h(1 - \bar{p}_h) \, (1/n_{h1\cdot} + 1/n_{h2\cdot})$$

and

$$\bar{p}_h = (n_{h1\cdot} \hat{p}_{h1\cdot} + n_{h2\cdot} \hat{p}_{h2\cdot}) \; / \; (n_{h1\cdot} + n_{h2\cdot})$$

The two-sided p-value is $\mathrm{Prob}(|Z| > |z_{\mathrm{MR}}|)$, where Z has a standard normal distribution.

If you specify the VAR=SAMPLE option for COMMONRISKDIFF(TEST=MR), PROC FREQTAB uses the sample variance estimate $\widehat{V}(\widehat{d}_{\mathrm{MR}})$ instead of the null variance estimate $\widehat{V}_0(\widehat{d}_{\mathrm{MR}})$ in the denominator of the test statistic z_{MR}. If you specify the COMMONRISKDIFF(CORRECT=NO) option, the continuity correction is not included in the test statistic.

Minimum Risk Weights The estimate of the minimum risk weight for stratum h is defined by Mehrotra and Railkar (2000) as

$$w_h^* = \frac{\beta_h}{\sum_i \widehat{V}_i^{-1}} - \left(\frac{\alpha_h \widehat{V}_h^{-1}}{\sum_i \widehat{V}_i^{-1} + \sum_i \alpha_i \widehat{d}_i \widehat{V}_i^{-1}} \right) \left(\frac{\sum_i \widehat{d}_i \beta_i}{\sum_i \widehat{V}_i^{-1}} \right)$$

where

$$\alpha_h = \widehat{d}_h \sum_i \widehat{V}_i^{-1} - \sum_i \widehat{d}_i \widehat{V}_i^{-1}$$

$$\beta_h = \widehat{V}_h^{-1} \left(1 + \alpha_h \sum_i f_i \widehat{d}_i \right)$$

and f_h is the fraction in stratum h

$$f_h = n_h \; / \; \sum_i n_h$$

All sums are over the s strata (2×2 tables) in the multiway table request, $\widehat{d}_i$ denotes the risk difference estimate in stratum i, and $\widehat{V}_i$ denotes the sample variance estimate of the risk difference in stratum i.

Summary Score Confidence Limits

PROC FREQTAB computes the summary score estimate of the common risk difference (Agresti 2013, p. 231) by using inverse-variance stratum weights and Miettinen-Nurminen (score) confidence limits for the stratum risk differences. For more information, see the section "Miettinen-Nurminen (Score) Confidence Limits."

The score confidence interval for the risk difference in stratum h can be expressed as $\widehat{d}'_h \pm z_{\alpha/2}\, s'_h$, where $\widehat{d}'_h$ is the midpoint of the score confidence interval and s'_h is the width of the confidence interval divided by $2z_{\alpha/2}$. The summary score estimate of the common risk difference is computed as

$$\widehat{d}_S = \sum_h \widehat{d}'_h \, w'_h$$

where

$$w'_h = (1/{s'_h}^2) \; / \; \sum_i (1/{s'_i}^2)$$

The variance of $\widehat{d}_S$ is computed as

$$\widehat{\sigma}^2(\widehat{d}_S) = 1 \; / \; \sum_h (1/{s'_h}^2)$$

The $100(1-\alpha)\%$ summary score confidence limits for the common risk difference are

$$\widehat{d}_S \pm \left(z_{\alpha/2} \times \widehat{\sigma}(\widehat{d}_S)\right)$$

If you specify the COMMONRISKDIFF(TEST=SCORE) option, PROC FREQTAB provides a summary score test of the null hypothesis that the common risk difference is 0. The test statistic is $z_S = \widehat{d}_S / \widehat{\sigma}(\widehat{d}_S)$ The two-sided p-value is $\mathrm{Prob}(|Z| > |z_S|)$ where Z has a standard normal distribution.

Stratified Newcombe Confidence Limits

PROC FREQTAB computes stratified Newcombe confidence limits for the common risk (proportion) difference by using the method of Yan and Su (2010). The stratified Newcombe confidence limits are constructed from stratified Wilson confidence limits for the common (overall) row proportions. By default, the strata are weighted by Mantel-Haenszel weights; if you specify the COMMONRISKDIFF(CL=NEWCOMBEMR) option, the strata are weighted by minimum risk weights.

PROC FREQTAB first computes individual Wilson confidence limits for the row proportions in each 2×2 table (stratum), as described in the section "Wilson (Score) Confidence Limits" on page 495. These stratum Wilson confidence limits are then combined to form stratified Wilson confidence limits for the overall row proportions by using stratum weights (either Mantel-Haenszel or minimum risk). The confidence levels of the stratum Wilson confidence limits are chosen so that the overall confidence coefficient (for the stratified Wilson confidence limits) is $100(1-\alpha)\%$ (Yan and Su 2010).

Denote the lower and upper stratified Wilson score confidence limits for the common row 1 proportion as L_1 and U_1, respectively, and denote the lower and upper stratified Wilson confidence limits for the common row 2 proportion as L_2 and U_2, respectively. The $100(1-\alpha)\%$ stratified Newcombe confidence limits for the common risk (proportion) difference are

$$\begin{aligned} L &= \widehat{d} - z_{\alpha/2}\sqrt{\lambda_1 L_1(1-L_1) + \lambda_2 U_2(1-U_2)} \\ U &= \widehat{d} + z_{\alpha/2}\sqrt{\lambda_2 L_2(1-L_2) + \lambda_1 U_1(1-U_1)} \end{aligned}$$

where $\widehat{d}$ is the weighted estimate of the common risk difference and

$$\begin{aligned} \lambda_1 &= \sum_h w_h^2 \,/\, n_{h1\cdot} \\ \lambda_2 &= \sum_h w_h^2 \,/\, n_{h2\cdot} \end{aligned}$$

By default, the strata are weighted by Mantel-Haenszel weights, which are defined as

$$w_h = \frac{n_{h1\cdot} n_{h2\cdot}}{n_h} \,/\, \sum_i \frac{n_{i1\cdot} n_{i2\cdot}}{n_i}$$

and the weighted estimate of the common risk difference is $\widehat{d}_{\mathrm{MH}}$. For more information, see the section "Mantel-Haenszel Confidence Limits and Test" on page 511. Optionally, the strata are weighted by minimum risk weights, and the weighted estimate of the common risk difference is $\widehat{d}_{\mathrm{MR}}$. For more information, see the section "Minimum Risk Confidence Limits and Test" on page 513.

When there is a single stratum, the stratified Newcombe confidence interval is equivalent to the (unstratified) Newcombe confidence interval. For more information, see the subsection "Newcombe Confidence Limits" in the section "Confidence Limits for the Risk Difference" on page 502. See also Kim and Won (2013).

Odds Ratio and Relative Risks

Odds Ratio

The odds ratio is a useful measure of association for a variety of study designs. For a retrospective design called a *case-control study*, the odds ratio can be used to estimate the relative risk when the probability of positive response is small (Agresti 2002). In a case-control study, two independent samples are identified based on a binary (yes-no) response variable, and the conditional distribution of a binary explanatory variable is examined within fixed levels of the response variable. For more information, see Stokes, Davis, and Koch (2012), Agresti (2013), and Agresti (2007).

The odds of a positive response (column 1) in row 1 is n_{11}/n_{12}. Similarly, the odds of a positive response in row 2 is n_{21}/n_{22}. The odds ratio is formed as the ratio of the row 1 odds to the row 2 odds. The odds ratio for a 2×2 table is defined as

$$\mathrm{OR} = \frac{n_{11}/n_{12}}{n_{21}/n_{22}} = \frac{n_{11}\, n_{22}}{n_{12}\, n_{21}}$$

The odds ratio can be any nonnegative number. When the row and column variables are independent, the true value of the odds ratio is 1. An odds ratio greater than 1 indicates that the odds of a positive response are higher in row 1 than in row 2. An odds ratio less than 1 indicates that the odds of a positive response are higher in row 2. The strength of association increases as the deviation from 1 increases.

The transformation $G = (\mathrm{OR} - 1)/(\mathrm{OR} + 1)$ transforms the odds ratio to the range (–1,1), where $G = 0$ when OR = 1; $G = -1$ when OR = 0; and G approaches 1 as OR approaches infinity. G is the gamma statistic, which PROC FREQTAB computes when you specify the MEASURES option.

Confidence Limits for the Odds Ratio The following types of confidence limits are available for the odds ratio: exact, exact mid-*p*, likelihood ratio, score, Wald, and Wald modified.

Wald Confidence Limits

The asymptotic Wald confidence limits are based on a log transformation of the odds ratio (Woolf 1955; Haldane 1956). PROC FREQTAB computes the Wald confidence limits as

$$\left(\mathrm{OR} \times \exp(-z\sqrt{v}),\ \ \mathrm{OR} \times \exp(z\sqrt{v}) \right)$$

where

$$v = \mathrm{Var}(\log \mathrm{OR}) = 1/n_{11} + 1/n_{12} + 1/n_{21} + 1/n_{22}$$

and z is the $100(1 - \alpha/2)$th percentile of the standard normal distribution. The confidence level α is determined by the ALPHA= option in the TABLES statement; by default, ALPHA=0.05, which produces 95% confidence limits for the odds ratio. If any of the four cell frequencies are 0, v is undefined and the Wald confidence limits cannot be computed. For more information, see Agresti (2013, p. 70).

Wald Modified Confidence Limits

PROC FREQTAB computes Wald modified confidence limits (Haldane 1956) for the odds ratio by replacing the n_{ij} by $(n_{ij} + 0.5)$ in the estimate and variance as follows:

$$\mathrm{OR}_m = \frac{(n_{11} + 0.5)\ (n_{22} + 0.5)}{(n_{12} + 0.5)\ (n_{21} + 0.5)}$$

$$v = \mathrm{Var}(\log \mathrm{OR}_m) = 1/(n_{11} + 0.5) + 1/(n_{12} + 0.5) + 1/(n_{21} + 0.5) + 1/(n_{22} + 0.5)$$

The modified confidence limits are computed as

$$\left(\mathrm{OR}_m \times \exp(-z\sqrt{v}),\ \ \mathrm{OR}_m \times \exp(z\sqrt{v}) \right)$$

where z is the $100(1-\alpha/2)$th percentile of the standard normal distribution. For more information, see Fleiss, Levin, and Paik (2003) and Agresti (2013).

Score Confidence Limits

Score confidence limits for the odds ratio (Miettinen and Nurminen 1985) are computed by inverting score tests for the odds ratio. A score-based chi-square test statistic for the null hypothesis that the odds ratio is θ can be expressed as

$$Q(\theta) = \{n_{1\cdot}\,(\hat{p}_1 - \tilde{p}_1)\}^2 \,/\, \{n/(n-1)\}\,\{1/\,(n_{1\cdot}\tilde{p}_1(1-\tilde{p}_1)) + 1/\,(n_{2\cdot}\tilde{p}_2(1-\tilde{p}_2))\}^{-1}$$

where $\hat{p}_1$ is the observed row 1 risk ($n_{11}/n_{1\cdot}$), and $\tilde{p}_1$ and $\tilde{p}_2$ are the maximum likelihood estimates of the row 1 and row 2 risks under the restriction that the odds ratio ($n_{11}n_{22}/n_{12}n_{21}$) is θ. For more information, see Miettinen and Nurminen (1985) and Miettinen (1985, chapter 14).

The $100(1-\alpha)\%$ score confidence interval for the odds ratio consists of all values of θ for which the test statistic $Q(\theta)$ falls in the acceptance region,

$$\{\theta : Q(\theta) < \chi^2_{1,\alpha}\}$$

where $\chi^2_{1,\alpha}$ is the $100(1-\alpha)$th percentile of the chi-square distribution with 1 degree of freedom. For more information about score confidence limits, see Agresti (2013).

By default, the score confidence limits include the bias correction factor $n/(n-1)$ in the denominator of $Q(\theta)$ (Miettinen and Nurminen 1985, p. 217). If you specify the CL=SCORE(CORRECT=NO) option, PROC FREQTAB does not include this factor in the computation.

The maximum likelihood estimates of p_1 and p_2, subject to the constraint that the odds ratio is θ, are computed as

$$\tilde{p}_2 = \left(-b + \sqrt{b^2 - 4ac}\right)/2a \quad \text{and} \quad \tilde{p}_1 = \tilde{p}_2\theta/\,(1 + \tilde{p}_2(\theta - 1))$$

where

$$\begin{aligned} a &= n_{2\cdot}(\theta - 1) \\ b &= n_{1\cdot}\theta + n_{2\cdot} - \hat{p}_{\cdot 1}(\theta - 1) \\ c &= -\hat{p}_{\cdot 1} \end{aligned}$$

For more information, see Miettinen and Nurminen (1985, pp. 217–218) and Miettinen (1985, chapter 14).

Likelihood Ratio Confidence Limits

Likelihood ratio (profile likelihood) confidence limits for the odds ratio are computed by inverting likelihood ratio tests. The likelihood ratio test statistic for the null hypothesis that the odds ratio is θ can be expressed as

$$G^2(\theta) \;=\; 2\left(n_{11}\log(\hat{p}_1/\tilde{p}_1) + n_{12}\log((1-\hat{p}_1)/(1-\tilde{p}_1)) + n_{21}\log(\hat{p}_2/\tilde{p}_2) + n_{22}\log((1-\hat{p}_2)/(1-\tilde{p}_2))\right)$$

where $\hat{p}_i$ is the observed row i risk ($n_{11}/n_{1\cdot}$) and $\tilde{p}_i$ is the maximum likelihood estimate of the row i risk under the restriction that the odds ratio is θ. The computation of the maximum likelihood estimates is described in the subsection "Score Confidence Limits" in this section. For more information, see Agresti (2013), Miettinen and Nurminen (1985), and Miettinen (1985, chapter 14).

The $100(1-\alpha)\%$ likelihood ratio confidence interval for the odds ratio consists of all values of θ for which the test statistic $G^2(\theta)$ falls in the acceptance region,

$$\{\theta : G^2(\theta) < \chi^2_{1,\alpha}\}$$

where $\chi^2_{1,\alpha}$ is the $100(1-\alpha)$th percentile of the chi-square distribution with 1 degree of freedom.

Exact Confidence Limits

PROC FREQTAB computes exact confidence limits for the odds ratio by inverting two one-sided (equal-tail) exact tests that are based on the noncentral hypergeometric distribution, where the distribution is conditional on the observed marginal totals of the 2×2 table. The exact confidence limits ϕ_1 and ϕ_2 are the solutions to the equations

$$\begin{aligned} \sum_{i=n_{11}}^{n_{\cdot 1}} f(i : n_{\cdot 1},\ n_{1\cdot},\ n_{2\cdot},\ \phi_1) &= \alpha/2 \\ \sum_{i=0}^{n_{11}} f(i : n_{\cdot 1},\ n_{1\cdot},\ n_{2\cdot},\ \phi_2) &= \alpha/2 \end{aligned}$$

where

$$f(i : n_{\cdot 1},\ n_{1\cdot},\ n_{2\cdot},\ \phi) = \binom{n_{1\cdot}}{i}\binom{n_{2\cdot}}{n_{\cdot 1}-i}\phi^i \ \Big/ \ \sum_{i=0}^{n_{\cdot 1}}\binom{n_{1\cdot}}{i}\binom{n_{2\cdot}}{n_{\cdot 1}-i}\phi^i$$

For more information, see Fleiss, Levin, and Paik (2003), Thomas (1971), and Gart (1971).

Because this is a discrete problem, the confidence coefficient for the exact confidence interval is not exactly $(1-\alpha)$ but is at least $(1-\alpha)$; thus, these confidence limits are conservative. For more information, see Agresti (1992).

When the odds ratio is 0, which occurs when either $n_{11} = 0$ or $n_{22} = 0$, PROC FREQTAB sets the lower exact confidence limit to 0 and determines the upper limit by using the level α (instead of $\alpha/2$). Similarly, when the odds ratio is infinity, which occurs when either $n_{12} = 0$ or $n_{21} = 0$, PROC FREQTAB sets the upper exact confidence limit to infinity and determines the lower limit by using level α.

Exact Mid-p Confidence Limits

PROC FREQTAB computes exact mid-p confidence limits for the odds ratio by inverting two one-sided hypergeometric tests that include mid-p tail areas. The mid-p approach replaces the probability of the observed table with half of that probability in the hypergeometric probability sums, which are described in the subsection "Exact Confidence Limits" in this section. The exact mid-p confidence limits ϕ_1 and ϕ_2 are

the solutions to the equations

$$\begin{aligned}
\sum_{i=n_{11}+1}^{n_{\cdot 1}} \big(f(i : n_{\cdot 1},\, n_{1\cdot},\, n_{2\cdot},\, \phi_1)\big) \;+\; (1/2) f(n_{11} : n_{\cdot 1},\, n_{1\cdot},\, n_{2\cdot},\, \phi_1) &= \alpha/2 \\
\sum_{i=0}^{n_{11}-1} \big(f(i : n_{\cdot 1},\, n_{1\cdot},\, n_{2\cdot},\, \phi_2)\big) \;+\; (1/2) f(n_{11} : n_{\cdot 1},\, n_{1\cdot},\, n_{2\cdot},\, \phi_2) &= \alpha/2
\end{aligned}$$

where

$$f(i : n_{\cdot 1}, n_{1\cdot}, n_{2\cdot}, \phi) = \binom{n_{1\cdot}}{i}\binom{n_{2\cdot}}{n_{\cdot 1}-i}\phi^i \;\Big/\; \sum_{i=0}^{n_{\cdot 1}} \binom{n_{1\cdot}}{i}\binom{n_{2\cdot}}{n_{\cdot 1}-i}\phi^i$$

For more information, see Agresti (2013).

When the odds ratio is 0, which occurs when either $n_{11} = 0$ or $n_{22} = 0$, PROC FREQTAB sets the lower exact confidence limit to 0 and determines the upper limit by using the level α (instead of $\alpha/2$). Similarly, when the odds ratio is infinity, which occurs when either $n_{12} = 0$ or $n_{21} = 0$, PROC FREQTAB sets the upper exact confidence limit to infinity and determines the lower limit by using level α.

Relative Risks

Relative risks are useful measures in *cohort* (prospective) study designs, where two samples are identified based on the presence or absence of an explanatory factor. The two samples are observed in future time for the binary (yes-no) response variable under study. Relative risks are also useful in cross-sectional studies, where two variables are observed simultaneously. For more information, see Stokes, Davis, and Koch (2012) and Agresti (2007).

The relative risk is the ratio of the row 1 risk to the row 2 risk in a 2×2 table. The column 1 risk in row 1 is the proportion of row 1 observations that are classified in column 1, which can be expressed as

$$p_1 = n_{11} \,/\, n_{1\cdot}$$

Similarly, the column 1 risk in row 2 is

$$p_2 = n_{21} \,/\, n_{2\cdot}$$

The column 1 relative risk is defined as

$$R = p_1 \,/\, p_2$$

A relative risk greater than 1 indicates that the probability of positive response is greater in row 1 than in row 2. Similarly, a relative risk less than 1 indicates that the probability of positive response is less in row 1 than in row 2. The strength of association increases as the deviation from 1 increases.

Confidence Limits for the Relative Risk PROC FREQTAB provides the following types of confidence limits for the relative risk: exact unconditional, likelihood ratio, score, Wald, and Wald modified.

Wald Confidence Limits

The asymptotic Wald confidence limits are based on a log transformation of the relative risk. PROC FREQTAB computes the Wald confidence limits for the column 1 relative risk as

$$\left(\hat{r} \times \exp(-z\sqrt{v}),\ \ \hat{r} \times \exp(z\sqrt{v}) \right)$$

where $\hat{r}$ is the observed value of the relative risk, $\hat{p}_1/\hat{p}_2$, and

$$v = \mathrm{Var}(\log(\hat{r})) = 1/n_{11} + 1/n_{21} - 1/n_{1\cdot} - 1/n_{2\cdot}$$

and z is the $100(1-\alpha/2)$th percentile of the standard normal distribution. The confidence level α is determined by the ALPHA= option in the TABLES statement; by default, ALPHA=0.05, which produces 95% confidence limits. If either cell frequency n_{11} or n_{21} is 0, v is undefined and the Wald confidence limits cannot be computed.

PROC FREQTAB computes the confidence limits for the column 2 relative risk in the same way.

Wald Modified Confidence Limits

PROC FREQTAB computes Wald modified confidence limits (Haldane 1956) for the relative risk by replacing the n_{ij} with $(n_{ij}+0.5)$ and the $n_{i\cdot}$ with $(n_{i\cdot}+0.5)$ in the estimate and variance as follows:

$$\hat{r}_m = \frac{(n_{11}+0.5)/(n_{1\cdot}+0.5)}{(n_{21}+0.5)/(n_{2\cdot}+0.5)}$$

$$v = \mathrm{Var}(\log(\hat{r}_m)) = 1/(n_{11}+0.5) + 1/(n_{21}+0.5) - 1/(n_{1\cdot}+0.5) - 1/(n_{2\cdot}+0.5)$$

The confidence limits are computed as

$$\left(\hat{r}_m \times \exp(-z\sqrt{v}),\ \ \hat{r}_m \times \exp(z\sqrt{v}) \right)$$

where z is the $100(1-\alpha/2)$th percentile of the standard normal distribution. For more information, see Fleiss, Levin, and Paik (2003) and Agresti (2013).

Score Confidence Limits

Score confidence limits (Miettinen and Nurminen 1985; Farrington and Manning 1990) are computed by inverting score tests for the relative risk. A score-based chi-square test statistic for the null hypothesis that the relative risk is r_0 can be expressed as

$$Q(r_0) = (\hat{p}_1 - r_0\hat{p}_2)^2 \ / \ \widetilde{\mathrm{Var}}(r_0)$$

where $\hat{p}_1$ and $\hat{p}_2$ are the observed row 1 and row 2 risks (proportions), respectively,

$$\widetilde{\mathrm{Var}}(r_0) = (n/(n-1))\ \left(\tilde{p}_1(1-\tilde{p}_1)/n_{1\cdot} \ + \ {r_0}^2\ \tilde{p}_2(1-\tilde{p}_2)/n_{2\cdot} \right)$$

where $\tilde{p}_1$ and $\tilde{p}_2$ are the maximum likelihood estimates of p_1 and p_2, respectively, under the null hypothesis that the relative risk is r_0. For more information, see Miettinen and Nurminen (1985) and Miettinen (1985, chapter 13).

The $100(1-\alpha)\%$ score confidence interval for the relative risk consists of all values of r_0 for which the test statistic $Q(r_0)$ falls in the acceptance region,

$$\{r_0 : Q(r_0) < \chi^2_{1,\alpha}\}$$

where $\chi^2_{1,\alpha}$ is the $100(1-\alpha)$th percentile of the chi-square distribution with 1 degree of freedom. For more information, see Agresti (2013).

By default, the score confidence limits include the bias correction factor $n/(n-1)$ in the denominator of $Q(r_0)$ (Miettinen and Nurminen 1985, p. 217). If you specify the CL=SCORE(CORRECT=NO) option, PROC FREQTAB does not include this factor in the computation.

The maximum likelihood estimates of p_1 and p_2, subject to the constraint that the relative risk is r_0, are computed as

$$\tilde{p}_1 = \left(-b - \sqrt{b^2 - 4ac}\right)/2a \quad \text{and} \quad \tilde{p}_2 = \tilde{p}_1/r_0$$

where

$$\begin{aligned} a &= 1+\theta \\ b &= -(r_0(1+\theta\hat{p}_2)+\theta+\hat{p}_1) \\ c &= r_0(\hat{p}_1+\theta\hat{p}_2) \\ \theta &= n_{2\cdot}/n_{1\cdot} \end{aligned}$$

For more information, see Farrington and Manning (1990, p. 1454) and Miettinen and Nurminen (1985, p. 217).

Likelihood Ratio Confidence Limits

Likelihood ratio (profile likelihood) confidence limits for the relative risk are computed by inverting likelihood ratio tests. The likelihood ratio test statistic for the null hypothesis that the relative risk ratio is r_0 can be expressed as

$$G^2(r_0) = 2\left(n_{11}\log(\hat{p}_1/\tilde{p}_1) + n_{12}\log((1-\hat{p}_1)/(1-\tilde{p}_1)) + n_{21}\log(\hat{p}_2/\tilde{p}_2) + n_{22}\log((1-\hat{p}_2)/(1-\tilde{p}_2))\right)$$

where $\hat{p}_i$ is the observed row i risk ($n_{i1}/n_{i\cdot}$) and $\tilde{p}_i$ is the maximum likelihood estimate of the row i risk under the restriction that the relative risk is r_0. Expressions for the maximum likelihood estimates $\tilde{p}_1$ and $\tilde{p}_2$ are given in the subsection "Score Confidence Limits" in this section. For more information, see Miettinen and Nurminen (1985) and Miettinen (1985, chapter 13).

The $100(1-\alpha)\%$ likelihood ratio confidence interval for the relative risk consists of all values of r_0 for which the test statistic $G^2(r_0)$ falls in the acceptance region,

$$\{\theta : G^2(r_0) < \chi^2_{1,\alpha}\}$$

where $\chi^2_{1,\alpha}$ is the $100(1-\alpha)$th percentile of the chi-square distribution with 1 degree of freedom.

Exact Unconditional Confidence Limits

If you specify the RELRISK option in the EXACT statement, PROC FREQTAB provides exact unconditional confidence limits for the relative risk. The exact unconditional approach fixes the row margins of the 2×2 table and eliminates the nuisance parameter p_2 by using the maximum p-value (worst-case scenario) over all possible values of p_2 (Santner and Snell 1980). The conditional approach, which is described in the section "Exact Statistics" on page 547, does not apply to the relative risk because of the nuisance parameter (Agresti 1992).

By default, PROC FREQTAB computes the confidence limits by the tail method, which inverts two separate one-sided exact tests of the relative risk, where the tests are based on the score statistic (Chan and Zhang 1999). The size of each one-sided exact test is at most $\alpha/2$, and the confidence coefficient is at least $(1-\alpha)$. If you specify the RELRISK(METHOD=NOSCORE) option in the EXACT statement, PROC FREQTAB computes the confidence limits by inverting two separate one-sided exact tests that are based on the unstandardized relative risk. If you specify the RELRISK(METHOD=SCORE2) option in the EXACT statement, PROC FREQTAB computes the confidence limits by inverting a single two-sided exact test that is based on the score statistic (Agresti and Min 2001).

PROC FREQTAB uses the relative risk score statistic (or the modified form of the unstandardized relative risk) to compute the exact confidence limits as described in the subsection "Exact Unconditional Confidence Limits" in the section "Confidence Limits for the Risk Difference" on page 502.

The score statistic is a less discrete statistic than the unstandardized risk difference and produces less conservative confidence limits (Agresti and Min 2001). For more information, see Santner et al. (2007). The relative risk score statistic (Miettinen and Nurminen 1985; Farrington and Manning 1990) is computed as

$$z(r_0) = (\hat{p}_1 - r_0\hat{p}_2) \;/\; \mathrm{se}(r_0)$$

where

$$\mathrm{se}(r_0) = \sqrt{\tilde{p}_1(1-\tilde{p}_1)/n_{1\cdot} \;+\; {r_0}^2\;\tilde{p}_2(1-\tilde{p}_2)/n_{2\cdot}}$$

where $\tilde{p}_1$ and $\tilde{p}_2$ are the maximum likelihood estimates of p_1 and p_2 under the restriction that the relative risk is r_0. Expressions for the maximum likelihood estimates $\tilde{p}_1$ and $\tilde{p}_2$ are given in the subsection "Score Confidence Limits" in this section. For more information, see Farrington and Manning (1990, p. 1454) and Miettinen and Nurminen (1985, p. 217).

When the confidence limits are computed by using the unstandardized relative risk as the test statistic (METHOD=NOSCORE), PROC FREQTAB uses a modified form of the relative risk to ensure that the statistic is defined when there are zero-frequency table cells. The modified form adds 0.5 to the table cell and row frequencies (Gart and Nam 1988) and is computed as

$$\hat{r}_m = \frac{(n_{11}+0.5) \;/\; (n_{1\cdot}+0.5)}{(n_{21}+0.5) \;/\; (n_{2\cdot}+0.5)}$$

For more information, see the subsection "Wald Modified Confidence Limits" in this section.

Relative Risk Tests PROC FREQTAB provides tests of equality, noninferiority, superiority, and equivalence for the relative risk. The following analysis methods are available: Wald (which is based on a log transformation), Wald modified, score, and likelihood ratio. You can specify the method by using the METHOD= *relrisk-option*; by default, PROC FREQTAB provides Wald tests.

Equality Test

An equality test for the relative risk can be expressed as

$$H_0\colon R = r_0$$

versus the alternative

$$H_a\colon R \neq r_0$$

where $R = p_1/p_2$ denotes the relative risk (for column 1 or column 2) and r_0 denotes the null value. You can specify a null value by using the EQUAL(NULL=) *relrisk-option*; by default, the null value is 1.

The test statistic is computed by the method that you specify; by default, PROC FREQTAB uses the Wald test. For information about test statistic computation, see the subsections "Wald Test," "Wald Modified Test," "Farrington-Manning (Score) Test," and "Likelihood Ratio Test" in this section.

For the Wald and score methods, the test statistics z have standard normal distributions under the null hypothesis. For the likelihood ratio test, the test statistic G^2 has a chi-square distribution with 1 degree of freedom under the null hypothesis.

When the test statistic z is greater than 0, PROC FREQTAB displays the right-sided p-value, which is the probability of a larger value occurring under the null hypothesis. The one-sided p-value can be expressed as

$$P_1 = \begin{cases} \text{Prob}(Z > z) & \text{if } z > 0 \\ \text{Prob}(Z < z) & \text{if } z \leq 0 \end{cases}$$

where Z has a standard normal distribution. The two-sided p-value is computed as $P_2 = 2 \times P_1$.

Noninferiority Test

A noninferiority test for the relative risk can be expressed as

$$H_0: R \leq \delta$$

versus the alternative

$$H_a: R > \delta$$

where $R = p_1/p_2$ denotes the relative risk (for column 1 or column 2) and δ denotes the noninferiority margin (limit). You can specify the margin by using the MARGIN= *relrisk-option*; by default, the noninferiority margin is 0.8. The noninferiority margin for a relative risk test should be less than 1. Rejection of the null hypothesis indicates that the row 1 risk is not inferior to the row 2 risk. For more information, see Chow, Shao, and Wang (2008).

The test statistic z is computed by the method that you specify. For information about test statistic computation, see the subsections "Wald Test," "Wald Modified Test," "Farrington-Manning (Score) Test," and "Likelihood Ratio Test" in this section. The test statistic z is computed by using the noninferiority margin (limit) as the null value of the relative risk. Under the null hypothesis, the test statistic has a standard normal distribution. The p-value for the noninferiority test is the right-sided p-value (the probability that $Z > z$).

As part of the noninferiority analysis, PROC FREQTAB also provides confidence limits for the relative risk. The confidence coefficient is $100(1 - 2\alpha)\%$ (Schuirmann 1999). The confidence level α is determined by the ALPHA= option in the TABLES statement; by default, ALPHA=0.05, which produces 90% confidence limits for the noninferiority analysis. You can compare the confidence limits to the value of the noninferiority limit δ.

Superiority Test

A superiority test for the relative risk can be expressed as

$$H_0: R \leq \delta$$

versus the alternative

$$H_a: R > \delta$$

where $R = p_1/p_2$ denotes the relative risk (for column 1 or column 2) and δ denotes the superiority margin (limit). You can specify the margin by using the MARGIN= *relrisk-option*; by default, the superiority margin is 1.25. The superiority margin for a relative risk test should be greater than 1. Rejection of the null hypothesis indicates that the row 1 risk is superior to the row 2 risk. For more information, see Chow, Shao, and Wang (2008).

The test statistic z is computed by using the superiority margin (limit) as the null value of the relative risk. Under the null hypothesis, the test statistic has a standard normal distribution. The p-value for the superiority test is the right-sided p-value (the probability that $Z > z$).

The computations for the superiority analysis are the same as the computations for the noninferiority analysis, which are described in the subsection "Noninferiority Test" in this section.

Equivalence Test

An equivalence test for the relative risk can be expressed as

$$H_0: R \leq \delta_L \quad \text{or} \quad R \geq \delta_U$$

versus the alternative

$$H_a: \delta_L < R < \delta_U$$

where δ_L is the lower margin and δ_U is the upper margin. Rejection of the null hypothesis indicates that the two risks are equivalent. For more information, see Chow, Shao, and Wang (2008).

You can specify the margins by using the MARGIN= *relrisk-option*; by default, the lower margin is 0.8 and the upper margin is 1.25. If you specify a single margin value, PROC FREQTAB uses this value as the lower margin for the equivalence test and computes the upper margin as the inverse of the lower margin.

PROC FREQTAB computes two one-sided tests (TOST) for equivalence analysis (Schuirmann 1987), which include a right-sided test for the lower margin δ_L and a left-sided test for the upper margin δ_U. The lower test statistic uses the lower margin as the null relative risk value, and the p-value is the right-sided probability ($Z > z_L$). The upper test statistic uses the upper margin as the null value, and the p-value is the left-sided probability ($Z < z_U$). The overall p-value is taken to be the larger of the two p-values for the lower and upper tests.

The test statistics are computed by the method that you specify. For more information about the test statistic computation, see the subsections "Wald Test," "Wald Modified Test," "Farrington-Manning (Score) Test," and "Likelihood Ratio Test" in this section.

As part of the equivalence analysis, PROC FREQTAB also provides confidence limits for the relative risk. The confidence coefficient is $100(1 - 2\alpha)\%$ (Schuirmann 1999). The confidence level α is determined by the ALPHA= option in the TABLES statement; by default, ALPHA=0.05, which produces 90% confidence limits for the equivalence analysis. You can compare the confidence limits to the equivalence limits, which are δ_L and δ_U.

Wald Test

The Wald test statistic (which is based on a log transformation of the relative risk) is computed as $z(r_0) = (\log(\hat{r}) - \log(r_0))/\sqrt{v}$, where $\hat{r}$ is the relative risk estimate $(\hat{p}_1/\hat{p}_2)$, r_0 is the null value of the relative risk, and

$$v = \mathrm{Var}(\log(\hat{r})) = 1/n_{11} + 1/n_{21} - 1/n_{1\cdot} - 1/n_{2\cdot}$$

The null value is determined by the type of test (equality, noninferiority, superiority, or equivalence) and the null or margin values that you specify. The side of the p-value and the interpretation of the test are also determined by the type of test; for more information, see the subsections "Equality Test," "Noninferiority Test," "Superiority Test," and "Equivalence Test" in this section.

Wald Modified Test

The Wald modified test statistic is computed by replacing the n_{ij} with $(n_{ij} + 0.5)$ and the $n_{i\cdot}$ with $(n_{i\cdot} + 0.5)$ in the relative risk estimate and variance. The test statistic is computed as $z(r_0) = (\log(\hat{r}_m) - \log(r_0))/\sqrt{v}$, where r_0 is the null value of the relative risk,

$$\hat{r}_m = \frac{(n_{11} + 0.5)/(n_{1\cdot} + 0.5)}{(n_{21} + 0.5)/(n_{2\cdot} + 0.5)}$$

$$v = \mathrm{Var}(\log(\hat{r}_m)) = 1/(n_{11} + 0.5) + 1/(n_{21} + 0.5) - 1/(n_{1\cdot} + 0.5) - 1/(n_{2\cdot} + 0.5)$$

The null value is determined by the type of test (equality, noninferiority, superiority, or equivalence) and the null or margin values that you specify. The side of the p-value and the interpretation of the test are also determined by the type of test; for more information, see the subsections "Equality Test," "Noninferiority Test," "Superiority Test," and "Equivalence Test" in this section.

Farrington-Manning (Score) Test

The relative risk score test statistic (Miettinen and Nurminen 1985; Farrington and Manning 1990) for the null value r_0 is computed as

$$z(r_0) = (\hat{p}_1 - r_0\hat{p}_2) \;/\; \mathrm{se}(r_0)$$

where

$$\mathrm{se}(r_0) = \sqrt{\tilde{p}_1(1-\tilde{p}_1)/n_{1\cdot} \;+\; r_0{}^2\;\tilde{p}_2(1-\tilde{p}_2)/n_{2\cdot}}$$

where $\tilde{p}_1$ and $\tilde{p}_2$ are the maximum likelihood estimates of p_1 and p_2 under the null value r_0. Expressions for the maximum likelihood estimates $\tilde{p}_1$ and $\tilde{p}_2$ are given in the subsection "Score Confidence Limits" in this section.

The null value is determined by the type of test (equality, noninferiority, superiority, or equivalence) and the null or margin values that you specify. The side of the p-value and the interpretation of the test are also determined by the type of test; for more information, see the subsections "Equality Test," "Noninferiority Test," "Superiority Test," and "Equivalence Test" in this section.

Likelihood Ratio Test

The likelihood ratio statistic for the null relative risk value r_0 is computed as

$$G^2(r_0) \;=\; 2\left(n_{11}\log(\hat{p}_1/\tilde{p}_1) + n_{12}\log((1-\hat{p}_1)/(1-\tilde{p}_1)) + n_{21}\log(\hat{p}_2/\tilde{p}_2) + n_{22}\log((1-\hat{p}_2)/(1-\tilde{p}_2))\right)$$

where $\tilde{p}_1$ and $\tilde{p}_2$ are the maximum likelihood estimates of p_1 and p_2 under the null value r_0. Expressions for the maximum likelihood estimates $\tilde{p}_1$ and $\tilde{p}_2$ are given in the subsection "Score Confidence Limits" in this section. For more information, see Miettinen and Nurminen (1985) and Miettinen (1985, chapter 13).

PROC FREQTAB computes the likelihood ratio test statistic $z(r_0)$ for the noninferiority, superiority, and equivalence tests as $\sqrt{G^2(r_0)}$, where the sign is positive if the estimate is greater than the null value ($\hat{r} \geq r_0$) and negative otherwise ($\hat{r} < r_0$).

The null value is determined by the type of test (equality, noninferiority, superiority, or equivalence) and the null or margin values that you specify. The side of the p-value and the interpretation of the test are also determined by the type of test; for more information, see the subsections "Equality Test," "Noninferiority Test," "Superiority Test," and "Equivalence Test" in this section.

Cochran-Armitage Test for Trend

The TREND option in the TABLES statement provides the Cochran-Armitage test for trend, which tests for trend in binomial proportions across levels of a single factor or covariate. This test is appropriate for a two-way table where one variable has two levels and the other variable is ordinal. The two-level variable represents the response, and the other variable represents an explanatory variable with ordered levels. When the two-way has two columns and R rows, PROC FREQTAB tests for trend across the R levels of the row variable, and the binomial proportion is computed as the proportion of observations in the first column. When the table has two rows and C columns, PROC FREQTAB tests for trend across the C levels of the column variable, and the binomial proportion is computed as the proportion of observations in the first row.

The trend test is based on the regression coefficient for the weighted linear regression of the binomial proportions on the scores of the explanatory variable levels. For more information, see Margolin (1988) and Agresti (2002). If the table has two columns and R rows, the trend test statistic is computed as

$$T = \sum_{i=1}^{R} n_{i1}(R_i - \bar{R}) \; / \; \sqrt{p_{\cdot 1}\,(1 - p_{\cdot 1})\,s^2}$$

where R_i is the score of row i, $\bar{R}$ is the average row score, and

$$s^2 = \sum_{i=1}^{R} n_{i\cdot}(R_i - \bar{R})^2$$

The SCORES= option in the TABLES statement determines the type of row scores used in computing the trend test (and other score-based statistics). By default, SCORES=TABLE. For more information, see the section "Scores" on page 475. For character variables, the table scores for the row variable are the row numbers (for example, 1 for the first row, 2 for the second row, and so on). For numeric variables, the table score for each row is the numeric value of the row level. When you perform the trend test, the explanatory variable might be numeric (for example, dose of a test substance), and the variable values might be appropriate scores. If the explanatory variable has ordinal levels that are not numeric, you can assign meaningful scores to the variable levels. Sometimes equidistant scores, such as the table scores for a character variable, might be appropriate. For more information on choosing scores for the trend test, see Margolin (1988).

The null hypothesis for the Cochran-Armitage test is no trend, which means that the binomial proportion $p_{i1} = n_{i1}/n_{i\cdot}$ is the same for all levels of the explanatory variable. Under the null hypothesis, the trend statistic has an asymptotic standard normal distribution.

PROC FREQTAB computes one-sided and two-sided p-values for the trend test. When the test statistic is greater than its null hypothesis expected value of 0, PROC FREQTAB displays the right-sided p-value, which is the probability of a larger value of the statistic occurring under the null hypothesis. A small right-sided p-value supports the alternative hypothesis of increasing trend in proportions from row 1 to row R. When the test statistic is less than or equal to 0, PROC FREQTAB displays the left-sided p-value. A small left-sided p-value supports the alternative of decreasing trend.

The one-sided p-value for the trend test is computed as

$$P_1 = \begin{cases} \text{Prob}(Z > T) & \text{if } T > 0 \\ \text{Prob}(Z < T) & \text{if } T \leq 0 \end{cases}$$

where Z has a standard normal distribution. The two-sided p-value is computed as

$$P_2 = \text{Prob}(|Z| > |T|)$$

PROC FREQTAB also provides exact p-values for the Cochran-Armitage trend test. You can request the exact test by specifying the TREND option in the EXACT statement. See the section "Exact Statistics" on page 547 for more information.

Jonckheere-Terpstra Test

The JT option in the TABLES statement provides the Jonckheere-Terpstra test, which is a nonparametric test for ordered differences among classes. It tests the null hypothesis that the distribution of the response variable does not differ among classes. It is designed to detect alternatives of ordered class differences, which can be expressed as $\tau_1 \leq \tau_2 \leq \cdots \leq \tau_R$ (or $\tau_1 \geq \tau_2 \geq \cdots \geq \tau_R$), with at least one of the inequalities being strict, where τ_i denotes the effect of class i. For such ordered alternatives, the Jonckheere-Terpstra test can be preferable to tests of more general class difference alternatives, such as the Kruskal–Wallis test (produced by the WILCOXON option in the NPAR1WAY procedure). See Pirie (1983) and Hollander and Wolfe (1999) for more information about the Jonckheere-Terpstra test.

The Jonckheere-Terpstra test is appropriate for a two-way table in which an ordinal column variable represents the response. The row variable, which can be nominal or ordinal, represents the classification variable. The levels of the row variable should be ordered according to the ordering you want the test to detect. The order of variable levels is determined by the ORDER= option in the PROC FREQTAB statement. By default, ORDER=INTERNAL, which orders by unformatted values. For more information about how to order variable levels, see the ORDER= option.

The Jonckheere-Terpstra test statistic is computed by first forming $R(R-1)/2$ Mann-Whitney counts $M_{i,i'}$, where $i < i'$, for pairs of rows in the contingency table,

$$\begin{aligned} M_{i,i'} &= \{ \text{ number of times } X_{i,j} < X_{i',j'}, \quad j = 1,\ldots,n_{i.}; \quad j' = 1,\ldots,n_{i'.} \} \\ &\quad + \tfrac{1}{2} \{ \text{ number of times } X_{i,j} = X_{i',j'}, \quad j = 1,\ldots,n_{i.}; \quad j' = 1,\ldots,n_{i'.} \} \end{aligned}$$

where $X_{i,j}$ is response j in row i. The Jonckheere-Terpstra test statistic is computed as

$$J = \sum_{1 \leq i < i' \leq R} \sum M_{i,i'}$$

This test rejects the null hypothesis of no difference among classes for large values of J. Asymptotic p-values for the Jonckheere-Terpstra test are obtained by using the normal approximation for the distribution of the standardized test statistic. The standardized test statistic is computed as

$$J^* = (J - \mathrm{E}_0(J)) \ / \ \sqrt{\mathrm{Var}_0(J)}$$

where $\mathrm{E}_0(J)$ and $\mathrm{Var}_0(J)$ are the expected value and variance of the test statistic under the null hypothesis,

$$\mathrm{E}_0(J) = \left(n^2 - \sum_i n_{i\cdot}^2 \right) / 4$$

$$\mathrm{Var}_0(J) = A/72 + B/\left(36n(n-1)(n-2)\right) + C/\left(8n(n-1)\right)$$

where

$$A = n(n-1)(2n+5) - \sum_i n_{i\cdot}(n_{i\cdot}-1)(2n_{i\cdot}+5) - \sum_j n_{\cdot j}(n_{\cdot j}-1)(2n_{\cdot j}+5)$$

$$B = \left(\sum_i n_{i\cdot}(n_{i\cdot}-1)(n_{i\cdot}-2) \right) \left(\sum_j n_{\cdot j}(n_{\cdot j}-1)(n_{\cdot j}-2) \right)$$

$$C = \left(\sum_i n_{i\cdot}(n_{i\cdot}-1) \right) \left(\sum_j n_{\cdot j}(n_{\cdot j}-1) \right)$$

PROC FREQTAB computes one-sided and two-sided p-values for the Jonckheere-Terpstra test. When the standardized test statistic is greater than its null hypothesis expected value of 0, PROC FREQTAB displays the right-sided p-value, which is the probability of a larger value of the statistic occurring under the null hypothesis. A small right-sided p-value supports the alternative hypothesis of increasing order from row 1 to row R. When the standardized test statistic is less than or equal to 0, PROC FREQTAB displays the left-sided p-value. A small left-sided p-value supports the alternative of decreasing order from row 1 to row R.

The one-sided p-value for the Jonckheere-Terpstra test, P_1, is computed as

$$P_1 = \begin{cases} \mathrm{Prob}(Z > J^*) & \text{if } J^* > 0 \\ \mathrm{Prob}(Z < J^*) & \text{if } J^* \leq 0 \end{cases}$$

where Z has a standard normal distribution. The two-sided p-value, P_2, is computed as

$$P_2 = \mathrm{Prob}(|Z| > |J^*|)$$

PROC FREQTAB also provides exact p-values for the Jonckheere-Terpstra test. You can request the exact test by specifying the JT option in the EXACT statement. See the section "Exact Statistics" on page 547 for more information.

Tests and Measures of Agreement

When you specify the AGREE option in the TABLES statement, PROC FREQTAB computes tests and measures of agreement for square tables (for which the number of rows equals the number of columns). By default, these statistics include McNemar's test for 2×2 tables, Bowker's symmetry test, the simple kappa coefficient, and the weighted kappa coefficient. For multiple strata (n-way tables, where $n > 2$), the AGREE option provides the overall simple and weighted kappa coefficients, in addition to tests for equal kappas (simple and weighted) among strata. For $2 \times 2 \times \cdots \times 2$ tables, the AGREE option provides Cochran's Q test.

Optionally, PROC FREQTAB provides kappa tests and other agreement statistics. In addition to the asymptotic tests described in this section, PROC FREQTAB provides exact p-values for McNemar's test, the simple kappa coefficient test, and the weighted kappa coefficient test. You can request these exact tests by specifying the corresponding options in the EXACT statement. For more information, see the section "Exact Statistics" on page 547.

The following sections provide the formulas that PROC FREQTAB uses to compute agreement statistics. For information about the use and interpretation of these statistics, see Agresti (2002, 2007); Fleiss, Levin, and Paik (2003), and the other references cited for each statistic.

McNemar's Test

PROC FREQTAB computes McNemar's test (McNemar 1947) for 2×2 tables when you specify the AGREE option. This test is appropriate when you are analyzing data from matched pairs of subjects with a dichotomous (yes-no) response. By default, the null hypothesis for McNemar's test is marginal homogeneity, which can be expressed as $p_{1\cdot} = p_{\cdot 1}$; this is equivalent to a discordant proportion ratio (p_{12}/p_{21}) of 1. The corresponding test statistic is computed as

$$Q_M = (n_{12} - n_{21})^2 \;/\; (n_{12} + n_{21})$$

Under the null hypothesis, Q_M has an asymptotic chi-square distribution with 1 degree of freedom.

Optionally, you can specify the null ratio of discordant proportions (p_{12}/p_{21}) by using the AGREE(MNULLRATIO=) option. When the null ratio is r, McNemar's test is computed as

$$Q_M(r) = (n_{12} - e_{12})^2)/e_{12} \;+\; (n_{21} - e_{21})^2/e_{21}$$

where $e_{12} = D/(1 + 1/r)$, $e_{21} = D/(1 + r)$, and D is the number of discordant pairs, $(n_{12} + n_{21})$. Under the null hypothesis, $Q_M(r)$ has an asymptotic chi-square distribution with 1 degree of freedom.

PROC FREQTAB also computes an exact p-value for McNemar's test when you specify the MCNEM option in the EXACT statement.

Bowker's Symmetry Test

The null hypothesis for Bowker's symmetry test (Bowker 1948) is symmetric table-cell proportions, which can be expressed as $p_{ij} = p_{ji}$ for all off-diagonal pairs of table cells. For 2×2 tables, Bowker's test is identical to McNemar's test; therefore, PROC FREQTAB provides Bowker's test only for square tables that are larger than 2×2.

Bowker's symmetry test is computed as

$$Q_B = \sum_{i<j}\sum (n_{ij} - n_{ji})^2 \;/\; (n_{ij} + n_{ji})$$

For large samples, Q_B has an asymptotic chi-square distribution with $R(R-1)/2$ degrees of freedom under the null hypothesis of symmetry, where R is the dimension of the square, two-way table.

By default, the number of degrees of freedom for this test ($R(R-1)/2$) is the number of off-diagonal table-cell comparisons. You can specify the number of degrees of freedom in the AGREE(DFSYM=) option. Alternatively, you can specify the AGREE(DFSYM=ADJUST) option, which reduces the degrees of freedom by the number of off-diagonal table-cell pairs that have a total frequency of 0. For more information, see Hoenig, Morgan, and Brown (1995).

Exact Symmetry Test When you specify the SYMMETRY option in the EXACT statement, PROC FREQTAB provides an exact symmetry test by using the method of Krauth (1973). This exact test is computed by conditioning on the observed frequency sums of the complementary off-diagonal table-cell pairs ($n_{ij} + n_{ji}$). PROC FREQTAB evaluates the symmetry test statistic for all tables in the reference set, which includes all possible tables in which the frequency sums of the off-diagonal table-cell pairs match the corresponding frequency sums in the observed table. The exact p-value is then computed as the sum of the table probabilities for those tables for which the symmetry test statistic is greater than or equal to the observed test statistic. The table probabilities are computed as products of $R(R-1)/2$ binomial probabilities (which correspond to the off-diagonal table-cell pairs in tables of dimension R) by using the binomial proportion 0.5 under the null hypothesis of symmetry. For more information, see the section "Exact Statistics" on page 547.

Alternatively, you can request a Monte Carlo estimate of the exact p-value by specifying the SYMMETRY option together with the MC *computation-option* in the EXACT statement. The Monte Carlo computation for the exact symmetry test is conditional on the same reference set that the exact test uses (tables in which the frequency sums of the off-diagonal table-cell pairs match the corresponding sums in the observed table). For more information, see the section "Monte Carlo Estimation" on page 550.

Simple Kappa Coefficient

The simple kappa coefficient (Cohen 1960) is a measure of interrater agreement. PROC FREQTAB computes the simple kappa coefficient as

$$\hat{\kappa} = (P_o - P_e) \ / \ (1 - P_e)$$

where $P_o = \sum_i p_{ii}$ and $P_e = \sum_i p_{i.}p_{.i}$. The component P_o is the proportion of observed agreement, and the component P_e represents the proportion of chance-expected agreement.

If the two response variables are viewed as two independent ratings of the n subjects, the kappa coefficient is +1 when there is complete agreement of the raters. When the observed agreement exceeds the chance-expected agreement, the kappa coefficient is positive, and its magnitude reflects the strength of agreement. When the observed agreement is less than the chance-expected agreement, the kappa coefficient is negative. The minimum value of kappa is between –1 and 0, depending on the marginal proportions of the table.

PROC FREQTAB computes the asymptotic variance of the simple kappa coefficient as

$$\mathrm{Var}(\hat{\kappa}) = (A + B - C) \ / \ (1 - P_e)^2 \ n$$

where

$$A = \sum_i p_{ii}\,(1-(p_{i\cdot}+p_{\cdot i})(1-\hat{\kappa}))^2$$

$$B = (1-\hat{\kappa})^2 \sum_{i\neq j}\sum p_{ij}(p_{\cdot i}+p_{j\cdot})^2$$

$$C = (\,\hat{\kappa} - P_e(1-\hat{\kappa})\,)^2$$

For more information, see Fleiss, Cohen, and Everitt (1969).

Confidence limits for the simple kappa coefficient are computed as

$$\hat{\kappa} \pm \left(z_{\alpha/2} \times \sqrt{\mathrm{Var}(\hat{\kappa})} \right)$$

where $z_{\alpha/2}$ is the $100(1-\alpha/2)$th percentile of the standard normal distribution. The value of α is determined by the ALPHA= option; by default ALPHA=0.05, which produces 95% confidence limits.

PROC FREQTAB provides an asymptotic test for the simple kappa coefficient. By default, the null hypothesis value of kappa is 0; alternatively, you can specify a nonzero null value of kappa (by using the AGREE(NULLKAPPA=) option in the TABLES statement). When the null value of kappa is nonzero, PROC FREQTAB computes the test statistic as

$$z = (\hat{\kappa} - \kappa_0) \;/\; \sqrt{\mathrm{Var}(\hat{\kappa})}$$

where κ_0 is the null value that you specify and $\mathrm{Var}(\hat{\kappa})$ is the variance of the kappa coefficient.

When the null value of kappa is 0, PROC FREQTAB computes the test statistic as

$$z = \hat{\kappa} \;/\; \sqrt{\mathrm{Var}_0(\hat{\kappa})}$$

where $\mathrm{Var}_0(\hat{\kappa})$ is the variance of the kappa coefficient under the null hypothesis (that kappa is 0) and is computed as

$$\mathrm{Var}_0(\hat{\kappa}) = \left(P_e + P_e^2 - \sum_i p_{i\cdot}\,p_{\cdot i}\,(p_{i\cdot}+p_{\cdot i}) \right) \;/\; (1-P_e)^2\, n$$

This test statistic has an asymptotic standard normal distribution under the null hypothesis. For more information, see Fleiss, Levin, and Paik (2003).

PROC FREQTAB also provides an exact test for the simple kappa coefficient. You can request the exact test by specifying the KAPPA or AGREE option in the EXACT statement. For more information, see the section "Exact Statistics" on page 547.

Kappa Details When you specify the AGREE(KAPPADETAILS) option, PROC FREQTAB displays the "Kappa Details" table, which includes the observed agreement P_o, chance-expected agreement P_e, maximum kappa, and B_n measure.

The maximum kappa, which is the maximum possible value of the kappa coefficient given the marginal proportions of the two-way table, is computed as

$$\max(\kappa) = (\max(P_o) - P_e) \;/\; (1-P_e)$$

where

$$\max(P_o) = \left(\sum_i \min(n_{i\cdot}, n_{\cdot i}) \right) / n$$

The B_n measure (Bangdiwala 1988; Bangdiwala et al. 2008) is computed as

$$B_n = \left(\sum_i n_{ii}^2 \right) / \left(\sum_i \sum_j n_{i\cdot} n_{\cdot i} \right)$$

For 2×2 tables, the "Kappa Details" table also includes the prevalence index and the bias index. The prevalence index is the absolute difference between the agreement proportions, $|p_{11} - p_{22}|$. The bias index is the absolute difference between the disagreement proportions, $|p_{12} - p_{21}|$. For more information, see Sim and Wright (2005) and Byrt, Bishop, and Carlin (1993).

Weighted Kappa Coefficient

The weighted kappa coefficient is a generalization of the simple kappa coefficient that uses weights to quantify the relative differences between categories. For 2×2 tables, the weighted kappa coefficient is equivalent to the simple kappa coefficient; therefore, PROC FREQTAB displays the weighted kappa coefficient only for tables larger than 2×2. PROC FREQTAB computes the kappa weights from the column scores, by using either Cicchetti-Allison weights or Fleiss-Cohen weights, both of which are described in the section "Kappa Weights" on page 533. The kappa weights w_{ij} are constructed so that $0 \leq w_{ij} < 1$ for all $i \neq j$, $w_{ii} = 1$ for all i, and $w_{ij} = w_{ji}$. The weighted kappa coefficient is computed as

$$\hat{\kappa}_w = \left(P_{o(w)} - P_{e(w)} \right) \; / \; \left(1 - P_{e(w)} \right)$$

where

$$P_{o(w)} = \sum_i \sum_j w_{ij} \, p_{ij}$$

$$P_{e(w)} = \sum_i \sum_j w_{ij} \, p_{i\cdot} p_{\cdot j}$$

The component $P_{o(w)}$ is the proportion of observed (weighted) agreement, and the component $P_{e(w)}$ represents the proportion of chance-expected (weighted) agreement. When you specify the AGREE(WTKAPDETAILS) option, PROC FREQTAB displays these components in the "Weighted Kappa Details" table.

PROC FREQTAB computes the asymptotic variance of the weighted kappa coefficient as

$$\mathrm{Var}(\hat{\kappa}_w) = \left(\sum_i \sum_j p_{ij} \left(w_{ij} - (\overline{w}_{i\cdot} + \overline{w}_{\cdot j})(1 - \hat{\kappa}_w) \right)^2 - \left(\hat{\kappa}_w - P_{e(w)}(1 - \hat{\kappa}_w) \right)^2 \right) / \, (1 - P_{e(w)})^2 \, n$$

where

$$\overline{w}_{i\cdot} = \sum_j p_{\cdot j} \, w_{ij}$$

$$\overline{w}_{\cdot j} = \sum_i p_{i\cdot} w_{ij}$$

For more information, see Fleiss, Cohen, and Everitt (1969).

Confidence limits for the weighted kappa coefficient are computed as

$$\hat{\kappa}_w \pm \left(z_{\alpha/2} \times \sqrt{\mathrm{Var}(\hat{\kappa}_w)} \right)$$

where $z_{\alpha/2}$ is the $100(1-\alpha/2)$th percentile of the standard normal distribution. The value of α is determined by the ALPHA= option; by default ALPHA=0.05, which produces 95% confidence limits.

PROC FREQTAB provides an asymptotic test for the weighted kappa coefficient. By default, the null hypothesis value of weighted kappa is 0; alternatively, you can specify a nonzero null value of weighted kappa (by using the AGREE(NULLWTKAPPA=) option in the TABLES statement). When the null value of weighted kappa is nonzero, PROC FREQTAB computes the test statistic as

$$z = (\hat{\kappa}_w - \kappa_{w(0)}) \; / \; \sqrt{\mathrm{Var}(\hat{\kappa}_w)}$$

where $\kappa_{w(0)}$ is the null value that you specify and $\mathrm{Var}(\hat{\kappa}_w)$ is the variance of the weighted kappa coefficient.

When the null value of weighted kappa is 0, PROC FREQTAB computes the test statistic as

$$z = \hat{\kappa}_w \; / \; \sqrt{\mathrm{Var}_0(\hat{\kappa}_w)}$$

where $\mathrm{Var}_0(\hat{\kappa}_w)$ is the variance of the weighted kappa coefficient under the null hypothesis (that weighted kappa is 0) and is computed as

$$\mathrm{Var}_0(\hat{\kappa}_w) = \left(\sum_i \sum_j p_{i\cdot} p_{\cdot j} \left(w_{ij} - (\overline{w}_{i\cdot} + \overline{w}_{\cdot j}) \right)^2 - P_{e(w)}^2 \right) \; / \; (1 - P_{e(w)})^2 \, n$$

This test statistic has an asymptotic standard normal distribution under the null hypothesis. For more information, see Fleiss, Levin, and Paik (2003).

PROC FREQTAB also provides an exact test for the weighted kappa coefficient. You can request the exact test by specifying the KAPPA or AGREE option in the EXACT statement. For more information, see the section "Exact Statistics" on page 547.

Kappa Weights PROC FREQTAB computes kappa coefficient weights by using the column scores and one of the two available weight types. The column scores are determined by the SCORES= option in the TABLES statement. The two available types of kappa weights are Cicchetti-Allison and Fleiss-Cohen weights. By default, PROC FREQTAB uses Cicchetti-Allison weights. If you specify the AGREE(WT=FC) option, PROC FREQTAB uses Fleiss-Cohen weights to compute the weighted kappa coefficient.

PROC FREQTAB computes Cicchetti-Allison kappa coefficient weights as

$$w_{ij} = 1 - \frac{|C_i - C_j|}{C_C - C_1}$$

where C_i is the score for column i and C is the number of categories or columns. For more information, see Cicchetti and Allison (1971).

The SCORES= option in the TABLES statement determines the type of column scores used to compute the kappa weights (and other score-based statistics). By default, SCORES=TABLE. For more information, see

the section "Scores" on page 475. For numeric variables, table scores are the values of the variable levels. You can assign numeric values to the levels in a way that reflects their level of similarity. For example, suppose you have four levels and order them according to similarity. If you assign them values of 0, 2, 4, and 10, the Cicchetti-Allison kappa weights take the following values: $w_{12} = 0.8$, $w_{13} = 0.6$, $w_{14} = 0$, $w_{23} = 0.8$, $w_{24} = 0.2$, and $w_{34} = 0.4$. Note that when there are only two categories (that is, $C = 2$), the weighted kappa coefficient is identical to the simple kappa coefficient.

If you specify the AGREE(WT=FC) option in the TABLES statement, PROC FREQTAB computes Fleiss-Cohen kappa coefficient weights as

$$w_{ij} = 1 - \frac{(C_i - C_j)^2}{(C_C - C_1)^2}$$

For more information, see Fleiss and Cohen (1973).

For the preceding example, the Fleiss-Cohen kappa weights are $w_{12} = 0.96$, $w_{13} = 0.84$, $w_{14} = 0$, $w_{23} = 0.96$, $w_{24} = 0.36$, and $w_{34} = 0.64$.

Prevalence-Adjusted Bias-Adjusted Kappa

When you specify the AGREE(PABAK) option, PROC FREQTAB provides the prevalence-adjusted bias-adjusted kappa coefficient (PABAK) (Byrt, Bishop, and Carlin 1993). This coefficient is computed as

$$\hat{\kappa}_a = (P_o - 1/R) \ / \ (1 - 1/R)$$

where $P_o = \sum_i p_{ii}$ and R is the dimension of the square, two-way table. The component P_o is the proportion of observed agreement, and the component $1/R$ represents the chance-expected agreement. When the table is 2×2, $\hat{\kappa}_a = 2P_o - 1$. For more information, see Sim and Wright (2005), Xie (2013), and Holley and Guilford (1964).

PROC FREQTAB computes the variance of the prevalence-adjusted bias-adjusted kappa as

$$\mathrm{Var}(\hat{\kappa}_a) = (R/(R-1))^2 \, (P_o(1 - P_o)/n)$$

Confidence limits are computed as

$$\hat{\kappa}_a \ \pm \ \left(z_{\alpha/2} \times \sqrt{\mathrm{Var}(\hat{\kappa}_a)} \right)$$

where $z_{\alpha/2}$ is the $100(1-\alpha/2)$th percentile of the standard normal distribution. The value of α is determined by the ALPHA= option; by default ALPHA=0.05, which produces 95% confidence limits.

AC1 Agreement Coefficient

When you specify the AGREE(AC1) option, PROC FREQTAB provides Gwet's first-order agreement coefficient, AC1 (Gwet 2008). This coefficient is computed as

$$\hat{\gamma} = \left(P_o - P_{e(\gamma)}\right) \ / \ \left(1 - P_{e(\gamma)}\right)$$

where $P_o = \sum_i p_{ii}$, $P_e = \sum_i e_i(1 - e_i)/(R - 1)$, and $e_i = (p_{i\cdot} + p_{\cdot i})/2$ The component P_o is the proportion of observed agreement, and the component $P_{e(\gamma)}$ represents the proportion of chance-expected agreement. For more information, see Xie (2013) and Blood and Spratt (2007).

PROC FREQTAB computes the variance of AC1 as

$$\mathrm{Var}(\hat{\gamma}) = \left(P_o(1 - P_o) - 4(1 - \hat{\gamma})A + 4(1 - \hat{\gamma}^2)B\right) \ / \ n(1 - P_{e(\gamma)})^2$$

where

$$A = \sum_i p_{ii}(1-e_i)/(R-1) - P_o P_{e(\gamma)}$$

$$B = \sum_i \sum_j p_{ij} \left(1-(e_i+e_j)/2\right)^2 /(R-1)^2 - P^2_{e(\gamma)}$$

Confidence limits for AC1 are computed as

$$\hat{\gamma} \pm \left(z_{\alpha/2} \times \sqrt{\mathrm{Var}(\hat{\gamma})} \right)$$

where $z_{\alpha/2}$ is the $100(1-\alpha/2)$th percentile of the standard normal distribution. The value of α is determined by the ALPHA= option; by default ALPHA=0.05, which produces 95% confidence limits.

Overall Kappa Coefficient

When there are multiple strata, PROC FREQTAB combines the stratum-level estimates of kappa into an overall estimate of the supposed common value of kappa. Assume there are q strata, indexed by $h = 1, 2, \ldots, q$, and let $\mathrm{Var}(\hat{\kappa}_h)$ denote the variance of $\hat{\kappa}_h$. The estimate of the overall kappa coefficient is computed as

$$\hat{\kappa}_T = \sum_{h=1}^{q} \frac{\hat{\kappa}_h}{\mathrm{Var}(\hat{\kappa}_h)} \Big/ \sum_{h=1}^{q} \frac{1}{\mathrm{Var}(\hat{\kappa}_h)}$$

For more information, see Fleiss, Levin, and Paik (2003).

PROC FREQTAB computes an estimate of the overall weighted kappa in the same way.

Tests for Equal Kappa Coefficients

When there are multiple strata, the following chi-square statistic tests whether the stratum-level values of kappa are equal:

$$Q_K = \sum_{h=1}^{q} (\hat{\kappa}_h - \hat{\kappa}_T)^2 \Big/ \mathrm{Var}(\hat{\kappa}_h)$$

Under the null hypothesis of equal kappas for the q strata, Q_K has an asymptotic chi-square distribution with q–1 degrees of freedom. See Fleiss, Levin, and Paik (2003) for more information. PROC FREQTAB computes a test for equal weighted kappa coefficients in the same way.

Cochran's Q Test

Cochran's Q is computed for multiway tables in which each variable has two levels ($2 \times 2 \times \cdots \times 2$ tables). Cochran's Q statistic is used to test the homogeneity of the one-dimensional margins. Let m denote the number of variables and N denote the total number of subjects. Cochran's Q statistic is computed as

$$Q_C = m(m-1) \left(\sum_{j=1}^{m} T_j^2 - T^2/m \right) \Big/ \left(mT - \sum_{k=1}^{N} S_k^2 \right)$$

where T_j is the number of positive responses for variable j, T is the total number of positive responses over all variables, and S_k is the number of positive responses for subject k. Under the null hypothesis, Cochran's Q has an asymptotic chi-square distribution with m–1 degrees of freedom. For more information, see Cochran (1950). When there are only two binary response variables (m=2), Cochran's Q simplifies to McNemar's test. When there are more than two response categories, you can test for marginal homogeneity by using the repeated measures capabilities of the CATMOD procedure.

Tables with Zero-Weight Rows or Columns

The AGREE statistics are defined only for square tables, where the number of rows equals the number of columns; if a table is not square, PROC FREQTAB does not compute AGREE statistics for the table. In the kappa statistic framework, where two independent raters assign ratings to each of n subjects, suppose one of the raters does not use all possible r rating levels. If the corresponding table contains r rows but only r–1 columns, the table is not square and PROC FREQTAB does not compute AGREE statistics. To create a square table in this situation, you can use the ZEROS option in the WEIGHT statement, which includes zero-weight observations in the analysis. You can include zero-weight observations in the input data table to represent any rating levels that are not used by a rater, so that the input data table has at least one observation for each possible rater and rating combination. When you use this input data table and specify the ZEROS option, the analysis includes all rating levels (even when all levels are not actually assigned by both raters). The resulting table (of rater 1 by rater 2) is a square table, and AGREE statistics can be computed.

For more information, see the description of the ZEROS option in the WEIGHT statement. By default, PROC FREQTAB does not process observations that have weights of 0 because these observations do not contribute to the total frequency count, and because many of the tests and measures of association are undefined for tables that contain zero-weight rows or columns. However, kappa statistics are defined for tables that contain zero-weight rows or columns, and the ZEROS option enables you to input zero-weight observations and construct the tables needed to compute kappa statistics.

Cochran-Mantel-Haenszel Statistics

The CMH option in the TABLES statement gives a stratified statistical analysis of the relationship between the row and column variables after controlling for the strata variables in a multiway table. For example, for the table request A*B*C*D, the CMH option provides an analysis of the relationship between C and D, after controlling for A and B. The stratified analysis provides a way to adjust for the possible confounding effects of A and B without being forced to estimate parameters for them.

The CMH analysis produces Cochran-Mantel-Haenszel statistics, which include the correlation statistic, the ANOVA (row mean scores) statistic, and the general association statistic. For 2×2 tables, the CMH option also provides Mantel-Haenszel and logit estimates of the common odds ratio and the common relative risks, in addition to the Breslow-Day test for homogeneity of the odds ratios.

Exact statistics are also available for stratified 2×2 tables. If you specify the EQOR option in the EXACT statement, PROC FREQTAB provides Zelen's exact test for equal odds ratios. If you specify the COMOR option in the EXACT statement, PROC FREQTAB provides exact confidence limits for the common odds ratio and an exact test that the common odds ratio equals one.

Let the number of strata be denoted by q, indexing the strata by $h = 1, 2, \ldots, q$. Each stratum contains a contingency table with X representing the row variable and Y representing the column variable. For table h, denote the cell frequency in row i and column j by n_{hij}, with corresponding row and column marginal totals denoted by $n_{hi.}$ and $n_{h.j}$, and the overall stratum total by n_h.

Because the formulas for the Cochran-Mantel-Haenszel statistics are more easily defined in terms of matrices,

the following notation is used. Vectors are presumed to be column vectors unless they are transposed ($'$).

$$\begin{aligned}
\mathbf{n}'_{hi} &= (n_{hi1}, n_{hi2}, \ldots, n_{hiC}) && (1 \times C)\\
\mathbf{n}'_{h} &= (\mathbf{n}'_{h1}, \mathbf{n}'_{h2}, \ldots, \mathbf{n}'_{hR}) && (1 \times RC)\\
p_{hi\cdot} &= n_{hi\cdot} \,/\, n_h && (1 \times 1)\\
p_{h\cdot j} &= n_{h\cdot j} \,/\, n_h && (1 \times 1)\\
\mathbf{P}'_{h*\cdot} &= (p_{h1\cdot}, p_{h2\cdot}, \ldots, p_{hR\cdot}) && (1 \times R)\\
\mathbf{P}'_{h\cdot *} &= (p_{h\cdot 1}, p_{h\cdot 2}, \ldots, p_{h\cdot C}) && (1 \times C)
\end{aligned}$$

Assume that the strata are independent and that the marginal totals of each stratum are fixed. The null hypothesis, H_0, is that there is no association between X and Y in any of the strata. The corresponding model is the multiple hypergeometric; this implies that, under H_0, the expected value and covariance matrix of the frequencies are, respectively,

$$\mathbf{m}_h = \mathbf{E}[\mathbf{n}_h \mid H_0] = n_h(\mathbf{P}_{h\cdot *} \otimes \mathbf{P}_{h*\cdot})$$

$$\mathbf{Var}[\mathbf{n}_h \mid H_0] = c\left((\mathbf{D}_{\mathbf{P}h\cdot *} - \mathbf{P}_{h\cdot *}\mathbf{P}'_{h\cdot *}) \otimes (\mathbf{D}_{\mathbf{P}h*\cdot} - \mathbf{P}_{h*\cdot}\mathbf{P}'_{h*\cdot}) \right)$$

where

$$c = n_h^2 \,/\, (n_h - 1)$$

and where $\otimes$ denotes Kronecker product multiplication and $\mathbf{D}_\mathbf{a}$ is a diagonal matrix with the elements of $\mathbf{a}$ on the main diagonal.

The generalized CMH statistic (Landis, Heyman, and Koch 1978) is defined as

$$Q_{\mathrm{CMH}} = \mathbf{G}'{\mathbf{V}_\mathbf{G}}^{-1}\mathbf{G}$$

where

$$\begin{aligned}
\mathbf{G} &= \sum_h \mathbf{B}_h(\mathbf{n}_h - \mathbf{m}_h)\\
\mathbf{V_G} &= \sum_h \mathbf{B}_h \left(\mathbf{Var}[\mathbf{n}_h \mid H_0]\right) \mathbf{B}'_h
\end{aligned}$$

and where

$$\mathbf{B}_h = \mathbf{C}_h \otimes \mathbf{R}_h$$

is a matrix of fixed constants based on column scores $\mathbf{C}_h$ and row scores $\mathbf{R}_h$. When the null hypothesis is true, the CMH statistic has an asymptotic chi-square distribution with degrees of freedom equal to the rank of $\mathbf{B}_h$. If $\mathbf{V_G}$ is found to be singular, PROC FREQTAB prints a message and sets the value of the CMH statistic to missing.

PROC FREQTAB computes three CMH statistics by using this formula for the generalized CMH statistic, with different row and column score definitions for each statistic. The CMH statistics that PROC FREQTAB computes are the correlation statistic, the ANOVA (row mean scores) statistic, and the general association

statistic. These statistics test the null hypothesis of no association against different alternative hypotheses. The following sections describe the computation of these CMH statistics.

CAUTION: The CMH statistics have low power for detecting an association in which the patterns of association for some of the strata are in the opposite direction of the patterns displayed by other strata. Thus, a nonsignificant CMH statistic suggests either that there is no association or that no pattern of association has enough strength or consistency to dominate any other pattern.

Correlation Statistic

The correlation statistic, popularized by Mantel and Haenszel, has 1 degree of freedom and is known as the Mantel-Haenszel statistic (Mantel and Haenszel 1959; Mantel 1963).

The alternative hypothesis for the correlation statistic is that there is a linear association between X and Y in at least one stratum. If either X or Y does not lie on an ordinal (or interval) scale, this statistic is not meaningful.

To compute the correlation statistic, PROC FREQTAB uses the formula for the generalized CMH statistic with the row and column scores determined by the SCORES= option in the TABLES statement. See the section "Scores" on page 475 for more information about the available score types. The matrix of row scores $\mathbf{R}_h$ has dimension $1 \times R$, and the matrix of column scores $\mathbf{C}_h$ has dimension $1 \times C$.

When there is only one stratum, this CMH statistic reduces to $(n-1)r^2$, where r is the Pearson correlation coefficient between X and Y. When nonparametric (RANK or RIDIT) scores are specified, the statistic reduces to $(n-1)r_s^2$, where r_s is the Spearman rank correlation coefficient between X and Y. When there is more than one stratum, this CMH statistic becomes a stratum-adjusted correlation statistic.

ANOVA (Row Mean Scores) Statistic

The ANOVA statistic can be used only when the column variable Y lies on an ordinal (or interval) scale so that the mean score of Y is meaningful. For the ANOVA statistic, the mean score is computed for each row of the table, and the alternative hypothesis is that, for at least one stratum, the mean scores of the R rows are unequal. In other words, the statistic is sensitive to location differences among the R distributions of Y.

The matrix of column scores $\mathbf{C}_h$ has dimension $1 \times C$, and the column scores are determined by the SCORES= option.

The matrix of row scores $\mathbf{R}_h$ has dimension $(R-1) \times R$ and is created internally by PROC FREQTAB as

$$\mathbf{R}_h = [\mathbf{I}_{R-1}, -\mathbf{J}_{R-1}]$$

where $\mathbf{I}_{R-1}$ is an identity matrix of rank $R-1$ and $\mathbf{J}_{R-1}$ is an $(R-1) \times 1$ vector of ones. This matrix has the effect of forming $R-1$ independent contrasts of the R mean scores.

When there is only one stratum, this CMH statistic is essentially an analysis of variance (ANOVA) statistic in the sense that it is a function of the variance ratio F statistic that would be obtained from a one-way ANOVA on the dependent variable Y. If nonparametric scores are specified in this case, the ANOVA statistic is a Kruskal-Wallis test.

When there is more than one stratum, this CMH statistic corresponds to a stratum-adjusted ANOVA or Kruskal-Wallis test. In the special case where there is one subject per row and one subject per column in the contingency table of each stratum, this CMH statistic is identical to Friedman's chi-square.

General Association Statistic

The alternative hypothesis for the general association statistic is that, for at least one stratum, there is some kind of association between X and Y. This statistic is always interpretable because it does not require an ordinal scale for either X or Y.

For the general association statistic, the matrix $\mathbf{R}_h$ is the same as the one used for the ANOVA statistic. The matrix $\mathbf{C}_h$ is defined similarly as

$$\mathbf{C}_h = [\mathbf{I}_{C-1}, -\mathbf{J}_{C-1}]$$

PROC FREQTAB generates both score matrices internally. When there is only one stratum, the general association CMH statistic reduces to $Q_P(n-1)/n$, where Q_P is the Pearson chi-square statistic. When there is more than one stratum, the CMH statistic becomes a stratum-adjusted Pearson chi-square statistic. Note that a similar adjustment can be made by summing the Pearson chi-squares across the strata. However, the latter statistic requires a large sample size in each stratum to support the resulting chi-square distribution with $q(R-1)(C-1)$ degrees of freedom. The CMH statistic requires only a large overall sample size because it has only $(R-1)(C-1)$ degrees of freedom.

See Cochran (1954); Mantel and Haenszel (1959); Mantel (1963); Birch (1965); Landis, Heyman, and Koch (1978).

Mantel-Fleiss Criterion

If you specify the CMH(MANTELFLEISS) option in the TABLES statement, PROC FREQTAB computes the Mantel-Fleiss criterion for stratified 2×2 tables. The Mantel-Fleiss criterion can be used to assess the validity of the chi-square approximation for the distribution of the Mantel-Haenszel statistic for 2×2 tables. For more information, see Mantel and Fleiss (1980); Mantel and Haenszel (1959); Stokes, Davis, and Koch (2012); Dmitrienko et al. (2005).

The Mantel-Fleiss criterion is computed as

$$\mathrm{MF} = \min\left(\left[\sum_h m_{h11} - \sum_h (n_{h11})_L\right],\ \left[\sum_h (n_{h11})_U - \sum_h m_{h11}\right]\right)$$

where m_{h11} is the expected value of n_{h11} under the hypothesis of no association between the row and column variables in table h, $(n_{h11})_L$ is the minimum possible value of the table cell frequency, and $(n_{h11})_U$ is the maximum possible value,

$$\begin{aligned} m_{h11} &= n_{h1\cdot}\, n_{h\cdot 1} \,/\, n_h \\ (n_{h11})_L &= \max(\,0,\ \ n_{h1\cdot} - n_{h\cdot 2}\,) \\ (n_{h11})_U &= \min(\,n_{h\cdot 1},\ \ n_{h1\cdot}\,) \end{aligned}$$

The Mantel-Fleiss guideline accepts the validity of the Mantel-Haenszel approximation when the value of the criterion is at least 5. When the criterion is less than 5, PROC FREQTAB displays a warning.

Adjusted Odds Ratio and Relative Risk Estimates

The CMH option provides adjusted odds ratio and relative risk estimates for stratified 2×2 tables. For each of these measures, PROC FREQTAB computes a Mantel-Haenszel estimate and a logit estimate. These estimates apply to n-way table requests in the TABLES statement, when the row and column variables both have two levels.

For example, for the table request A*B*C*D, if the row and column variables C and D both have two levels, PROC FREQTAB provides odds ratio and relative risk estimates, adjusting for the confounding variables A and B.

The choice of an appropriate measure depends on the study design. For case-control (retrospective) studies, the odds ratio is appropriate. For cohort (prospective) or cross-sectional studies, the relative risk is appropriate. See the section "Odds Ratio and Relative Risks" on page 516 for more information on these measures.

Throughout this section, z denotes the $100(1-\alpha/2)$th percentile of the standard normal distribution.

Odds Ratio, Case-Control Studies PROC FREQTAB provides Mantel-Haenszel and logit estimates for the common odds ratio for stratified 2×2 tables.

Mantel-Haenszel Estimator

The Mantel-Haenszel estimate of the common odds ratio is computed as

$$\mathrm{OR}_{\mathrm{MH}} = \left(\sum_h n_{h11}\, n_{h22}/n_h \right) \Big/ \left(\sum_h n_{h12}\, n_{h21}/n_h \right)$$

It is always computed unless the denominator is 0. For more information, see Mantel and Haenszel (1959) and Agresti (2002).

To compute confidence limits for the common odds ratio, PROC FREQTAB uses the Robins, Breslow, and Greenland (1986) variance estimate for $\log(\mathrm{OR}_{\mathrm{MH}})$. The $100(1-\alpha/2)\%$ confidence limits for the common odds ratio are

$$\left(\mathrm{OR}_{\mathrm{MH}} \times \exp(-z\hat{\sigma}),\ \ \mathrm{OR}_{\mathrm{MH}} \times \exp(z\hat{\sigma}) \right)$$

where

$$\begin{aligned}
\hat{\sigma}^2 &= \widehat{\mathrm{Var}}\left(\log(\mathrm{OR}_{\mathrm{MH}}) \right) \\
&= \frac{\sum_h (n_{h11}+n_{h22})(n_{h11}\, n_{h22})/n_h^2}{2\left(\sum_h n_{h11}\, n_{h22}/n_h\right)^2} \\
&\quad + \frac{\sum_h [(n_{h11}+n_{h22})(n_{h12}\, n_{h21}) + (n_{h12}+n_{h21})(n_{h11}\, n_{h22})]/n_h^2}{2\left(\sum_h n_{h11}\, n_{h22}/n_h\right)\left(\sum_h n_{h12}\, n_{h21}/n_h\right)} \\
&\quad + \frac{\sum_h (n_{h12}+n_{h21})(n_{h12}\, n_{h21})/n_h^2}{2\left(\sum_h n_{h12}\, n_{h21}/n_h\right)^2}
\end{aligned}$$

Note that the Mantel-Haenszel odds ratio estimator is less sensitive to small n_h than the logit estimator.

Logit Estimator

The adjusted logit estimate of the common odds ratio (Woolf 1955) is computed as

$$\mathrm{OR_L} = \exp\left(\sum_h w_h \log(\mathrm{OR}_h) \;/\; \sum_h w_h\right)$$

and the corresponding $100(1-\alpha)\%$ confidence limits are

$$\left(\mathrm{OR_L} \times \exp\left(-z/\sqrt{\sum_h w_h}\right),\;\; \mathrm{OR_L} \times \exp\left(z/\sqrt{\sum_h w_h}\right)\right)$$

where OR_h is the odds ratio for stratum h, and

$$w_h = 1/\mathrm{Var}(\log(\mathrm{OR}_h))$$

If any table cell frequency in a stratum h is 0, PROC FREQTAB adds 0.5 to each cell of the stratum before computing OR_h and w_h (Haldane 1956) for the logit estimate. The procedure provides a warning when this occurs.

Relative Risks, Cohort Studies PROC FREQTAB provides Mantel-Haenszel and logit estimates of the common relative risks for stratified 2×2 tables.

Mantel-Haenszel Estimator

The Mantel-Haenszel estimate of the common relative risk for column 1 is computed as

$$\mathrm{RR_{MH}} = \left(\sum_h n_{h11}\, n_{h2\cdot} \,/\, n_h\right) \;/\; \left(\sum_h n_{h21}\, n_{h1\cdot} \,/\, n_h\right)$$

It is always computed unless the denominator is 0. For more information, see Mantel and Haenszel (1959) and Agresti (2002).

To compute confidence limits for the common relative risk, PROC FREQTAB uses the Greenland and Robins (1985) variance estimate for $\log(\mathrm{RR_{MH}})$. The $100(1-\alpha/2)\%$ confidence limits for the common relative risk are

$$\left(\,\mathrm{RR_{MH}} \times \exp(-z\hat{\sigma}),\;\; \mathrm{RR_{MH}} \times \exp(z\hat{\sigma})\,\right)$$

where

$$\hat{\sigma}^2 = \widehat{\mathrm{Var}}(\,\log(\mathrm{RR_{MH}})\,) = \frac{\sum_h (n_{h1\cdot}\, n_{h2\cdot}\, n_{h\cdot 1} - n_{h11}\, n_{h21}\, n_h)/n_h^2}{\left(\sum_h n_{h11}\, n_{h2\cdot}/n_h\right)\left(\sum_h n_{h21}\, n_{h1\cdot}/n_h\right)}$$

Logit Estimator

The adjusted logit estimate of the common relative risk for column 1 is computed as

$$\mathrm{RR_L} = \exp\left(\sum_h w_h \log(\mathrm{RR}_h) \;/\; \sum w_h\right)$$

and the corresponding $100(1-\alpha)\%$ confidence limits are

$$\left(\mathrm{RR_L} \times \exp\left(-z \,/\, \sqrt{\sum_h w_h} \right),\ \mathrm{RR_L} \times \exp\left(z \,/\, \sqrt{\sum_h w_h} \right) \right)$$

where RR_h is the column 1 relative risk estimate for stratum h and

$$w_h = 1 \,/\, \mathrm{Var}(\log(\mathrm{RR}_h))$$

If n_{h11} or n_{h21} is 0, PROC FREQTAB adds 0.5 to each cell of the stratum before computing RR_h and w_h for the logit estimate. The procedure prints a warning when this occurs. For more information, see Kleinbaum, Kupper, and Morgenstern (1982, Sections 17.4 and 17.5).

Breslow-Day Test for Homogeneity of the Odds Ratios

When you specify the CMH option, PROC FREQTAB computes the Breslow-Day test for stratified 2×2 tables. It tests the null hypothesis that the odds ratios for the q strata are equal. When the null hypothesis is true, the statistic has approximately a chi-square distribution with q–1 degrees of freedom. See Breslow and Day (1980) and Agresti (2007) for more information.

The Breslow-Day statistic is computed as

$$Q_{\mathrm{BD}} = \sum_h (n_{h11} - \mathrm{E}(n_{h11} \mid \mathrm{OR_{MH}}))^2 \,/\, \mathrm{Var}(n_{h11} \mid \mathrm{OR_{MH}})$$

where E and Var denote expected value and variance, respectively. The summation does not include any table that contains a row or column that has a total frequency of 0. If $\mathrm{OR_{MH}}$ is 0 or undefined, PROC FREQTAB does not compute the statistic and prints a warning message.

For the Breslow-Day test to be valid, the sample size should be relatively large in each stratum, and at least 80% of the expected cell counts should be greater than 5. Note that this is a stricter sample size requirement than the requirement for the Cochran-Mantel-Haenszel test for $q \times 2 \times 2$ tables, in that each stratum sample size (not just the overall sample size) must be relatively large. Even when the Breslow-Day test is valid, it might not be very powerful against certain alternatives, as discussed in Breslow and Day (1980).

If you specify the BDT option, PROC FREQTAB computes the Breslow-Day test with Tarone's adjustment, which subtracts an adjustment factor from Q_{BD} to make the resulting statistic asymptotically chi-square. The Breslow-Day-Tarone statistic is computed as

$$Q_{\mathrm{BDT}} = Q_{\mathrm{BD}} - \left(\sum_h (n_{h11} - \mathrm{E}(n_{h11} \mid \mathrm{OR_{MH}})) \right)^2 \,/\, \sum_h \mathrm{Var}(n_{h11} \mid \mathrm{OR_{MH}})$$

For more information, see Tarone (1985); Jones et al. (1989); Breslow (1996).

Q Test for Homogeneity of Odds Ratios

PROC FREQTAB computes a Q test for homogeneity of odds ratios as

$$Q = \sum_h w_h (\theta_h - \bar{\theta})^2$$

where θ_h is the log odds ratio in stratum h and $\bar{\theta}$ is the logit estimate of the common log odds ratio. The stratum weights w_h are

$$w_h = 1/\mathrm{Var}(\theta_h)$$

where

$$\mathrm{Var}(\theta_h) = 1/n_{h11} + 1/n_{h12} + 1/n_{h21} + 1/n_{h22}$$

If any table cell frequency in a stratum is 0, PROC FREQTAB adds 0.5 to each cell frequency in the stratum before computing θ_h and w_h. For more information, see the sections "Odds Ratio" on page 516 and "Adjusted Odds Ratio and Relative Risk Estimates" on page 540.

Under the null hypothesis of homogeneity, the Q statistic has approximately a chi-square distribution with k–1 degrees of freedom, where k is the number of strata.

I-Square Measure of Heterogeneity

The I-square statistic (Higgins and Thompson 2002) is a measure of heterogeneity among strata for stratified 2×2 tables. I-square is expressed in percentage form and can be interpreted as the proportion of total variability that is due to between-strata variability. For more information, see Higgins et al. (2003) and Thorlund et al. (2012).

PROC FREQTAB computes I-square for the Q test for odds ratios as

$$I^2 = \max(\ 100\% \times (Q - (k-1))/Q,\ 0\ )$$

where k is the number of strata and Q is described in the section "Q Test for Homogeneity of Odds Ratios" on page 542.

PROC FREQTAB computes uncertainty limits for I-square by using the test-based method of Higgins and Thompson (2002). This method constructs confidence limits for H, where $H^2 = Q/(k-1)$. When $Q > k$ or $k = 2$, the standard error of $\log(H)$ is computed as

$$\mathrm{se}_1(\log(H)) = (\ \log(Q) - \log(k-1)\ )\ /\ 2\left(\sqrt{2Q} - \sqrt{2k-3}\right)$$

When $Q \le k$ and $k > 2$, the standard error of $\log(H)$ is computed as

$$\mathrm{se}_0(\log(H)) = \sqrt{\left(\ 1 - (1/3(k-2)^2)\ \right)\ /\ 2(k-2)}$$

The $100(1-\alpha)\%$ confidence limits for H are

$$\left(\ H \times \exp(-z_{\alpha/2} \times \mathrm{se}(\log(H)),\ \ H \times \exp(z_{\alpha/2} \times \mathrm{se}(\log(H))\ \right)$$

The uncertainty limits for I^2 are computed by transforming the confidence limits for H, where $I^2 = 1 - (1/H^2)$.

When I^2 is 0, PROC FREQTAB sets the lower confidence limit to 0 and determines the upper limit by using the level α (instead of $\alpha/2$).

Zelen's Exact Test for Equal Odds Ratios

If you specify the EQOR option in the EXACT statement, PROC FREQTAB computes Zelen's exact test for equal odds ratios for stratified 2×2 tables. Zelen's test is an exact counterpart to the Breslow-Day asymptotic test for equal odds ratios. The reference set for Zelen's test includes all possible $q \times 2 \times 2$ tables with the same row, column, and stratum totals as the observed multiway table and with the same sum of cell (1,1) frequencies as the observed table. The test statistic is the probability of the observed $q \times 2 \times 2$ table conditional on the fixed margins, which is a product of hypergeometric probabilities.

The p-value for Zelen's test is the sum of all table probabilities that are less than or equal to the observed table probability, where the sum is computed over all tables in the reference set determined by the fixed margins and the observed sum of cell (1,1) frequencies. This test is similar to Fisher's exact test for two-way tables. For more information, see Zelen (1971); Hirji (2006); Agresti (1992). PROC FREQTAB computes Zelen's exact test by using the polynomial multiplication algorithm of Hirji et al. (1996).

Exact Confidence Limits for the Common Odds Ratio

If you specify the COMOR option in the EXACT statement, PROC FREQTAB computes exact confidence limits for the common odds ratio for stratified 2×2 tables. This computation assumes that the odds ratio is constant over all the 2×2 tables. Exact confidence limits are constructed from the distribution of $S = \sum_h n_{h11}$, conditional on the marginal totals of the 2×2 tables.

Because this is a discrete problem, the confidence coefficient for these exact confidence limits is not exactly $(1 - \alpha)$ but is at least $(1 - \alpha)$. Thus, these confidence limits are conservative. See Agresti (1992) for more information.

PROC FREQTAB computes exact confidence limits for the common odds ratio by using an algorithm based on Vollset, Hirji, and Elashoff (1991). See also Mehta, Patel, and Gray (1985).

Conditional on the marginal totals of 2×2 table h, let the random variable S_h denote the frequency of table cell (1,1). Given the row totals $n_{h1\cdot}$ and $n_{h2\cdot}$ and column totals $n_{h\cdot 1}$ and $n_{h\cdot 2}$, the lower and upper bounds for S_h are l_h and u_h,

$$\begin{aligned} l_h &= \max\,(\,0,\;\; n_{h1\cdot} - n_{h\cdot 2}\,) \\ u_h &= \min\,(\,n_{h1\cdot},\;\; n_{h\cdot 1}\,) \end{aligned}$$

Let C_{s_h} denote the hypergeometric coefficient,

$$C_{s_h} = \binom{n_{h\cdot 1}}{s_h} \binom{n_{h\cdot 2}}{n_{h1\cdot} - s_h}$$

and let ϕ denote the common odds ratio. Then the conditional distribution of S_h is

$$P(\,S_h = s_h \mid n_{1\cdot},\; n_{\cdot 1},\; n_{\cdot 2}\,) = C_{s_h}\,\phi^{\,s_h} \,/ \sum_{x\,=\,l_h}^{x\,=\,u_h} C_x\,\phi^{\,x}$$

Summing over all the 2×2 tables, $S = \sum_h S_h$, and the lower and upper bounds of S are l and u,

$$l = \sum_h l_h \quad \text{and} \quad u = \sum_h u_h$$

The conditional distribution of the sum S is

$$P(\,S = s \mid n_{h1\cdot},\; n_{h\cdot 1},\; n_{h\cdot 2};\;\; h = 1, \ldots, q\,) = C_s\,\phi^{\,s} \,/ \sum_{x\,=\,l}^{x\,=\,u} C_x\,\phi^{\,x}$$

where

$$C_s = \sum_{s_1 + \cdots + s_q \,=\, s} \left(\prod_h C_{s_h} \right)$$

Let s_0 denote the observed sum of cell (1,1) frequencies over the q tables. The following two equations are solved iteratively for lower and upper confidence limits for the common odds ratio, ϕ_1 and ϕ_2:

$$\sum_{x=s_0}^{x=u} C_x \, {\phi_1}^x \; / \sum_{x=l}^{x=u} C_x \, {\phi_1}^x \;\; = \;\; \alpha/2$$

$$\sum_{x=l}^{x=s_0} C_x \, {\phi_2}^x \; / \sum_{x=l}^{x=u} C_x \, {\phi_2}^x \;\; = \;\; \alpha/2$$

When the observed sum s_0 equals the lower bound l, PROC FREQTAB sets the lower confidence limit to 0 and determines the upper limit with level α. Similarly, when the observed sum s_0 equals the upper bound u, PROC FREQTAB sets the upper confidence limit to infinity and determines the lower limit with level α.

When you specify the COMOR option in the EXACT statement, PROC FREQTAB also computes the exact test that the common odds ratio equals one. Setting $\phi = 1$, the conditional distribution of the sum S under the null hypothesis becomes

$$P_0(\, S = s \mid n_{h1\cdot},\, n_{h\cdot 1},\, n_{h\cdot 2};\;\; h = 1, \ldots, q \,) = C_s \; / \sum_{x=l}^{x=u} C_x$$

The point probability for this exact test is the probability of the observed sum s_0 under the null hypothesis, conditional on the marginals of the stratified 2×2 tables, and is denoted by $P_0(s_0)$. The expected value of S under the null hypothesis is

$$\mathrm{E}_0(S) = \sum_{x=l}^{x=u} x \, C_x \; / \sum_{x=l}^{x=u} C_x$$

The one-sided exact p-value is computed from the conditional distribution as $P_0(S >= s_0)$ or $P_0(S \leq s_0)$, depending on whether the observed sum s_0 is greater or less than $\mathrm{E}_0(S)$,

$$P_1 \;\; = \;\; P_0(\, S >= s_0 \,) = \sum_{x=s_0}^{x=u} C_x \; / \sum_{x=l}^{x=u} C_x \quad \text{if} \;\; s_0 > \mathrm{E}_0(S)$$

$$P_1 \;\; = \;\; P_0(\, S <= s_0 \,) = \sum_{x=l}^{x=s_0} C_x \; / \sum_{x=l}^{x=u} C_x \quad \text{if} \;\; s_0 \leq \mathrm{E}_0(S)$$

PROC FREQTAB computes two-sided p-values for this test according to three different definitions. A two-sided p-value is computed as twice the one-sided p-value, setting the result equal to one if it exceeds one,

$${P_2}^a = 2 \times P_1$$

In addition, a two-sided p-value is computed as the sum of all probabilities less than or equal to the point probability of the observed sum s_0, summing over all possible values of s, $\;l \leq s \leq u$,

$${P_2}^b = \sum_{l \leq s \leq u : P_0(s) \leq P_0(s_0)} P_0(s)$$

Also, a two-sided p-value is computed as the sum of the one-sided p-value and the corresponding area in the opposite tail of the distribution, equidistant from the expected value,

$${P_2}^c = P_0 \; (\, |S - \mathrm{E}_0(S)| \;\geq\; |s_0 - \mathrm{E}_0(S)| \,)$$

Gail-Simon Test for Qualitative Interactions

The GAILSIMON option in the TABLES statement provides the Gail-Simon test for qualitative interaction for stratified 2×2 tables. For more information, see Gail and Simon (1985); Silvapulle (2001); Dmitrienko et al. (2005).

The Gail-Simon test is based on the risk differences in stratified 2×2 tables, where the risk difference is defined as the row 1 risk (proportion in column 1) minus the row 2 risk. For more information, see the section "Risks and Risk Differences" on page 501. By default, PROC FREQTAB uses column 1 risks to compute the Gail-Simon test. If you specify the GAILSIMON(COLUMN=2) option, PROC FREQTAB uses column 2 risks.

PROC FREQTAB computes the Gail-Simon test statistics as described in Gail and Simon (1985),

$$
\begin{aligned}
Q- &= \sum_h (d_h/s_h)^2 \; I(d_h > 0) \\
Q+ &= \sum_h (d_h/s_h)^2 \; I(d_h < 0) \\
Q &= \min\,(Q-,\; Q+)
\end{aligned}
$$

where d_h is the risk difference in table h, s_h is the standard error of the risk difference, and $I(d_h > 0)$ equals 1 if $d_h > 0$ and 0 otherwise. Similarly, $I(d_h < 0)$ equals 1 if $d_h < 0$ and 0 otherwise. The q 2×2 tables (strata) are indexed by $h = 1, 2, \ldots, q$.

The p-values for the Gail-Simon statistics are computed as

$$
\begin{aligned}
P(Q-) &= \sum_h (1 - F_h(Q-)) \; B(h; n = q, p = 0.5) \\
P(Q+) &= \sum_h (1 - F_h(Q+)) \; B(h; n = q, p = 0.5) \\
P(Q) &= \sum_{h=1}^{q-1} (1 - F_h(Q)) \; B(h; n = (q-1), p = 0.5)
\end{aligned}
$$

where $F_h(\cdot)$ is the cumulative chi-square distribution function with h degrees of freedom and $B(h; n, p)$ is the binomial probability function with parameters n and p. The statistic Q tests the null hypothesis of no qualitative interaction. The statistic $Q-$ tests the null hypothesis of positive risk differences. A small p-value for $Q-$ indicates negative differences; similarly, a small p-value for $Q+$ indicates positive risk differences.

Exact Statistics

Exact statistics can be useful in situations where the asymptotic assumptions are not met and therefore the asymptotic p-values might not be close approximations for the true p-values. Standard asymptotic methods involve the assumption that the test statistic follows a particular distribution when the sample size is sufficiently large. When the sample size is not large, asymptotic results might not be valid. Asymptotic results might also be unreliable when the distribution of the data is sparse, skewed, or heavily tied. For more information, see Agresti (2007) and Bishop, Fienberg, and Holland (1975). Exact computations are based on the statistical theory of exact conditional inference for contingency tables, which is reviewed by Agresti (1992).

In addition to the computation of exact p-values, PROC FREQTAB provides the option to estimate exact p-values by Monte Carlo simulation. This can be useful for large problems where exact computations require a substantial amount of time and memory but asymptotic approximations might not be sufficient.

Exact p-values are available for many tests that PROC FREQTAB performs. For one-way tables, PROC FREQTAB provides exact p-values for the binomial proportion test, the chi-square goodness-of-fit test, and the likelihood ratio chi-square test. PROC FREQTAB also provides exact (Clopper-Pearson) confidence limits for the binomial proportion.

For two-way tables, PROC FREQTAB provides exact p-values for the following tests: Pearson chi-square test, likelihood ratio chi-square test, Mantel-Haenszel chi-square test, Fisher's exact test, Jonckheere-Terpstra test, Cochran-Armitage test for trend, and the symmetry test. PROC FREQTAB also computes exact p-values for tests of the following statistics: Pearson correlation coefficient, Spearman correlation coefficient, Kendall's tau-b, Stuart's tau-c, Somers' $D(C|R)$, Somers' $D(R|C)$, simple kappa coefficient, and weighted kappa coefficient.

For 2×2 tables, PROC FREQTAB provides the exact McNemar's test, exact confidence limits for the odds ratio, and Barnard's unconditional exact test for the risk (proportion) difference. PROC FREQTAB also provides exact unconditional confidence limits for the risk (proportion) difference and for the relative risk (ratio of proportions). For stratified 2×2 tables, PROC FREQTAB provides Zelen's exact test for equal odds ratios, exact confidence limits for the common odds ratio, and an exact test for the common odds ratio.

The following sections summarize the exact computational algorithms, define the exact p-values that PROC FREQTAB computes, discuss the computational resource requirements, and describe the Monte Carlo estimation option.

Computational Algorithms

PROC FREQTAB computes exact p-values for general $R \times C$ tables by using the network algorithm, which was developed by Mehta and Patel (1983). This algorithm provides a substantial advantage over direct enumeration, which can be very time-consuming and feasible only for small problems. See Agresti (1992) for a review of algorithms for computation of exact p-values, and see Mehta, Patel, and Tsiatis (1984) and Mehta, Patel, and Senchaudhuri (1991) for information about the performance of the network algorithm.

To implement the network algorithm, PROC FREQTAB defines a reference set from the input data. For most exact tests that PROC FREQTAB provides, the reference set includes all tables that have the same marginal row and column sums as the observed table. Corresponding to the reference set, the network algorithm forms a directed acyclic network consisting of nodes in a number of stages. A path through the network corresponds to a distinct table in the reference set. The distances between nodes are defined so that the total distance of a path through the network is the corresponding value of the test statistic. At each node, the algorithm computes the shortest and longest path distances for all the paths that pass through that node. For statistics

that can be expressed as a linear combination of cell frequencies multiplied by increasing row and column scores, PROC FREQTAB computes shortest and longest path distances by using the algorithm of Agresti, Mehta, and Patel (1990). For statistics of other forms, PROC FREQTAB computes an upper bound for the longest path and a lower bound for the shortest path by following the approach of Valz and Thompson (1994).

The longest and shortest path distances (bounds) for a node are compared to the value of the test statistic to determine whether all paths through the node contribute to the *p*-value, no paths through the node contribute to the *p*-value, or neither of these situations occurs. If all paths through the node contribute, the *p*-value is incremented accordingly, and these paths are eliminated from further analysis. If no paths contribute, these paths are eliminated from further analysis. Otherwise, the algorithm continues to process this node and the associated paths. The algorithm finishes when all nodes have been accounted for.

PROC FREQTAB performs the network algorithm by using full numerical precision to represent all statistics, row and column scores, and other quantities in the computations. Although it is possible to use rounding to improve the speed and memory requirements of the algorithm, PROC FREQTAB does not use rounding because it might reduce the accuracy of the results.

For one-way tables, PROC FREQTAB computes the exact chi-square goodness-of-fit test by the method of Radlow and Alf (1975). PROC FREQTAB generates all possible one-way tables with the observed total sample size and number of categories. For each possible table, PROC FREQTAB compares its chi-square value with the value for the observed table. If the table's chi-square value is greater than or equal to the observed chi-square, PROC FREQTAB increments the exact *p*-value by the probability of that table, which is calculated under the null hypothesis by using the multinomial frequency distribution. By default, the null hypothesis states that all categories have equal proportions. If you specify null hypothesis proportions or frequencies by using the TESTP= or TESTF= option in the TABLES statement, PROC FREQTAB calculates the exact chi-square test based on that null hypothesis.

Other exact computations are described in sections about the individual statistics. For information about the computation of exact confidence limits and tests for the binomial proportion, see the section "Binomial Proportion" on page 491. For information about computation of exact confidence limits for the odds ratio, see the subsection "Exact Confidence Limits" in the section "Confidence Limits for the Odds Ratio" on page 516. For information about other exact computations, see the subsection "Exact Unconditional Confidence Limits" in the section "Confidence Limits for the Risk Difference" on page 502, the subsection "Exact Unconditional Confidence Limits" in the section "Confidence Limits for the Relative Risk" on page 519, and the sections "Exact Symmetry Test" on page 530, "Exact Confidence Limits for the Common Odds Ratio" on page 544 and "Zelen's Exact Test for Equal Odds Ratios" on page 543.

Definition of *p*-Values

For several tests in PROC FREQTAB, the test statistic is nonnegative, and large values of the test statistic indicate a departure from the null hypothesis. Such nondirectional tests include the Pearson chi-square, the likelihood ratio chi-square, the Mantel-Haenszel chi-square, Fisher's exact test for tables larger than 2×2, McNemar's test, the symmetry test, and the one-way chi-square goodness-of-fit test. The exact *p*-value for a nondirectional test is the sum of probabilities for those tables having a test statistic greater than or equal to the value of the observed test statistic.

There are other tests where it might be appropriate to test against either a one-sided or a two-sided alternative hypothesis. For example, when you test the null hypothesis that the true parameter value equals 0 ($T = 0$), the alternative of interest might be one-sided ($T \leq 0$, or $T \geq 0$) or two-sided ($T \neq 0$). Such tests include the Pearson correlation coefficient, Spearman correlation coefficient, Jonckheere-Terpstra test, Cochran-Armitage test for trend, simple kappa coefficient, and weighted kappa coefficient. For these tests, PROC FREQTAB

displays the right-sided *p*-value when the observed value of the test statistic is greater than its expected value. The right-sided *p*-value is the sum of probabilities for those tables for which the test statistic is greater than or equal to the observed test statistic. Otherwise, when the observed test statistic is less than or equal to the expected value, PROC FREQTAB displays the left-sided *p*-value. The left-sided *p*-value is the sum of probabilities for those tables for which the test statistic is less than or equal to the one observed. The one-sided *p*-value P_1 can be expressed as

$$P_1 = \begin{cases} \text{Prob}(\text{ Test Statistic} \geq t\ ) & \text{if } \ t > \text{E}_0(T) \\ \text{Prob}(\text{ Test Statistic} \leq t\ ) & \text{if } \ t \leq \text{E}_0(T) \end{cases}$$

where t is the observed value of the test statistic and $\text{E}_0(T)$ is the expected value of the test statistic under the null hypothesis. PROC FREQTAB computes the two-sided *p*-value as the sum of the one-sided *p*-value and the corresponding area in the opposite tail of the distribution of the statistic, equidistant from the expected value. The two-sided *p*-value P_2 can be expressed as

$$P_2 = \text{Prob}\,(\,|\text{Test Statistic} - \text{E}_0(T)| \geq |t - \text{E}_0(T)|)$$

If you specify the POINT option in the EXACT statement, PROC FREQTAB provides exact point probabilities for the exact tests. The exact point probability is the exact probability that the test statistic equals the observed value.

If you specify the MIDP option in the EXACT statement, PROC FREQTAB provides exact mid-*p*-values. The exact mid *p*-value is defined as the exact *p*-value minus half the exact point probability, which equals the average of $\text{Prob}(\text{Test Statistic} \geq t)$ and $\text{Prob}(\text{Test Statistic} > t)$ for a right-sided test. The exact mid *p*-value is smaller and less conservative than the non-adjusted exact *p*-value. For more information, see Agresti (2013, section 1.1.4) and Hirji (2006, sections 2.5 and 2.11.1).

Computational Resources

PROC FREQTAB uses relatively fast and efficient algorithms for exact computations. These algorithms, together with improvements in computing power, make it feasible to perform exact computations for data where previously only asymptotic methods could be applied. Nevertheless, depending on your available computing resources, exact computations for some very large problems might require a prohibitive amount of time and memory. For such large problems, consider whether exact methods are really needed or whether asymptotic methods might give results that are very close to the exact results while requiring much less computing time and memory. When asymptotic methods might not be sufficient for such large problems, consider using Monte Carlo estimation of exact *p*-values, which is described in the section "Monte Carlo Estimation" on page 550.

There is no formula that can predict in advance how much time and memory are needed to compute an exact *p*-value for a specific data set and test. The time and memory requirements depend on several factors, which include the following: the total number of observations, the number of rows and columns in the table, the particular arrangement of the observations into table cells, and the test to be performed. Generally, larger problems (in terms of total sample size, number of rows, and number of columns) tend to require more time and memory. For a fixed total sample size, time and memory requirements tend to increase as the number of rows and number of columns increase because of the corresponding increase in the number of reference set tables. For a fixed sample size, time and memory requirements also tend to increase as the marginal row and column totals become more homogeneous. For more information, see Agresti, Mehta, and Patel (1990) and Gail and Mantel (1977).

While PROC FREQTAB is computing an exact *p*-value, you can terminate the computation by pressing the system interrupt key sequence and choosing to stop computations. For more information, see the *SAS Companion* for your system. After you terminate an exact computation, PROC FREQTAB completes all other remaining tasks. The procedure reports missing values for any exact *p*-values that were not computed before termination.

To limit the amount of time that PROC FREQTAB uses for exact computations, you can specify the MAXTIME= option in the EXACT statement. This option sets the maximum amount of clock time (in seconds) that PROC FREQTAB can use to compute an exact *p*-value. If PROC FREQTAB does not finish an exact computation in the time that you specify, the procedure terminates the computation and completes the remaining tasks.

Monte Carlo Estimation

When you specify the MC option in the EXACT statement, PROC FREQTAB computes Monte Carlo estimates of exact *p*-values. Monte Carlo estimation can be useful for large problems where exact computations require a substantial amount of time and memory but asymptotic approximations might not be sufficient. Monte Carlo estimates are available for all exact tests that PROC FREQTAB provides except the binomial proportion test and those tests that apply only to 2×2 or $h \times 2 \times 2$ tables.

To describe the precision of a Monte Carlo estimate, PROC FREQTAB provides the asymptotic standard error and $100(1-\alpha)\%$ confidence limits. You can specify the confidence level α in the ALPHA= option in the EXACT statement; by default, ALPHA=0.01, which produces 99% confidence limits.

You can specify the number of Monte Carlo samples by using the N=*n* option in the EXACT statement. By default, PROC FREQTAB uses 10,000 samples to compute a Monte Carlo estimate. To improve the precision of the Monte Carlo estimates, you can specify a larger value of *n*; this increases the computation time because more samples are generated. To reduce the computation time, you can specify a smaller value of *n*.

PROC FREQTAB computes a Monte Carlo estimate of an exact *p*-value by generating a random sample of tables from the reference set for the exact test. For most exact tests that PROC FREQTAB provides, the reference set includes tables that have the same total sample size, row sums, and column sums as the observed table. (For the exact symmetry test, the reference set includes tables that have the same total sample size as the observed table and the same frequency sums of the off-diagonal table cell pairs.)

PROC FREQTAB generates a random sample of tables from the reference set by using the algorithm of Agresti, Wackerly, and Boyett (1979), which generates tables in proportion to their hypergeometric probabilities conditional on the marginal frequencies. For each sample table, PROC FREQTAB computes the value of the test statistic and compares it to the value of the test statistic for the observed table. To estimate a right-sided *p*-value, PROC FREQTAB counts all sample tables for which the test statistic is greater than or equal to the observed test statistic. The estimate of the *p*-value is the number of these tables divided by the total number of sample tables, which can be expressed as

$$\begin{aligned} \hat{p}_{\mathrm{mc}} &= m \,/\, n \\ m &= \text{number of samples for which (test statistic} \geq t_o) \\ n &= \text{total number of samples} \\ t_o &= \text{observed test statistic} \end{aligned}$$

PROC FREQTAB computes estimates of left-sided and two-sided exact *p*-values similarly. For left-sided exact *p*-values, PROC FREQTAB evaluates whether the sample test statistics are less than or equal to the

observed test statistic. For two-sided exact *p*-values, PROC FREQTAB compares sample test statistics to the observed test statistic by using the definition of the two-sided *p*-value (P_2) for the test. For more information, see the section "Definition of *p*-Values" on page 548 and descriptions of the individual tests.

The variable m has a binomial distribution with n trials and success probability p. The asymptotic standard error of the Monte Carlo estimate is

$$\mathrm{se}(\hat{p}_{\mathrm{mc}}) = \sqrt{\hat{p}_{\mathrm{mc}}\,(1-\hat{p}_{\mathrm{mc}})\,/\,(n-1)}$$

PROC FREQTAB constructs asymptotic confidence limits for the exact *p*-value as

$$\hat{p}_{\mathrm{mc}} \pm \left(z_{\alpha/2} \times \mathrm{se}(\hat{p}_{\mathrm{mc}})\right)$$

where $z_{\alpha/2}$ is the $100(1-\alpha/2)$th percentile of the standard normal distribution and the confidence level α is determined by the ALPHA= option in the EXACT statement.

When the Monte Carlo estimate $\hat{p}_{\mathrm{mc}}$ is 0, PROC FREQTAB computes confidence limits for the *p*-value as

$$\left(0,\ \ 1-\alpha^{(1/n)}\right)$$

When the Monte Carlo estimate $\hat{p}_{\mathrm{mc}}$ is 1, PROC FREQTAB computes confidence limits for the *p*-value as

$$\left(\alpha^{(1/n)},\ \ 1\right)$$

Output Data Sets

PROC FREQTAB produces two types of output data sets that you can use with other statistical and reporting procedures. You can request these data sets as follows:

- Specify the OUT= option in a TABLES statement. This creates an output data set that contains frequency or crosstabulation table counts and percentages
- Specify an OUTPUT statement. This creates an output data set that contains statistics.

PROC FREQTAB does not display the output data sets. Use PROC PRINT, PROC REPORT, or any other SAS reporting tool to display an output data set.

In addition to these two output data sets, you can create a SAS data set from any piece of PROC FREQTAB output by using the Output Delivery System. See the section "ODS Table Names" on page 565 for more information.

Contents of the TABLES Statement Output Data Set

The OUT= option in the TABLES statement creates an output data set that contains one observation for each combination of variable values (or table cell) in the last table request. By default, each observation contains the frequency and percentage for the table cell. The output data set includes the following variables:

- BY variables
- table request variables, such as A, B, C, and D in the table request A*B*C*D
- COUNT, which contains the table cell frequency
- PERCENT, which contains the table cell percentage

If you specify the OUTEXPECT option in the TABLES statement for a two-way or multiway table, the output data set also includes expected cell frequencies. If you specify the OUTPCT option for a two-way or multiway table, the output data set also includes row, column, and table percentages. The additional variables are as follows:

- EXPECTED, which contains the expected frequency
- PCT_TABL, which contains the percentage of two-way table frequency, for n-way tables where $n > 2$
- PCT_ROW, which contains the percentage of row frequency
- PCT_COL, which contains the percentage of column frequency

The OUTEXPECT and OUTPCT options have no effect for one-way tables or for tables that you display in list format (which you can request by specifying the LIST option).

If you specify the OUTCUM option in the TABLES statement for a one-way table or for a table in list format, the output data set also includes cumulative frequencies and cumulative percentages. The additional variables are as follows:

- CUM_FREQ, which contains the cumulative frequency
- CUM_PCT, which contains the cumulative percentage

The following PROC FREQTAB statements create an output data set of frequencies and percentages:

```
proc freqtab;
   tables A A*B / out=D;
run;
```

The output data set D contains frequencies and percentages for the table of A by B, which is the last table request listed in the TABLES statement. If A has two levels (1 and 2), B has three levels (1,2, and 3), and no table cell count is 0 or missing, the output data set D includes six observations, one for each combination of A and B levels. The first observation corresponds to A=1 and B=1; the second observation corresponds to A=1 and B=2; and so on. The data set includes the variables COUNT and PERCENT. The value of COUNT is

the number of observations with the given combination of A and B levels. The value of PERCENT is the percentage of the total number of observations with that A and B combination.

When PROC FREQTAB combines different variable values into the same formatted level, the output data set contains the smallest internal value for the formatted level. For example, suppose a variable X has the values 1.1., 1.4, 1.7, 2.1, and 2.3. When you submit the statement

```
format X 1.;
```

in a PROC FREQTAB step, the formatted levels listed in the frequency table for X are 1 and 2. If you create an output data set with the frequency counts, the internal values of the levels of X are 1.1 and 1.7. To report the internal values of X when you display the output data set, use a format of 3.1 for X.

Contents of the OUTPUT Statement Output Data Set

The OUTPUT statement creates a SAS data set that contains statistics computed by PROC FREQTAB. Table 11.6 lists the statistics that can be stored in the output data set. You identify which statistics to include by specifying *output-options*. For more information, see the description of the OUTPUT statement.

If you specify multiple TABLES statements or multiple table requests in a single TABLES statement, the contents of the output data set correspond to the last table request.

For a one-way table or a two-way table, the output data set contains one observation that stores the requested statistics for the table. For a multiway table, the output data set contains an observation for each two-way table (stratum) of the multiway crosstabulation. If you request summary statistics for the multiway table, the output data set also contains an observation that stores the across-strata summary statistics. If you use a BY statement, the output data set contains an observation (for one-way or two-way tables) or set of observations (for multiway tables) for each BY group.

The OUTPUT data set can include the following variables:

- BY variables
- Variables that identify the stratum for multiway tables, such as A and B in the table request A*B*C*D
- Variables that contain the specified statistics

In addition to the specified estimate or test statistic, the output data set includes associated values such as standard errors, confidence limits, *p*-values, and degrees of freedom.

PROC FREQTAB constructs variable names for the statistics in the output data set by enclosing the *output-option* names in underscores. Variable names for the corresponding standard errors, confidence limits, *p*-values, and degrees of freedom are formed by combining the *output-option* names with prefixes that identify the associated values. Table 11.20 lists the prefixes and their descriptions.

Table 11.20 Output Data Set Variable Name Prefixes

Prefix	Description
E_	Asymptotic standard error (ASE)
L_	Lower confidence limit
U_	Upper confidence limit
E0_	Null hypothesis ASE

Table 11.20 *continued*

Prefix	Description
Z_	Standardized value
DF_	Degrees of freedom
P_	*p*-value
P2_	Two-sided *p*-value
PL_	Left-sided *p*-value
PR_	Right-sided *p*-value
XP_	Exact *p*-value
XP2_	Exact two-sided *p*-value
XPL_	Exact left-sided *p*-value
XPR_	Exact right-sided *p*-value
XPT_	Exact point probability
XMP_	Exact mid *p*-value
XL_	Exact lower confidence limit
XU_	Exact upper confidence limit

For example, the PCHI *output-option* in the OUTPUT statement includes the Pearson chi-square test in the output data set. The variable names for the Pearson chi-square statistic, its degrees of freedom, and the corresponding *p*-value are _PCHI_, DF_PCHI, and P_PCHI, respectively.

Displayed Output

Number of Variable Levels Table

If you specify the NLEVELS option in the PROC FREQTAB statement, PROC FREQTAB displays the "Number of Variable Levels" table. This table provides the number of levels for all variables named in the TABLES statements. PROC FREQTAB determines the variable levels by using the formatted variable values. The "Number of Variable Levels" table contains the following information:

- Variable name
- Levels, which is the total number of levels of the variable

One-Way Frequency Tables

PROC FREQTAB displays one-way frequency tables for all one-way table requests in the TABLES statements, unless you specify the NOPRINT option in the PROC FREQTAB statement or the NOPRINT option in the TABLES statement. For a one-way table showing the frequency distribution of a single variable, PROC FREQTAB displays the name of the variable and its values. For each variable value or level, PROC FREQTAB displays the following information:

- Frequency count, which is the number of observations in the level. (The ONEWAY(NOFREQ) option suppresses the frequencies.)

- Test Frequency count, if you specify the CHISQ(TESTF=) option to request a chi-square goodness-of-fit test for specified frequencies. (The ONEWAY(NOFREQ) option suppresses the test frequencies.)
- Expected frequency, if you specify the ONEWAY(EXPECTED) option
- Deviation of the frequency from the expected value, if you specify the ONEWAY(DEVIATION) option
- Pearson Residual, if you specify the ONEWAY(RESIDUAL) option
- Cell Chi-Square, which is the contribution to the Pearson chi-square statistic, if you specify the ONEWAY(CELLCHI2) option
- Percent, which is the percentage of the total number of observations. (The ONEWAY(NOPERCENT) option suppresses the percentages.)
- Test Percent, if you specify the CHISQ(TESTP=) option to request a chi-square goodness-of-fit test for specified percentages. (The ONEWAY(NOPERCENT) option suppresses the test percentages.)
- Cumulative Frequency, which is the accumulated frequency of the current level and all levels that are listed above it in the table. The last cumulative frequency in the table is the total number of nonmissing observations. (Both the ONEWAY(NOCUM) option and the ONEWAY(NOFREQ) option suppress the cumulative frequencies.)
- Cumulative Percent, which is the accumulated percentage of the current level and all levels that are listed above it in the table. (Both the ONEWAY(NOCUM) option and the ONEWAY(NOPERCENT) option suppress the cumulative percentages.)

The one-way table also displays the Frequency Missing, which is the total frequency of missing values.

Statistics for One-Way Frequency Tables

For one-way tables, two statistical options are available in the TABLES statement. The CHISQ option provides a chi-square goodness-of-fit test, and the BINOMIAL option provides binomial proportion statistics and tests. PROC FREQTAB displays the following information, unless you specify the NOPRINT option in the PROC FREQTAB statement:

- If you specify the CHISQ option for a one-way table, PROC FREQTAB provides a chi-square goodness-of-fit test, displaying the Chi-Square statistic, the degrees of freedom (DF), and the probability value (Pr > ChiSq). If you specify the CHISQ option in the EXACT statement, PROC FREQTAB also displays the exact probability value for this test. If you specify the POINT option with the CHISQ option in the EXACT statement, PROC FREQTAB displays the exact point probability for the test statistic. If you specify the MIDP option in the EXACT statement, PROC FREQTAB displays the exact mid *p*-value for the chi-square test.
- If you specify the BINOMIAL option for a one-way table, PROC FREQTAB displays the estimate of the binomial Proportion, which is the proportion of observations in the first class listed in the one-way table. PROC FREQTAB also displays the asymptotic standard error (ASE) and the asymptotic (Wald) and exact (Clopper-Pearson) confidence limits by default. For the binomial proportion test, PROC FREQTAB displays the asymptotic standard error under the null hypothesis (ASE Under H0), the standardized test statistic (Z), and the one-sided and two-sided probability values.

If you specify the BINOMIAL option in the EXACT statement, PROC FREQTAB also displays the exact one-sided and two-sided probability values for this test. If you specify the POINT option with the BINOMIAL option in the EXACT statement, PROC FREQTAB displays the exact point probability for the test. If you specify the MIDP option in the EXACT statement, PROC FREQTAB displays the exact mid *p*-value for the binomial proportion test.

- If you request binomial confidence limits by specifying the BINOMIAL(CL=) option, PROC FREQTAB displays the "Binomial Confidence Limits" table, which includes the Lower and Upper Confidence Limits for each confidence limit Type that you request. In addition to Wald and Clopper-Pearson (Exact) confidence limits, you can request the following confidence limit types for the binomial proportion: Agresti-Coull, Blaker, Jeffreys, Likelihood Ratio, Logit, Mid-p, and Wilson (score).

- If you request a binomial noninferiority or superiority test by specifying the NONINF or SUP *binomial-option*, PROC FREQTAB displays a Noninferiority Analysis or Superiority Analysis table that contains the following information: the binomial Proportion, the test ASE (under H0 or Sample), the test statistic Z, the probability value, the noninferiority or superiority limit, and the test confidence limits. If you specify the BINOMIAL option in the EXACT statement, PROC FREQTAB also provides the exact probability value for the test, and exact test confidence limits.

- If you request a binomial equivalence test by specifying the EQUIV *binomial-option*, PROC FREQTAB displays an Equivalence Analysis table that contains the following information: binomial Proportion and the test ASE (under H0 or Sample). PROC FREQTAB displays two one-sided tests (TOST) for equivalence, which include test statistics (Z) and probability values for the Lower and Upper tests, together with the Overall probability value. PROC FREQTAB also displays the equivalence limits and the test-based confidence limits. If you specify the BINOMIAL option in the EXACT statement, PROC FREQTAB provides exact probability values for the TOST and exact test-based confidence limits.

Two-Way and Multiway Tables

PROC FREQTAB displays all multiway table requests in the TABLES statements, unless you specify the NOPRINT option in the PROC FREQTAB statement or the NOPRINT option in the TABLES statement.

For two-way to multiway crosstabulation tables, the values of the last variable in the table request form the table columns. The values of the next-to-last variable form the rows. Each level (or combination of levels) of the other variables forms one stratum.

There are three ways to display multiway tables in PROC FREQTAB. By default, PROC FREQTAB displays multiway tables as separate two-way crosstabulation tables for each stratum of the multiway table. Also by default, PROC FREQTAB displays these two-way crosstabulation tables in table cell format. Alternatively, if you specify the CROSSLIST option, PROC FREQTAB displays the two-way crosstabulation tables in ODS column format. If you specify the LIST option, PROC FREQTAB displays multiway tables in list format, which presents the entire multiway crosstabulation in a single table.

Crosstabulation Tables

By default, PROC FREQTAB displays two-way crosstabulation tables in table cell format. The row variable values are listed down the side of the table, the column variable values are listed across the top of the table, and each row and column variable level combination forms a table cell.

Each cell of a crosstabulation table can contain the following information:

- Frequency, which is the number of observations in the table cell. (The NOFREQ option suppresses this information.)
- Expected frequency under the hypothesis of independence, if you specify the EXPECTED option
- Deviation of the cell frequency from the expected value, if you specify the DEVIATION option
- Cell Chi-Square, which is the cell's contribution to the total chi-square statistic, if you specify the CELLCHI2 option
- Tot Pct, which is the cell's percentage of the total multiway table frequency, for n-way tables when $n > 2$, if you specify the TOTPCT option
- Percent, which is the cell's percentage of the total (two-way table) frequency. (The NOPERCENT option suppresses this information.)
- Row Pct, or the row percentage, which is the cell's percentage of the total frequency for its row. (The NOROW option suppresses this information.)
- Col Pct, or column percentage, which is the cell's percentage of the total frequency for its column. (The NOCOL option suppresses this information.)
- Cumulative Col%, or cumulative column percentage, if you specify the CUMCOL option

The table also displays the Frequency Missing, which is the total frequency of missing values.

CROSSLIST Tables

If you specify the CROSSLIST option, PROC FREQTAB displays two-way crosstabulation tables in ODS column format. The CROSSLIST column format is different from the default crosstabulation table cell format, but the CROSSLIST table provides the same information (frequencies, percentages, and other statistics) as the default crosstabulation table.

In the CROSSLIST table format, the rows of the display correspond to the crosstabulation table cells, and the columns of the display correspond to descriptive statistics such as frequencies and percentages. Each table cell is identified by the values of its TABLES row and column variable levels, and all column variable levels are listed within each row variable level. The CROSSLIST table also provides row totals, column totals, and overall table totals.

PROC FREQTAB displays the following information in a CROSSLIST table:

- row variable name and values
- column variable name and values
- Frequency, which is the number of observations in the table cell. (The CROSSLIST(NOFREQ) option suppresses the frequencies.)
- Expected cell frequency under the hypothesis of independence, if you specify the CROSSLIST(EXPECTED) option
- Deviation of the observed frequency from the expected value, if you specify the CROSSLIST(DEVIATION) option

- Standardized Residual, if you specify the CROSSLIST(STDRES) option
- Pearson Residual, if you specify the CROSSLIST(PEARSONRES) option
- Cell Chi-Square, which is the cell's contribution to the total chi-square statistic, if you specify the CROSSLIST(CELLCHI2) option
- Total Percent, which is the cell's percentage of the total multiway table frequency, for n-way tables when $n > 2$, if you specify the CROSSLIST(TOTPCT) option
- Percent, which is the cell's percentage of the total (two-way table) frequency. (The CROSSLIST(NOPERCENT) option suppresses the percentages.)
- Row Percent, which is the cell's percentage of the total frequency in its row. (The CROSSLIST(NOROW) option suppresses the row percentages.)
- Column Percent, the cell's percentage of the total frequency in its column. (The CROSSLIST(NOCOL) option suppresses the column percentages.)

The table also displays the Frequency Missing, which is the total frequency of missing values.

LIST Tables

If you specify the LIST option in the TABLES statement, PROC FREQTAB displays two-way and multiway tables by using a list format instead of the default crosstabulation cell format. The list format displays an entire multiway table in a single table instead of separate two-way (stratum) tables. Each row of a table in list format corresponds to a single crosstabulation cell. Tables that are displayed in list format do not include row percentages, column percentages, or optional two-way table information such as expected frequencies and cell chi-squares.

PROC FREQTAB displays the following information in a list table:

- variable names and values
- Frequency, which is the number of observations in the table cell (level). (The LIST(NOFREQ) option suppresses the frequencies.)
- Percent, which is the level's percentage of the total number of observations. (The LIST(NOPERCENT) option suppresses the percentages.)
- Cumulative Frequency, which is the accumulated frequency of the current level and all levels that are listed above it in the table. The last cumulative frequency in the table is the total number of nonmissing observations. (Both the LIST(NOFREQ) option and the LIST(NOCUM) option suppress the cumulative frequencies.)
- Cumulative Percent, which is the accumulated percentage of the current level and all levels that are listed above it in the table. (Both the LIST(NOPERCENT) option and the LIST(NOCUM) option suppress the cumulative percentages.)

The table also displays the Frequency Missing, which is the total frequency of missing values.

Statistics for Two-Way and Multiway Tables

PROC FREQTAB computes statistical tests and measures for crosstabulation tables, depending on which statements and options you specify. You can suppress the display of these results by specifying the NOPRINT option in the PROC FREQTAB statement. With any of the following information, PROC FREQTAB also displays the Sample Size and the Frequency Missing.

- If you specify the SCOROUT option in the TABLES statement, PROC FREQTAB displays the Row Scores and Column Scores that it uses for statistical computations. The Row Scores table displays the row variable values and the Score corresponding to each value. The Column Scores table displays the column variable values and the corresponding Scores. PROC FREQTAB also identifies the score type used to compute the row and column scores. You can specify the score type with the SCORES= option in the TABLES statement.

- If you specify the CHISQ option, PROC FREQTAB displays the following statistics for each two-way table: Pearson Chi-Square, Likelihood Ratio Chi-Square, Continuity-Adjusted Chi-Square (for 2×2 tables), Mantel-Haenszel Chi-Square, the Phi Coefficient, the Contingency Coefficient, and Cramér's V. For each test statistic, PROC FREQTAB also displays the degrees of freedom (DF) and the probability value (Prob).

- If you specify the CHISQ option for 2×2 tables, PROC FREQTAB also displays Fisher's exact test. The test output includes the cell (1,1) frequency (F), the exact left-sided and right-sided probability values, the table probability (P), and the exact two-sided probability value. If you specify the POINT option in the EXACT statement, PROC FREQTAB displays the exact point probability for Fisher's exact test. If you specify the MIDP option in the EXACT statement, PROC FREQTAB displays the Mid p-Value for the test.

- If you specify the FISHER option in the TABLES statement (or, equivalently, the FISHER option in the EXACT statement), PROC FREQTAB displays Fisher's exact test for tables larger than 2×2. The test output includes the table probability (P) and the probability value. If you specify the POINT option in the EXACT statement, PROC FREQTAB displays the exact point probability for Fisher's exact test. If you specify the MIDP option in the EXACT statement, PROC FREQTAB displays the Mid p-Value for the test.

- If you specify the PCHI, LRCHI, or MHCHI option in the EXACT statement, PROC FREQTAB displays the corresponding exact test: Pearson Chi-Square, Likelihood Ratio Chi-Square, or Mantel-Haenszel Chi-Square, respectively. The test output includes the test statistic, the degrees of freedom (DF), and the asymptotic and exact probability values. If you also specify the POINT option in the EXACT statement, PROC FREQTAB displays the point probability for each exact test requested. If you specify the MIDP option in the EXACT statement, PROC FREQTAB displays the exact mid p-value for each test. If you specify the CHISQ option in the EXACT statement, PROC FREQTAB displays exact probability values for all three of these chi-square tests.

- If you specify the MC option in the EXACT statement, PROC FREQTAB displays Monte Carlo estimates for all exact p-values that you request in the EXACT statement. The Monte Carlo output includes the p-value Estimate, its Confidence Limits, the Number of Samples used to compute the Monte Carlo estimate, and the Initial Seed for random number generation.

- If you specify the MEASURES option, PROC FREQTAB displays the following statistics and their asymptotic standard errors (ASE) for each two-way table: Gamma, Kendall's Tau-b, Stuart's Tau-c,

Somers' $D(C|R)$, Somers' $D(R|C)$, Pearson Correlation, Spearman Correlation, Lambda Asymmetric $(C|R)$, Lambda Asymmetric $(R|C)$, Lambda Symmetric, Uncertainty Coefficient $(C|R)$, Uncertainty Coefficient $(R|C)$, and Uncertainty Coefficient Symmetric. If you specify the CL option, PROC FREQTAB also displays confidence limits for these measures.

- If you specify the PLCORR option, PROC FREQTAB displays the polychoric correlation and its asymptotic standard error (ASE). For 2×2 tables, this statistic is known as the tetrachoric correlation (and is labeled as such in the displayed output). If you specify the CL option, PROC FREQTAB also displays confidence limits for the polychoric correlation. If you specify the PLCORR option in the TEST statement, PROC FREQTAB displays the polychoric correlation, asymptotic standard error (ASE), confidence limits, and the following: the standardized test statistic (Z), the corresponding one-sided and two-sided probability values, the likelihood ratio (LR) chi-square, and the probability value (Pr > ChiSq).

- If you specify the GAMMA, KENTB, STUTC, SMDCR, SMDRC, PCORR, or SCORR option in the TEST statement, PROC FREQTAB displays asymptotic tests for Gamma, Kendall's Tau-*b*, Stuart's Tau-*c*, Somers' $D(C|R)$, Somers' $D(R|C)$, the Pearson Correlation, or the Spearman Correlation, respectively. If you specify the MEASURES option in the TEST statement, PROC FREQTAB displays all these asymptotic tests. The test output includes the statistic, its asymptotic standard error (ASE), Confidence Limits, the ASE under the null hypothesis H0, the standardized test statistic (Z), and the one-sided and two-sided probability values.

- If you specify the KENTB, STUTC, SMDCR, SMDRC, PCORR, or SCORR option in the EXACT statement, PROC FREQTAB displays asymptotic and exact tests for the corresponding measure of association: Kendall's Tau-*b*, Stuart's Tau-*c*, Somers' $D(C|R)$, Somers' $D(R|C)$, the Pearson Correlation, or the Spearman Correlation, respectively. The test output includes the correlation, its asymptotic standard error (ASE), Confidence Limits, the ASE under the null hypothesis H0, the standardized test statistic (Z), and the asymptotic and exact one-sided and two-sided probability values. If you also specify the POINT option in the EXACT statement, PROC FREQTAB displays the point probability for each exact test requested. If you specify the MIDP option in the EXACT statement, PROC FREQTAB displays the exact Mid *p*-Value for each test.

- If you specify the SENSPEC option for 2×2 tables, PROC FREQTAB displays the "Sensitivity and Specificity" table. This table displays the Estimate, Standard Error, and Confidence Limits for the following statistics: Sensitivity, Specificity, Accuracy, Positive Predictive Value, and Negative Predictive Value.

- If you specify the RISKDIFF option for 2×2 tables, PROC FREQTAB displays the Column 1 and Column 2 Risk Estimates. For each column, PROC FREQTAB displays the Row 1 Risk, Row 2 Risk, Total Risk, and Risk Difference, together with their asymptotic standard errors (ASE) and Asymptotic Confidence Limits. PROC FREQTAB also displays Exact Confidence Limits for the Row 1 Risk, Row 2 Risk, and Total Risk. If you specify the RISKDIFF option in the EXACT statement, PROC FREQTAB provides unconditional Exact Confidence Limits for the Risk Difference. You can suppress this table by specifying the RISKDIFF(NORISKS) option.

- If you specify the RISKDIFF(CL=) option for 2×2 tables, PROC FREQTAB displays the "Confidence Limits for the Proportion (Risk) Difference" table, which includes the Lower and Upper Confidence Limits for each confidence limit Type that you request (Agresti-Caffo, Exact, Hauck-Anderson, Miettinen-Nurminen, Newcombe, or Wald).

- If you specify the RISKDIFF(NONINF) option for 2 × 2 tables, PROC FREQTAB displays the "Noninferiority Analysis for the Risk Difference" table, which includes the Risk Difference, test ASE, standardized test statistic Z, probability value (Pr > Z), Noninferiority Limit, and (test-based) Confidence Limits.

- If you specify the RISKDIFF(SUP) option for 2 × 2 tables, PROC FREQTAB displays the "Superiority Analysis for the Risk Difference" table, which includes the Risk Difference, test ASE, standardized test statistic Z, probability value (Pr > Z), Superiority Limit, and (test-based) Confidence Limits.

- If you specify the RISKDIFF(EQUIV) option for 2 × 2 tables, PROC FREQTAB displays the "Equivalence Analysis for the Risk Difference" table, which includes the Risk Difference, test ASE, Equivalence Limits, and (test-based) Confidence Limits. PROC FREQTAB also displays the "Two One-Sided Tests (TOST)" table, which includes test statistics (Z) and P-Values for the Lower Margin and Upper Margin tests, along with the Overall P-Value.

- If you specify the RISKDIFF(EQUAL) option for 2 × 2 tables, PROC FREQTAB displays the "Risk Difference Test" table, which includes the Risk Difference, test ASE, standardized test statistic Z, One-sided probability value (Pr > Z or Pr < Z), and Two-sided probability value (Pr > |Z|).

- If you specify the MEASURES option or the RELRISK option for 2 × 2 tables, PROC FREQTAB displays the "Odds Ratio and Relative Risks" table, which includes the following statistics with their confidence limits: Odds Ratio, Relative Risk (Column 1), and Relative Risk (Column 2). If you specify the OR option in the EXACT statement, PROC FREQTAB also displays the "Exact Confidence Limits for the Odds Ratio" table. If you specify the RELRISK option in the EXACT statement, PROC FREQTAB displays the "Exact Confidence Limits for the Relative Risk" table.

- If you specify the OR(CL=) option for 2 × 2 tables, PROC FREQTAB displays the "Confidence Limits for the Odds Ratio" table, which includes the Lower and Upper Confidence Limits for each confidence limit Type that you request (Exact, Mid-p, Likelihood Ratio, Score, Wald, or Wald Modified).

- If you specify the RELRISK(CL=) option for 2 × 2 tables, PROC FREQTAB displays the "Confidence Limits for the Relative Risk" table, which includes the Lower and Upper Confidence Limits for each confidence limit Type that you request (Exact, Likelihood Ratio, Score, Wald, or Wald Modified).

- If you specify the RELRISK(NONINF) option, PROC FREQTAB displays the "Noninferiority Analysis for the Relative Risk" table, which includes the Relative Risk, standardized test statistic Z, probability value (Pr > Z), Noninferiority Limit, and Confidence Limits.

- If you specify the RELRISK(SUP) option, PROC FREQTAB displays the "Superiority Analysis for the Relative Risk" table, which includes the Relative Risk, standardized test statistic Z, probability value (Pr > Z), Superiority Limit, and Confidence Limits.

- If you specify the RELRISK(EQUIV) option, PROC FREQTAB displays the "Equivalence Analysis for the Relative Risk" table, which includes the Relative Risk, Equivalence Limits, and Confidence Limits. PROC FREQTAB also displays the "Two One-Sided Tests(TOST)" table, which includes test statistics (Z) and P-Values for the Lower Margin and Upper Margin tests, along with the Overall P-Value.

- If you specify the RELRISK(EQUAL) option, PROC FREQTAB displays the "Relative Risk Test" table, which includes the Relative Risk, standardized test statistic Z, One-sided probability value (Pr > Z or Pr < Z), and Two-sided probability value (Pr > |Z|).

- If you specify the TREND option, PROC FREQTAB displays the Cochran-Armitage Trend Test for tables that are $2 \times C$ or $R \times 2$. For this test, PROC FREQTAB gives the Statistic (Z) and the one-sided and two-sided probability values. If you specify the TREND option in the EXACT statement, PROC FREQTAB also displays the exact one-sided and two-sided probability values for this test. If you specify the POINT option with the TREND option in the EXACT statement, PROC FREQTAB displays the exact point probability for the test statistic. If you specify the MIDP option in the EXACT statement, PROC FREQTAB displays the exact Mid p-Value for the trend test.

- If you specify the JT option, PROC FREQTAB displays the Jonckheere-Terpstra Test, showing the Statistic (JT), the standardized test statistic (Z), and the one-sided and two-sided probability values. If you specify the JT option in the EXACT statement, PROC FREQTAB also displays the exact one-sided and two-sided probability values for this test. If you specify the POINT option with the JT option in the EXACT statement, PROC FREQTAB displays the exact point probability for the test statistic. If you specify the MIDP option in the EXACT statement, PROC FREQTAB displays the exact Mid p-Value for the Jonckheere-Terpstra test.

- If you specify the AGREE option for a 2×2 table, PROC FREQTAB displays the "McNemar's Test" table. This table includes the McNemar test statistic (chi-square), the degrees of freedom, and the p-value. If you specify the MCNEM option in the EXACT statement, this table also includes the exact p-value. If you specify the POINT option or the MIDP option in the EXACT statement, the "McNemar's Test" table includes the exact point probability or the exact mid p-value, respectively.

- If you specify the AGREE option for a square table of dimension greater than 2, PROC FREQTAB displays the "Symmetry Test" table. This table displays Bowker's symmetry test statistic (chi-square), the degrees of freedom, and the p-value. If you specify the SYMMETRY option in the EXACT statement, this table also includes the exact p-value. If you specify the POINT option or the MIDP option in the EXACT statement, the "Symmetry Test" table includes the exact point probability or the exact mid p-value, respectively.

- The AGREE option also produces the "Kappa Statistics" table, which displays the simple kappa coefficient. If the dimension of the two-way table is greater than 2, the "Kappa Statistics" table includes the weighted kappa coefficient. If you specify the AGREE(AC1) option or the AGREE(PABAK) option, this table includes the AC1 agreement coefficient or the prevalence-adjusted bias-adjusted kappa (PABAK), respectively. The "Kappa Statistics" table displays the standard error and confidence limits for each agreement statistic.

- If you specify the AGREE(KAPPADETAILS) option, PROC FREQTAB displays the "Kappa Details" table, which includes the observed agreement, the chance-expected agreement, the maximum kappa, and the B_N measure. For 2×2 tables, the "Kappa Details" table also includes the prevalence index and the bias index.

- If you specify the AGREE(WTKAPPADETAILS) or AGREE(KAPPADETAILS) option for a square table of dimension greater than 2, PROC FREQTAB produces the "Weighted Kappa Details" table, which displays the observed agreement and the chance-expected agreement components of the weighted kappa coefficient.

- If you specify the AGREE(PRINTKWTS) option for a square table of dimension greater than 2, PROC FREQTAB displays the matrix of agreement weights in the "Kappa Coefficient Weights" table.

- If you request a simple kappa coefficient test, PROC FREQTAB produces the "Kappa Test" table. You can request this test by specifying the KAPPA option in the TEST statement, the KAPPA option in the

EXACT statement, or the AGREE(NULLKAPPA=) option in the TABLES statement. The "Kappa Test" table displays the kappa coefficient, null test value, standard error (when the null value is 0), standardized test statistic (Z), and one-sided and two-sided *p*-values.

If you request an exact test (by specifying the KAPPA option in the EXACT statement), the "Kappa Test" table also includes the exact one-sided and two-sided *p*-values. If you specify the POINT option or the MIDP option in the EXACT statement, the "Kappa Test" table includes the point probability or the exact mid *p*-value, respectively.

- If you request a weighted kappa coefficient test for a square table of dimension greater than 2, PROC FREQTAB produces the "Weighted Kappa Test" table. You can request this test by specifying the WTKAPPA option in the TEST statement, the WTKAPPA option in the EXACT statement, or the AGREE(NULLWTKAPPA=) option in the TABLES statement. The "Weighted Kappa Test" table displays the weighted kappa coefficient, null test value, standard error (when the null value is 0), standardized test statistic (Z), and one-sided and two-sided *p*-values.

  If you request an exact test (by specifying the WTKAPPA option in the EXACT statement), the "Weighted Kappa Test" table also includes the exact one-sided and two-sided *p*-values. If you specify the POINT option or the MIDP option in the EXACT statement, the "Weighted Kappa Test" table includes the point probability or the exact mid *p*-value, respectively.

- If you specify the AGREE option for a multiway square table, PROC FREQTAB displays the "Overall Kappa Coefficients" table, which includes the overall simple kappa coefficient together with its standard error and confidence limits. This table also includes the overall weighted kappa coefficient if the two-way table dimension is greater than 2.

- For multiway square tables, the AGREE option also produces the "Tests for Equal Kappa Coefficients" table. This table includes the chi-square statistic, degrees of freedom, and *p*-value for the test of equal simple kappa coefficients (over all strata). If the two-way table dimension is greater than 2, this table also includes the test for equal weighted kappa coefficients.

- For multiway tables in which each variable has two levels, both the AGREE option and the CQ option display the "Cochran's Q" table, which includes Cochran's Q statistic (to test for marginal homogeneity), the degrees of freedom, and the *p*-value.

- If you specify the COMMONRISKDIFF option for a multiway 2×2 table, PROC FREQTAB displays the "Confidence Limits for the Common Risk Difference" table, which includes the Method, Value of the common risk difference, Standard Error, and Confidence Limits for each confidence limit type that you request (Klingenberg, Mantel-Haenszel, Miettinen-Nurminen, Miettinen-Nurminen MH, Minimum Risk, Newcombe, Newcombe MR, or Summary Score).

- If you specify the COMMONRISKDIFF(TEST) option for a multiway 2×2 table, PROC FREQTAB displays the "Common Risk Difference Tests" table, which includes Method, Risk Difference, Z, and Pr > |Z| for each test that you request (Mantel-Haenszel, Minimum Risk, or Summary Score).

- If you specify the COMMONRISKDIFF(PRINTWTS) option for a multiway 2×2 table, PROC FREQTAB displays the "Stratum Weights" table, which includes the following information for each stratum (2×2 table): Stratum index, variable levels, Risk Difference, Frequency, Fraction, and the stratum weights that you request (Mantel-Haenszel, Miettinen-Nurminen, Minimum Risk, or Summary Score Weights).

- If you specify the CMH option, PROC FREQTAB displays Cochran-Mantel-Haenszel Statistics for the following three alternative hypotheses: Nonzero Correlation, Row Mean Scores Differ (ANOVA Statistic), and General Association. For each of these statistics, PROC FREQTAB gives the degrees of freedom (DF) and the probability value (Prob). If you specify the MANTELFLEISS option, PROC FREQTAB displays the Mantel-Fleiss Criterion for 2×2 tables. For 2×2 tables, PROC FREQTAB also displays Estimates of the Common Relative Risk for Case-Control and Cohort studies, together with their confidence limits. These include both Mantel-Haenszel and Logit stratum-adjusted estimates of the common Odds Ratio, Column 1 Relative Risk, and Column 2 Relative Risk. Also for 2×2 tables, PROC FREQTAB displays the Breslow-Day Test for Homogeneity of the Odds Ratios. For this test, PROC FREQTAB gives the Chi-Square, the degrees of freedom (DF), and the probability value (Pr > ChiSq).

- If you specify the CMH(QOR) option for a stratified 2×2 table, PROC FREQTAB displays the "Q Test for Homogeneity of Odds Ratios" table, which includes the Chi-Square, the degrees of freedom (DF), and the probability value (Pr > ChiSq).

- If you specify the CMH(I2) option for a stratified 2×2 table, PROC FREQTAB displays the "I-Square Measure of Heterogeneity" table, which includes the I-Square, the degrees of freedom (DF), and the Confidence Limits.

- If you specify the CMH option in the TABLES statement and also specify the COMOR option in the EXACT statement for a multiway 2×2 table, PROC FREQTAB displays exact confidence limits for the Common Odds Ratio. PROC FREQTAB also displays the Exact Test of H0: Common Odds Ratio = 1. The test output includes the Cell (1,1) Sum (S), Mean of S Under H0, One-sided Pr <= S, and Point Pr = S. PROC FREQTAB also provides exact two-sided probability values for the test, computed according to the following three methods: 2 * One-sided, Sum of probabilities <= Point probability, and Pr >= |S - Mean|. If you specify the MIDP option in the EXACT statement, PROC FREQTAB provides the exact Mid *p*-Value for the common odds ratio test.

- If you specify the CMH option in the TABLES statement and also specify the EQOR option in the EXACT statement for a multiway 2×2 table, PROC FREQTAB computes Zelen's exact test for equal odds ratios. PROC FREQTAB displays Zelen's test along with the asymptotic Breslow-Day test produced by the CMH option. PROC FREQTAB displays the test statistic, Zelen's Exact Test (P), and the probability value, Exact Pr <= P.

- If you specify the GAILSIMON option in the TABLES statement for a multiway 2×2 tables, PROC FREQTAB displays the Gail-Simon test for qualitative interactions. The display include the following statistics and their *p*-values: Q+ (Positive Risk Differences), Q- (Negative Risk Differences), and Q (Two-Sided).

ODS Table Names

PROC FREQTAB assigns a name to each table that it creates. You can use these names to refer to tables when you use the Output Delivery System (ODS) to select tables and create output data sets. For more information about ODS, see the *SAS Output Delivery System: User's Guide*.

Table 11.21 lists the ODS table names together with their descriptions and the options that are required to produce the tables.

Table 11.21 ODS Tables Produced by PROC FREQTAB

ODS Table Name	Description	Statement	Option
BarnardsTest	Barnard's exact test	EXACT	BARNARD
Binomial	Binomial proportion	TABLES	BINOMIAL
BinomialCLs	Binomial confidence limits	TABLES	BINOMIAL(CL=)
BinomialEquiv	Binomial equivalence analysis	TABLES	BINOMIAL(EQUIV)
BinomialEquivLimits	Binomial equivalence limits	TABLES	BINOMIAL(EQUIV)
BinomialEquivTest	Binomial equivalence test	TABLES	BINOMIAL(EQUIV)
BinomialNoninf	Binomial noninferiority test	TABLES	BINOMIAL(NONINF)
BinomialSup	Binomial superiority test	TABLES	BINOMIAL(SUP)
BinomialTest	Binomial proportion test	TABLES	BINOMIAL
BnMeasure	Agreement measures	TABLES	PLOTS=AGREEPLOT(STATS)
BreslowDayTest	Breslow-Day test	TABLES	CMH ($h \times 2 \times 2$ table)
ChiSq	Chi-square tests	TABLES	CHISQ
CMH	Cochran-Mantel-Haenszel statistics	TABLES	CMH
CochransQ	Cochran's Q	TABLES	AGREE or CQ ($2 \times 2 \times \cdots \times 2$ table)
ColScores	Column scores	TABLES	SCOROUT
CommonOddsRatioCl	Exact confidence limits for the common odds ratio	EXACT	COMOR ($h \times 2 \times 2$ table)
CommonOddsRatioTest	Common odds ratio exact test	EXACT	COMOR ($h \times 2 \times 2$ table)
CommonPdiff	Common risk difference confidence limits	TABLES	COMMONRISKDIFF ($h \times 2 \times 2$ table)
CommonPdiffTests	Common risk difference tests	TABLES	COMMONRISKDIFF(TESTS) ($h \times 2 \times 2$ table)
CommonRelRisks	Common relative risks	TABLES	CMH ($h \times 2 \times 2$ table)

ODS Graphics

Statistical procedures use ODS Graphics to create graphs as part of their output. ODS Graphics is described in detail in the "Statistical Graphics Using ODS" chapter in *SAS/STAT User's Guide*.

Before you create graphs, ODS Graphics must be enabled (for example, by using the ODS GRAPHICS ON statement). For more information about enabling and disabling ODS Graphics, see the section "Enabling and Disabling ODS Graphics" in that chapter.

The overall appearance of graphs is controlled by ODS styles. Styles and other aspects of using ODS Graphics are discussed in the section "A Primer on ODS Statistical Graphics" in that chapter.

When ODS Graphics is enabled, you can request specific plots by specifying the PLOTS= option in the TABLES statement. To produce a frequency plot or cumulative frequency plot, you must specify the FREQPLOT or CUMFREQPLOT *plot-request*, respectively, in the PLOTS= option. To produce a mosaic plot, you must specify the MOSAICPLOT *plot-request* in the PLOTS= option. You can also produce frequency, cumulative frequency, and mosaic plots by specifying the PLOTS=ALL option. By default, PROC FREQTAB produces all other plots that are associated with the analyses that you request in the TABLES statement. You can suppress the default plots and request specific plots by using the PLOTS(ONLY)= option. For more information, see the description of the PLOTS= option.

PROC FREQTAB assigns a name to each graph that it creates by using ODS Graphics. You can use these names to refer to the graphs. Table 11.22 lists the names of the graphs that PROC FREQTAB generates together with their descriptions, their PLOTS= options (*plot-requests*), and the TABLES statement options that are required to produce the graphs.

Table 11.22 Graphs Produced by PROC FREQTAB

ODS Graph Name	Description	PLOTS= Option	TABLES Statement Option
AgreePlot	Agreement plot	AGREEPLOT	AGREE ($r \times r$ table)
CumFreqPlot	Cumulative frequency plot	CUMFREQPLOT	One-way table request
DeviationPlot	Deviation plot	DEVIATIONPLOT	CHISQ (one-way table)
FreqPlot	Frequency plot	FREQPLOT	Any table request
KappaPlot	Kappa plot	KAPPAPLOT	AGREE ($h \times r \times r$ table)
MosaicPlot	Mosaic plot	MOSAICPLOT	Two-way or multiway table request
ORPlot	Odds ratio plot	ODDSRATIOPLOT	MEASURES, OR, or RELRISK ($h \times 2 \times 2$ table)
RelRiskPlot	Relative risk plot	RELRISKPLOT	MEASURES or RELRISK ($h \times 2 \times 2$ table)
RiskDiffPlot	Risk difference plot	RISKDIFFPLOT	RISKDIFF ($h \times 2 \times 2$ table)
WtKappaPlot	Weighted kappa plot	WTKAPPAPLOT	AGREE ($h \times r \times r$ table, $r > 2$)

The examples in this chapter are available in the GitHub repository located at `https://github.com/sascommunities/doc-supplement-casstat`.

Overview: GAMMOD Procedure

The GAMMOD procedure fits generalized additive models that are based on low-rank regression splines (Wood 2006) in SAS Viya.

Generalized additive models are extensions of generalized linear models. They relax the generalized linear models' assumption of linearity by allowing spline terms that characterize nonlinear dependency structures. Each spline term is constructed by the thin-plate regression spline technique (Wood 2003). A roughness penalty is applied to each spline term by a smoothing parameter that controls the balance between goodness of fit and the roughness of the spline curve. PROC GAMMOD fits models for standard distributions in the exponential family, such as the normal, Poisson, gamma, and Tweedie distributions.

PROC GAMMOD Features

PROC GAMMOD offers the following basic features:

- estimates the regression parameters of a generalized additive model that has fixed smoothing parameters by using penalized likelihood estimation
- estimates the smoothing parameters of a generalized additive model by using either the performance iteration method or the outer iteration method
- estimates the regression parameters of a generalized linear model by using maximum likelihood techniques
- tests the total contribution of each spline term based on the Wald statistic
- provides model-building syntax in the CLASS statement and effect-based parametric effects in the MODEL statement, which are used in other SAS/STAT analytic procedures (in particular, the GLM, LOGISTIC, GLIMMIX, and MIXED procedures)
- provides response-variable options
- enables you to construct a spline term by using multiple variables
- provides control options for constructing a spline term, such as fixed degrees of freedom, initial smoothing parameter, fixed smoothing parameter, smoothing parameter search range, user-supplied knot values, and so on
- provides multiple link functions for any distribution
- provides a WEIGHT statement for weighted analysis
- provides a FREQ statement for grouped analysis
- provides an OUTPUT statement to produce a data table that has predicted values and other observationwise statistics
- produces graphs via ODS Graphics

Because the GAMMOD procedure runs on SAS Cloud Analytic Services (CAS), it also does the following:

- enables you to run on a cluster of machines that distribute the data and the computations
- enables you to run in single-machine mode
- exploits all the available cores and concurrent threads (for information about how PROC GAMMOD uses threads, see the section "Multithreading" on page 102 in Chapter 2, "Shared Concepts")

PROC GAMMOD Compared with Other SAS Procedures

The GAMMOD procedure provides generalized additive modeling functionality that is comparable to that of GAMPL and GAM procedures in SAS/STAT software.

PROC GAMMOD Compared with the GAMPL Procedure

The functionality of the GAMMOD procedure closely resembles that of the GAMPL procedure, which is a high-performance SAS/STAT procedure. The GAMMOD procedure is the next generation of the GAMPL procedure, and it was developed specifically for SAS Viya. Both procedures are designed to run on a cluster of machines that distribute the data and the computations. Both procedures perform computations in multiple threads.

PROC GAMMOD provides all the features and options that PROC GAMPL supports; in addition, it supports BY processing and analytic stores. The default link functions for two distributions differ between the two procedures, as shown in Table 12.1.

Table 12.1 Default Link Function

Distribution	PROC GAMMOD	PROC GAMPL
Gamma	Log	Reciprocal
Inverse Gaussian	Log	Reciprocal square

You should expect close results between these two procedures, although exactly equivalent models are not guaranteed because their implementations are different.

PROC GAMMOD Compared with the GAM Procedure

Both the GAMMOD procedure and the GAM procedure in SAS/STAT software fit generalized additive models. However, the GAMMOD procedure uses different approaches for constructing spline basis expansions, fitting generalized additive models, and testing smoothing components. The GAMMOD procedure focuses on automatic smoothing parameter selection by using global model-evaluation criteria to find optimal models. The GAM procedure focuses on constructing models by fitting partial residuals against each smoothing term with fixed degrees of freedom. In general, you should not expect similar results from these two procedures. Table 12.2 summarizes the main differences.

Table 12.2 PROC GAMMOD Compared with PROC GAM

Functionality	PROC GAMMOD	PROC GAM
Constructing spline basis expansions	Uses thin-plate regression splines to construct basis expansions for each spline term, and each term allows multiple variables	Uses univariate or bivariate smoothing splines to construct basis expansions, and each term allows only one or two variables. Also allows loess smoothers.
Fitting generalized additive models	Fits models that have fixed smoothness terms by optimizing penalized likelihood. For models that have varying smoothness terms, PROC GAMMOD estimates smoothing parameters simultaneously by optimizing global model fit criteria such as generalized cross validation (GCV).	Fits models that have fixed smoothness terms by fitting partial residuals against each smoothing term. For models that have varying smoothness terms, PROC GAM estimates each smoothing parameter by optimizing the local GCV criterion for one spline term at a time.
Distribution families and link functions	Supports more distributions, including the negative binomial and the Tweedie families. Also supports any applicable link functions for each distribution.	Supports major distribution families and the canonical link function for each distribution
Testing smoothing components	Tests the total contribution for a spline term	Tests the existence of nonlinearity for a spline term beyond the linear trend
Model inference	A global Bayesian posterior covariance matrix is available. The confidence limits for each observation's prediction is available, in addition to componentwise confidence limits.	A local Bayesian posterior covariance matrix is available for each spline term. Only the componentwise confidence limits are available.
Model degrees of freedom	Uses the trace of the global degrees-of-freedom matrix	Uses the summation of the traces of individual smoothing matrix for each smoothing term
Multithreading scheme	Specifically designed to operate in SAS Viya and performs computations in multiple threads	Executes in a single thread on a single machine

Using CAS Sessions and CAS Engine Librefs

SAS Cloud Analytic Services (CAS) is the analytic server and associated cloud services in SAS Viya. This section describes how to create a CAS session and set up a CAS engine libref that you can use to connect to the CAS session. It assumes that you have a CAS server already available; contact your system administrator if you need help starting and terminating a server. This CAS server is identified by specifying the host on which it runs and the port on which it listens for communications. To simplify your interactions with this CAS server, the host information and port information for the server are stored as SAS option values that are retrieved automatically whenever this CAS server needs to be accessed. You can examine the host and port values for the server at your site by using the following statements:

```
proc options option=(CASHOST CASPORT);
run;
```

In addition to starting a CAS server, your system administrator might also have created a CAS session and a CAS engine libref for your use. You can define your own sessions and CAS engine librefs that connect to the CAS server as shown in the following statements:

```
cas mysess;
libname mylib cas sessref=mysess;
```

The CAS statement creates the CAS session named mysess, and the LIBNAME statement creates the mylib CAS engine libref that you use to connect to this session. It is not necessary to explicitly name the CASHOST and CASPORT of the CAS server in the CAS statement, because these values are retrieved from the corresponding SAS option values.

If you have created the mysess session, you can terminate it by using the TERMINATE option in the CAS statement as follows:

```
cas mysess terminate;
```

For more information about the CAS and LIBNAME statements, see the section "Introduction to Shared Concepts" on page 6 in Chapter 2, "Shared Concepts."

Getting Started: GAMMOD Procedure

(View the complete code for this example at https://github.com/sascommunities/doc-supplement-casstat/tree/main/Examples/gammodgs1.sas.)

This example concerns the proportions and demographic and geographic characteristics of votes that were cast in 3,107 counties in the United States in the 1980 presidential election. You can use the data set sashelp.Vote1980 directly from the Sashelp library or download it from the StatLib data sets archive (Vlachos 1998). For more information about the data set, see Pace and Barry (1997).

NOTE: Input data must be in a CAS table that is accessible in your CAS session. You must refer to this table by using a two-level name. The first level must be a CAS engine libref, and the second level must be the table name. For more information, see the sections "Using CAS Sessions and CAS Engine Librefs" on page 7 and "Loading a SAS Data Set onto a CAS Server" on page 7 in Chapter 2, "Shared Concepts."

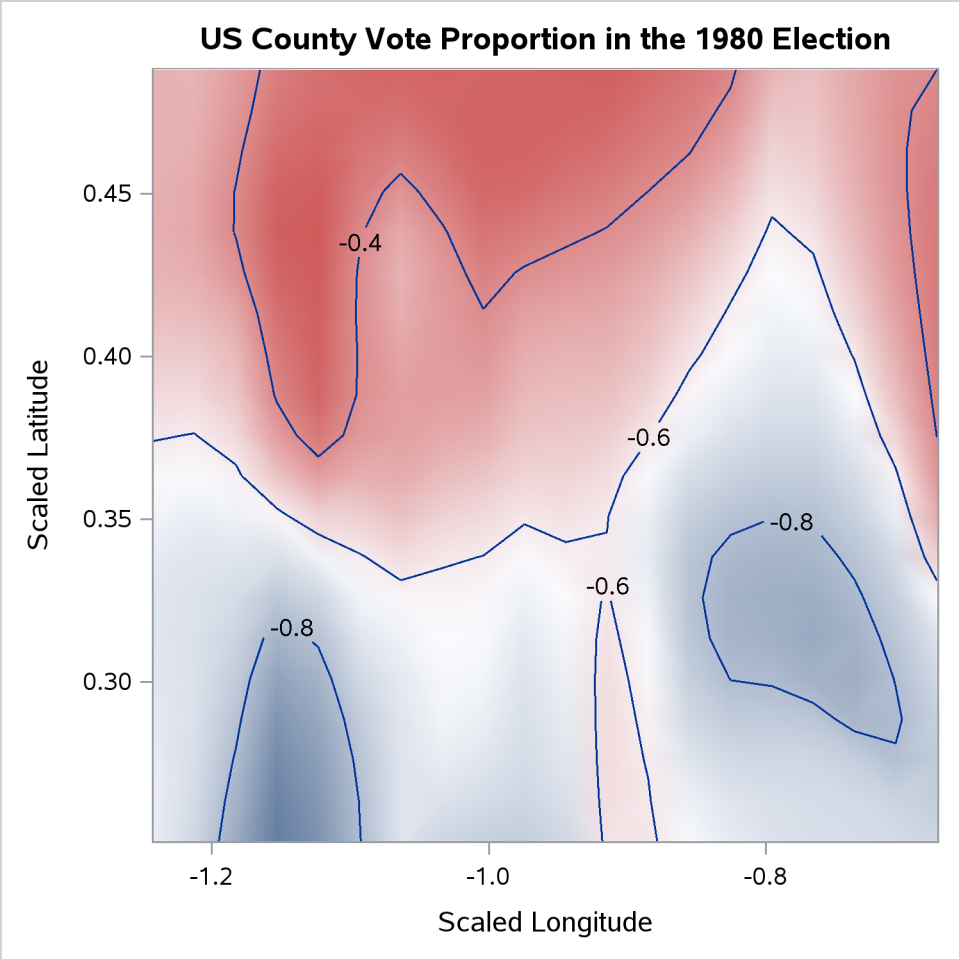
You can load the sashelp.Vote1980 data set into your CAS session by using your CAS engine libref with the following DATA step:

```
data mylib.Vote1980;
   set sashelp.Vote1980;
run;
```

These statements assume that your CAS engine libref is named mylib, as in the section "Using CAS Sessions and CAS Engine Librefs" on page 583, but you can substitute any appropriately defined CAS engine libref.

The data table contains 3,107 observations and seven variables. The dependent variable LogVoteRate is the logarithm transformation of the proportion of the county population who voted for any candidate. The six explanatory variables are the number of people in the county 18 years of age or older (Pop), the number of people in the county who have a 12th-grade or higher education (Edu), the number of owned housing units (Houses), the aggregate income (Income), and the scaled longitude and latitude of geographic centroids (Longitude and Latitude).

The following statements produce a plot of LogVoteRate with respect to the geographic locations Longitude and Latitude:



```
%let off0 = offsetmin=0 offsetmax=0
            linearopts=(thresholdmin=0 thresholdmax=0);
proc template;
   define statgraph surface;
      dynamic _title _z;
      begingraph / designwidth=defaultDesignHeight;
         entrytitle _title;
         layout overlay / xaxisopts=(&off0) yaxisopts=(&off0);
            contourplotparm z=_z y=Latitude x=Longitude / gridded=FALSE;
         endlayout;
      endgraph;
   end;
run;

proc sgrender data=mylib.Vote1980 template=surface;
   dynamic _title = 'US County Vote Proportion in the 1980 Election'
           _z     = 'LogVoteRate';
```

```
run;
```

Figure 12.1 shows the map of the logarithm transformation of the proportion of the county population who voted for any candidate in the 1980 US presidential election.

Figure 12.1 US County Vote Proportion in the 1980 Election

The objective is to explore the nonlinear dependency structure between the dependent variable and the demographic variables (Pop, Edu, Houses, and Income), in addition to the nonlinear dependency structure between the response and the Longitude and Latitude variables. The following statements use thin-plate regression splines to fit a generalized additive model:

```
ods graphics on;

proc gammod data=mylib.Vote1980 plots seed=12345;
   model LogVoteRate = spline(Pop    ) spline(Edu) spline(Houses)
                       spline(Income) spline(Longitude Latitude);
   output out=mylib.VotePred copyvars=(Longitude Latitude);
run;
```

With ODS Graphics enabled by the first statement, the PLOTS option in the PROC GAMMOD statement requests a smoothing component panel of fitted spline terms. The SEED option specifies the random seed so that you can reproduce the analysis.

The default output from this analysis is presented in Figure 12.2 through Figure 12.9.

Figure 12.2 displays the "Model Information" table. The response variable LogVoteRate is modeled by using a normal distribution whose mean is modeled by an identity link function. The GAMMOD procedure uses the performance iteration method and the generalized cross validation (GCV) criterion as the fitting criterion. PROC GAMMOD searches for the optimum smoothing parameters by using the Newton-Raphson algorithm to optimize the fitting criterion. The random number seed is set to 12,345. Random number generation is used for sampling from observations to form spline knots and truncated eigendecomposition. Changing the random number seed might yield slightly different model fits.

Figure 12.2 Model Information

The GAMMOD Procedure

Model Information	
Data Source	VOTE1980
Response Variable	LogVoteRate
Distribution	Normal
Link Function	Identity
Fitting Method	Performance Iteration
Fitting Criterion	GCV
Optimization Technique for Smoothing	Newton-Raphson
Random Number Seed	12345

Figure 12.3 displays the "Number of Observations" table. All 3,107 observations in the data table are used in the analysis. For data tables that have missing or invalid values, the number of used observations might be less than the number of observations read.

Figure 12.3 Number of Observations

Number of Observations Read	3107
Number of Observations Used	3107

Figure 12.4 displays the convergence status of the performance iteration method.

Figure 12.4 Convergence Status

The performance iteration converged after 2 steps.

Figure 12.5 shows the "Fit Statistics" table. The penalized log likelihood and the roughness penalty are displayed. You can use effective degrees of freedom to compare generalized additive models with generalized linear models that do not have spline transformations. Information criteria such as Akaike's information criterion (AIC), Akaike's bias-corrected information criterion (AICC), and Schwarz Bayesian information criterion (BIC) can also be used for comparisons. These criteria penalize the –2 log likelihood for effective degrees of freedom. The GCV criterion is used to compare against other generalized additive models or models that are penalized.

Figure 12.5 Fit Statistics

Fit Statistics	
Penalized Log Likelihood	2729.51482
Roughness Penalty	0.25787
Effective Degrees of Freedom	48.70944
Effective Degrees of Freedom for Error	3055.44725
AIC (smaller is better)	-5361.86863
AICC (smaller is better)	-5360.28467
BIC (smaller is better)	-5067.59479
GCV (smaller is better)	0.01042

.

The "Parameter Estimates" table in Figure 12.6 shows the regression parameter and dispersion parameter estimates. In this model, the intercept is the only regression parameter because (1) all variables are characterized by spline terms and no parametric effects are present and (2) the intercept absorbs the constant effect that is extracted from each spline term to make fitted splines identifiable. The dispersion parameter is estimated by maximizing the likelihood, given other model parameters.

Figure 12.6 Regression Parameter Estimates

Parameter Estimates					
Parameter	**DF**	**Estimate**	**Standard Error**	**Chi-Square**	**Pr > ChiSq**
Intercept	1	-0.576234	0.001803	102119.645	<.0001
Dispersion	1	0.010103	0.014287		

The "Estimates for Smoothing Components" table is shown in Figure 12.7. For each spline term, the effective degrees of freedom, the estimated smoothing parameter, and the corresponding roughness penalty are displayed. The table also displays additional information about spline terms, such as the number of parameters, penalty matrix rank, and number of spline knots.

Figure 12.7 Estimates for Smoothing Components

Estimates for Smoothing Components						
Component	**Effective DF**	**Smoothing Parameter**	**Roughness Penalty**	**Number of Parameters**	**Rank of Penalty Matrix**	**Number of Knots**
Spline(Pop)	7.80559	0.0398	0.0114	9	10	2000
Spline(Edu)	7.12453	0.2729	0.0303	9	10	2000
Spline(Houses)	7.20940	0.1771	0.0370	9	10	2000
Spline(Income)	5.92854	0.7498	0.0488	9	10	2000
Spline(Longitude Latitude)	18.64138	0.000359	0.1304	19	20	2000

Figure 12.8 displays the hypothesis testing results for each smoothing component. The null hypothesis for each spline term is whether the total dependency on each variable is 0. The effective degrees of freedom for fit and the effective degrees of freedom for test are displayed.

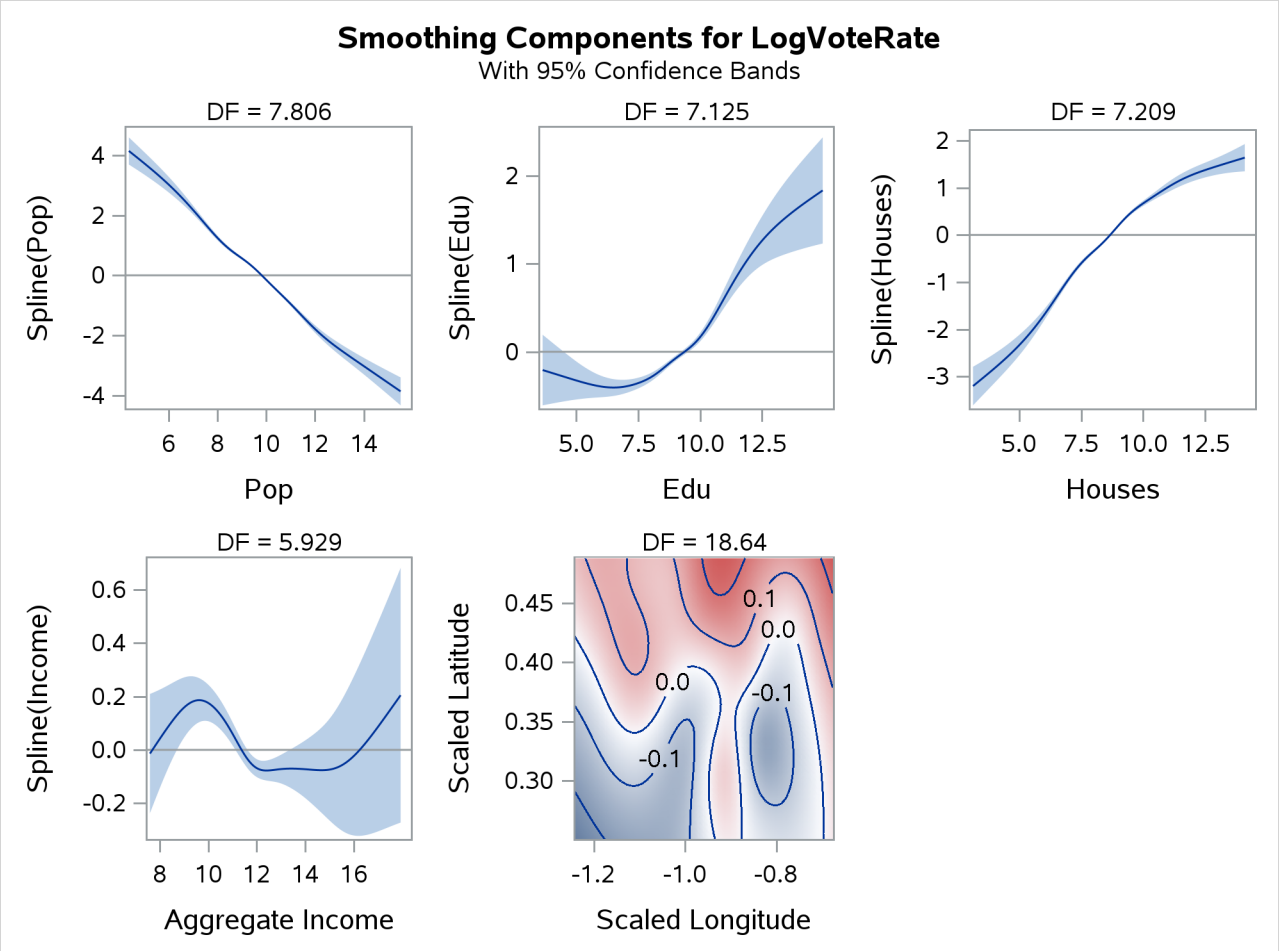


Figure 12.8 Tests for Smoothing Components

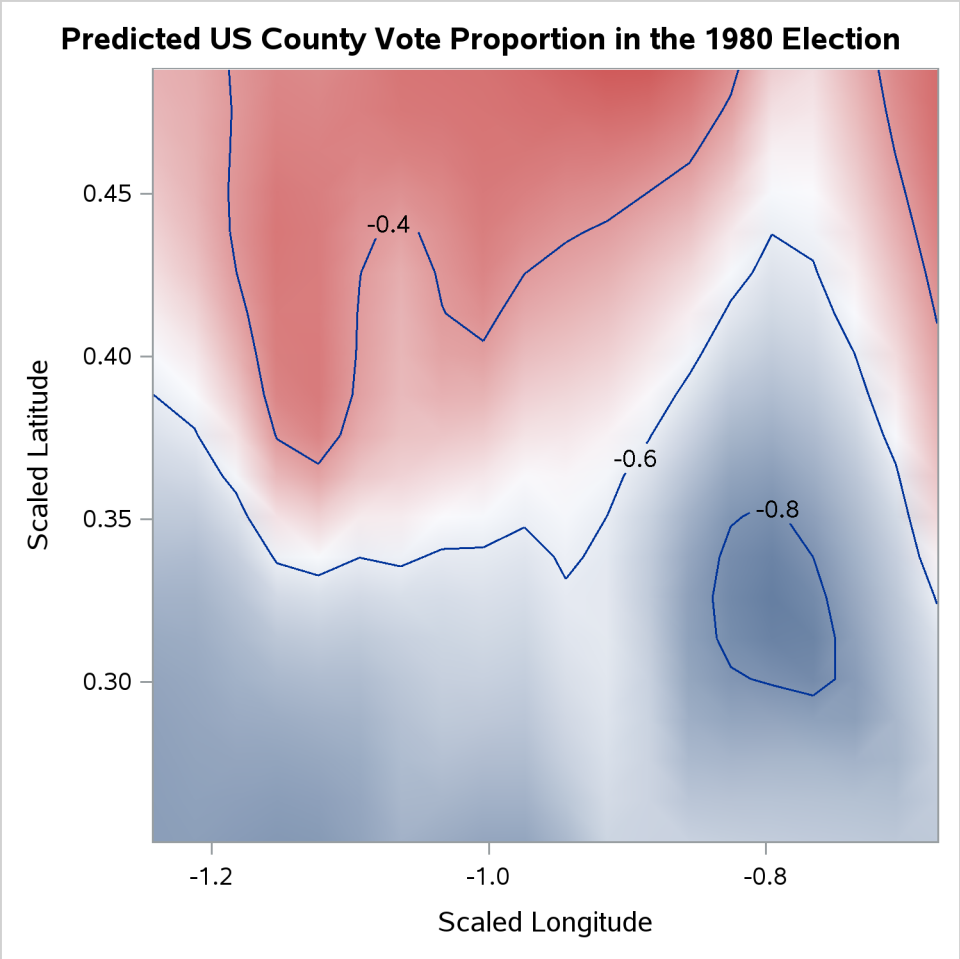
Tests for Smoothing Components

Component	Effective DF	Effective DF for Test	F Value	Pr > F
Spline(Pop)	7.80559	8	1443.64	<.0001
Spline(Edu)	7.12453	8	153.94	<.0001
Spline(Houses)	7.20940	8	1213.94	<.0001
Spline(Income)	5.92854	7	43.17	<.0001
Spline(Longitude Latitude)	18.64138	19	1619.15	<.0001

Figure 12.9 displays the "Smoothing Component Panel" for all the spline terms used in the model. It displays predicted spline curves and 95% Bayesian posterior confidence bands for each univariate spline term.

Figure 12.9 Smoothing Component Panel



The preceding program requests the prediction for each observation by default, and the OUTPUT statement saves the results in the data table mylib.VotePred. The COPYVARS= option in the OUTPUT statement copies the specified variables (Longitude and Latitude) from the input data table, mylib.Vote1980, to the output data table, mylib.VotePred. The following run of the SGRENDER procedure produces the fitted surface of the log vote proportion in the 1980 presidential election:

```
proc sgrender data=mylib.VotePred template=surface;
   dynamic _title='Predicted US County Vote Proportion in the 1980 Election'
           _z    ='Pred';
run;
```

Figure 12.10 shows the map of predictions of the logarithm transformation of the proportion of county population who voted for any candidates in the 1980 US presidential election from the fitted generalized additive model.

Figure 12.10 Predicted US County Vote Proportion in the 1980 Election

Compared to the map of the logarithm transformations of the proportion of votes cast shown in Figure 12.1, the map of the predictions of the logarithm transformations of the proportion of votes cast has a smoother surface.

Syntax: GAMMOD Procedure

The following statements are available in the GAMMOD procedure:

PROC GAMMOD < *options* > **;**
BY *variables* **;**
CLASS *variable* < **(***options***)** >. . . < *variable* < **(***options***)** > > < / *global-options* > **;**
DISPLAY < *table-list* > < / *options* > **;**
DISPLAYOUT *table-spec-list* < / *options* > **;**
FREQ *variable* **;**
MODEL *response* < **(***response-options***)** > **=** < **PARAM(***effects***)** >
< *spline-effects* > < / *model-options* > **;**
MODEL *events* / *trials* **=** < **PARAM(***effects***)** > < *spline-effects* > < / *model-options* > **;**
OUTPUT OUT=*libref.data-table*
< **ALPHA=***number* > < **COMPONENT** > < **COPYVARS=(***variables***)** >
< *keyword* < **=***name* > >. . . < *keyword* < **=***name* > > **;**
STORE < **OUT=** >*libref.data-table* **;**
WEIGHT *variable* **;**

The PROC GAMMOD statement and a single MODEL statement are required. The CLASS statement can appear multiple times. If a CLASS statement is specified, it must precede the MODEL statement. The following sections describe the PROC GAMMOD statement and then describe the other statements in alphabetical order.

PROC GAMMOD Statement

PROC GAMMOD < *options* > **;**

The PROC GAMMOD statement invokes the procedure. Table 12.3 summarizes the available options in the PROC GAMMOD statement by function. The options are then described fully in alphabetical order.

Table 12.3 PROC GAMMOD Statement Options

Option	Description
Basic Options	
ALPHA=	Specifies a global significance level
DATA=	Specifies the input data table
SEED=	Sets the seed for pseudorandom number generation
Display Options	
ITDETAILS	Displays the “Iteration History” table
NOCLPRINT	Limits or suppresses the display of classification variable levels
NOPRINT	Suppresses ODS output
PLOTS=	Controls plots that are produced through ODS Graphics
Optimization Subject Options	
PLIKEOPTIONS	Sets optimization parameters for likelihood estimation

Table 12.3 *continued*

Option	Description
SMOOTHOPTIONS	Sets optimization parameters for smoothing parameter estimation
Tolerance Options	
SINGCHOL=	Tunes the singularity criterion for Cholesky decompositions
SINGULAR=	Tunes the general singularity criterion

You can specify the following *options* in the PROC GAMMOD statement.

ALPHA=*number*

specifies a global significance level for the hypothesis testing of smoothing components and the construction of Bayesian confidence bands of predictions. The confidence level is 1 – *number*. The value of *number* must be between 0 and 1; the default is 0.05. You can override this global significance level for Bayesian confidence bands of predictions by specifying the ALPHA= option in the OUTPUT statement.

DATA=*libref.data-table*

names the input data table for PROC GAMMOD to use. The default is the most recently created data table. *libref.data-table* is a two-level name, where

libref refers to a collection of information that is defined in the LIBNAME statement and includes the library, which includes a path to the data, and a session identifier, which defaults to the active session but which can be explicitly defined in the LIBNAME statement. For more information about *libref*, see the section "Using CAS Sessions and CAS Engine Librefs" on page 583.

data-table specifies the name of the input data table.

ITDETAILS

adds to the "Iteration History" table the current values of the parameter estimates and their gradients. If the optimization algorithm is used to determine at least one smoothing parameter, the table lists values for smoothing parameters. If all smoothing parameters are fixed or a parametric generalized linear model is specified, the table lists values for regression parameters. These quantities are reported only for parameters that participate in the optimization.

NOCLPRINT< =*number* **>**

suppresses the display of the "Class Level Information" table if you do not specify *number*. If you specify *number*, the values of the classification variables are displayed for only those variables whose number of levels is less than *number*. Specifying a *number* helps reduce the size of the "Class Level Information" table if some classification variables have a large number of levels.

NOPRINT

suppresses the generation of ODS output.

PLIKEOPTIONS(*optimization-parameters***)**
specifies optimization parameters for either maximum or penalized likelihood estimation. For more information about which *optimization-parameters* you can specify, see the section "Optimization Parameters" on page 593. For the performance iteration method, only the ABSFCONV=, FCONV=, and MAXITER= options are effective for determining when the performance iteration should have converged. If the distribution family involves a dispersion parameter that needs to be estimated by the maximum likelihood method, all the optimization parameters in this option are applicable.

PLOTS < (*global-plot-option***) > < = *plot-requests* < (***option***) > >**
controls the plots that are produced through ODS Graphics. When ODS Graphics is enabled, PROC GAMMOD produces by default a panel of plots of partial prediction curves or surfaces of smoothing components.

```
ods graphics on;

proc gammod plots;
   model y=spline(x1) spline(x2);
run;

ods graphics off;
```

You can specify the following *global-plot-option*, which applies to the smoothing component plots that the GAMMOD procedure generates:

UNPACK | UNPACKPANEL
suppresses paneling. By default, multiple smoothing component plots can appear in some output panels. Specify UNPACK to get each plot individually.

You can specify the following *plot-requests*:

ALL
requests that all default plots be produced.

COMPONENTS < (*component-option***) >**
plots a panel of smoothing components of the fitted model. You can specify the following *component-option*:

COMMONAXES
requests that the smoothing component plots use a common vertical axis except for bivariate contour plots. This option enables you to visually judge the relative effect size.

NONE
suppresses all plots.

SEED=*number*
specifies an integer that is used to start the pseudorandom number generator for truncated eigendecomposition and for subset sampling from observations to form knots if necessary. If you do not specify this option or if *number* ≤ 0, the seed is generated from the time of day, which is read from the computer's clock.

SINGCHOL=*number*
tunes the singularity criterion in Cholesky decomposition and matrix inversion operations. The default is 1E4 times the machine epsilon; this product is approximately 1E–12 on most computers.

SINGULAR=*number*
tunes the singularity criterion in truncated eigendecomposition to determine its convergence. The default is 1E4 times the machine epsilon; this product is approximately 1E–12 on most computers.

SMOOTHOPTIONS(*optimization-parameters***)**
specifies optimization parameters for smoothing parameter estimation. For more information about which *optimization-parameters* you can specify, see the next section. For parametric generalized linear models or generalized additive models that have fixed smoothing parameters, any optimization parameters that you specify for this option are ignored.

Optimization Parameters

You can specify *optimization-parameters* for both the PLIKEOPTIONS and SMOOTHOPTIONS options. Depending on the modeling context, some optimization parameters might have no effect. The optimization algorithm is considered to have converged when any one of the convergence criteria that are specified in *optimization-parameters* is satisfied. Table 12.4 lists the available optimization parameters for both the PLIKEOPTIONS and SMOOTHOPTIONS options.

Table 12.4 Optimization Parameters

Option	Description
ABSCONV=	Tunes the absolute function convergence criterion
ABSFCONV=	Tunes the absolute function difference convergence criterion
ABSGCONV=	Tunes the absolute gradient convergence criterion
FCONV=	Tunes the relative function difference convergence criterion
GCONV=	Tunes the relative gradient convergence criterion
MAXFUNC=	Specifies the maximum number of function evaluations in any optimization
MAXITER=	Chooses the maximum number of iterations in any optimization
MAXTIME=	Specifies the upper limit of CPU time (in seconds) for any optimization
MINITER=	Specifies the minimum number of iterations in any optimization
TECHNIQUE=	Selects the optimization technique

The *optimization-parameters* are fully described in the section "Optimization Options" on page 57 in Chapter 2, "Shared Concepts."

NOTE: By default, TECHNIQUE=NEWRAP for the performance iteration (METHOD=PERFORMANCE), and TECHNIQUE=QUANEW for the outer iteration (METHOD=OUTER).

BY Statement

BY *variables* **;**

You can specify a BY statement in PROC GAMMOD to obtain separate analyses of observations in groups that are defined by the values of the BY variables. If you specify more than one BY statement, only the last one specified is used. For more information, see the discussion of BY-group processing in the "Grouping Data" section of *SAS Programmers Guide: Essentials*.

CLASS Statement

CLASS *variable* < **(***options***)** >. . . < *variable* < **(***options***)** > > < / *global-options* > **;**

The CLASS statement names the classification variables to be used as explanatory variables in the analysis. You can list the response variable for binary models in the CLASS statement, but this is not required. Table 12.5 summarizes the values that you can use for either an *option* or a *global-option*. The options are fully documented in the section "CLASS Statement" on page 9 in Chapter 2, "Shared Concepts."

Table 12.5 CLASS Statement Options

Option	Description
DESCENDING	Reverses the sort order
MISSING	Treats missing values as valid levels
ORDER=	Specifies the sort order for the levels
PARAM=	Specifies the parameterization of the variable
REF=	Specifies the reference level of the variable

DISPLAY Statement

DISPLAY < *table-list* > < / *options* > **;**

The DISPLAY statement enables you to specify a list of display tables to display or exclude. This statement is similar to the ODS SELECT, ODS EXCLUDE, and ODS TRACE statements. However, the DISPLAY statement can improve performance when a large number of tables could be generated (such as in BY-group processing). The procedure processes the DISPLAY statement on a CAS server and thus sends only a subset of ODS tables to the SAS client. Because ODS statements are processed on a SAS client, first all the generated display tables are sent to the client, and then the client creates a subset.

If you use both DISPLAY and ODS statements together, the DISPLAY statement takes precedence over the ODS statements. Note that the ODS EXCLUDE statement processes tables that are sent to the client after they have been filtered by the DISPLAY statement. In some cases, it might appear that the ODS EXCLUDE statement is taking precedence because it can further filter the tables. For more information about ODS, see *SAS Output Delivery System: Procedures Guide*.

You can specify the *table-list* as a list of table names, paths, partial pathnames, and regular expressions.

The table names that you can specify are listed in the section "ODS Table Names" on page 621. A path is a table name that is prefixed with dot-separated grouping information. For example, a SelectionSummary table that a procedure produces during a selection routine might have the path *Bygroup1.Summary.SelectionSummary*. A partial pathname does not include all groups; for example, *SelectionSummary* and *Summary.SelectionSummary* are partial pathnames for *Bygroup1.Summary.SelectionSummary*.

When you specify a table name or partial pathname, all display tables whose paths end in the specified name are selected for display or exclusion. For example, both *SelectionSummary* and *Summary.SelectionSummary* select *Bygroup1.Summary.SelectionSummary*.

A regular expression is enclosed in forward slashes (/). For example, specifying "/tions/" selects all pathnames that contain the substring "tions"; in particular, the *Bygroup1.Summary.SelectionSummary* table is selected. Specifying "!/tions/" selects all pathnames that do not contain the substring "tions"; in particular, the *Bygroup1.Summary.SelectionSummary* table is not selected.

You can specify the following *options* after a slash (/):

CASESENSITIVE
performs a case-sensitive comparison of table names in the *table-list* to display table names when tables are subsetted for display. To preserve case, you must enclose table names in the *table-list* in quotation marks.

EXCLUDE
displays all display tables except those that you specify in the *table-list*.

EXCLUDEALL
suppresses display of all tables. This option takes precedence over the other options.

TRACE
displays the display table names, labels, and paths.

DISPLAYOUT Statement

DISPLAYOUT *table-spec-list* < / *options* > **;**

The DISPLAYOUT statement enables you to create output tables from your displayed output. This statement is similar to the ODS OUTPUT statement. For more information about ODS, see *SAS Output Delivery System: Procedures Guide*.

The *table-spec-list* specifies a list of output tables to create. Each entry in the list has either a *key=value* format or a *key* format:

key=value specifies *key* as the ODS table name, path, or partial pathname, and specifies *value* as the output table name.

key specifies *key* as the ODS table name and also as the output table name.

The ODS table names that you can specify are listed in the section "ODS Table Names" on page 621. You cannot specify the ODS table named OutputCasTables in the *table-spec-list*.

Table names and partial pathnames are discussed under the DISPLAY statement. The DISPLAYOUT statement does not support regular expressions.

You can specify the following *options* after a slash (/):

INCLUDEALL
creates output tables for all display tables. The name of the created output table is the same as the name of the corresponding display table. If you specify this option, the *table-spec-list* specification is ignored.

NOREPLACE
does not replace any existing output table of the same name.

REPEATED
replicates all output tables on all nodes.

FREQ Statement

FREQ *variable* **;**

The *variable* in the FREQ statement identifies a numeric variable in the input data table that contains the frequency of occurrence of each observation. PROC GAMMOD treats each observation as if it appears f times, where f is the value of the FREQ *variable* for the observation. If f is not an integer, it is truncated to an integer. If f is less than 1 or missing, the observation is not used in the analysis. When you omit the FREQ statement, each observation is assigned a frequency of 1.

MODEL Statement

MODEL *response* < **(***response-options***)** > **=** < **PARAM(***effects***)** > < *spline-effects* > < / *model-options* > **;**

MODEL *events* / *trials* **=** < **PARAM(***effects***)** > < *spline-effects* > < / *model-options* > **;**

The MODEL statement specifies the response (dependent or target) variable and the predictor (independent or explanatory) effects of the model. You can specify the response in the form of a single variable or in the form of a ratio of two variables, which are denoted *events/trials*. The first form applies to all distribution families; the second form applies only to summarized binomial response data. When you have binomial data, the *events* variable contains the number of positive responses (or events) and the *trials* variable contains the number of trials. The values of both *events* and (*trials* – *events*) must be nonnegative, and the value of *trials* must be positive. If you specify a single *response* variable that is in a CLASS statement, then the response is assumed to be binary.

You can specify parametric effects that are constructed from variables in the input data and include the effects in the parentheses of a PARAM( ) option, which can appear multiple times. For information about constructing the model effects, see the section "Specification and Parameterization of Model Effects" on page 64 in Chapter 2, "Shared Concepts."

You can specify *spline-effects* by including independent variables inside the parentheses of the SPLINE( ) option. Only continuous variables (not classification variables) can be specified in *spline-effects*. Each *spline-effect* can have at least one variable and optionally some *spline-options*. You can specify any number of *spline-effects*. The following table shows some examples.

Spline Effect Specification	Meaning
`spline(x)`	Constructs a univariate spline by using x and uses the observed data points as knots. The maximum degrees of freedom is 10. PROC GAMMOD uses an optimization algorithm to determine the optimal smoothing parameter.
`spline(x1/knots=list(1 to 10))`	Constructs a univariate spline by using x1 and a supplied list of knots from 1 to 10. PROC GAMMOD uses an optimization algorithm to determine the optimal smoothing parameter.
`spline(x2 x3/smooth=0.3)`	Constructs a bivariate spline by using x2 and x3 and a fixed smoothing parameter 0.3.
`spline(x4 x5 x6/maxdf=40)`	Constructs a trivariate spline by using x4, x5, and x6 and a maximum of 40 degrees of freedom. PROC GAMMOD uses an optimization algorithm to determine the optimal smoothing parameter.

Both parametric effects and spline effects are optional. If none are specified, a model that contains only an intercept is fitted. If only parametric effects are present, PROC GAMMOD fits a parametric generalized linear model by using the terms inside the parentheses of all PARAM( ) terms. If only spline effects are present, PROC GAMMOD fits a nonparametric additive model. If both types of effects are present, PROC GAMMOD fits a semiparametric model by using the parametric effects as the linear part of the model.

There are three sets of options in the MODEL statement. The *response-options* determine how the GAMMOD procedure models probabilities for binary data. The *spline-options* controls how each spline term forms basis expansions. The *model-options* control other aspects of model formation and inference. Table 12.6 summarizes these options, and subsequent sections describe them in detail.

Table 12.6 MODEL Statement Options

Option	Description
Response Variable Options	
DESCENDING	Reverses the response categories
EVENT=	Specifies the event category
ORDER=	Specifies the sort order
REF=	Specifies the reference category
Spline Effect Options	
DETAILS	Requests detailed spline information
DF=	Specifies the fixed degrees of freedom
INITSMOOTH=	Specifies the starting value for the smoothing parameter
KNOTS=	Specifies the knots to use for constructing the spline
M=	Specifies polynomial orders for constructing the spline
MAXDF=	Specifies the maximum degrees of freedom
MAXKNOTS=	Specifies the maximum number of knots to use for constructing the spline
MAXSMOOTH=	Specifies the upper bound for the smoothing parameter

Table 12.6 *continued*

Option	Description
MINSMOOTH=	Specifies the lower bound for the smoothing parameter
SMOOTH=	Specifies a fixed smoothing parameter
Model Options	
ALLOBS	Requests all nonmissing values of spline variables for constructing spline basis functions regardless of other model variables
CRITERION=	Specifies the model evaluation criterion
DISPERSION | PHI=	Specifies the fixed dispersion parameter
DISTRIBUTION | DIST=	Specifies the response distribution
FDHESSIAN	Requests a finite-difference Hessian for smoothing parameter selection
INITIALPHI=	Specifies the starting value of the dispersion parameter
LINK=	Specifies the link function
NORMALIZE	Requests normalized spline basis functions for model fitting
MAXPHI=	Specifies the upper bound for searching the dispersion parameter
METHOD=	Specifies the algorithm for selecting smoothing parameters
MINPHI=	Specifies the lower bound for searching the dispersion parameter
OFFSET=	Specifies the offset variable
RIDGE=	Specifies the ridge parameter
SCALE=	Specifies the method for estimating the dispersion parameter

Response Variable Options

Response variable options determine how the GAMMOD procedure models probabilities for binary data.

You can specify the following *response-options* by enclosing them in parentheses after the *response* variable.

DESCENDING

DESC

reverses the order of the response categories. If you specify both the DESCENDING and ORDER= options, PROC GAMMOD orders the response categories according to the ORDER= option and then reverses that order.

EVENT='*category***' | FIRST | LAST**

specifies the event category for the binary response model. PROC GAMMOD models the probability of the event category. This option has no effect when there are more than two response categories.

You can specify any of the following:

'*category*' specifies that observations whose value matches *category* (formatted, if a format is applied) in quotation marks represent events in the data. For example, the following statements specify that observations that have a formatted value of '1' represent events in the data. The probability that is modeled by the GAMMOD procedure is thus the probability that the variable def takes on the (formatted) value '1'.

```
proc gammod data=mylib.MyData;
   class A B C;
   model def(event ='1') = param(A B C) spline(x1 x2 x3);
run;
```

FIRST designates the first ordered category as the event.

LAST designates the last ordered category as the event.

By default, EVENT=FIRST.

ORDER=FORMATTED | FREQ | INTERNAL
specifies the sort order for the levels of the *response* variable. You can specify the following values:

FORMATTED sorts the levels by external formatted value, except for numeric variables that have no explicit format, which are sorted by their unformatted (internal) value. For numeric variables for which you have supplied no explicit format (that is, for which there is no corresponding FORMAT statement in the current PROC GAMMOD run or in the DATA step that created the data table), the levels are ordered by their internal (numeric) value. The sort order is machine-dependent.

FREQ sorts the levels by descending frequency count (levels that have the most observations come first in the order).

INTERNAL sorts the levels by unformatted value. The sort order is machine-dependent.

By default, ORDER=FORMATTED.

For more information about sort order, see the chapter about the SORT procedure in *Base SAS Procedures Guide* and the discussion of BY-group processing in *SAS Language Reference: Concepts*.

REF='*category*' **| FIRST | LAST**
specifies the reference category for the binary response model. Specifying one response category as the reference is the same as specifying the other response category as the event category. You can specify any of the following:

'*category*' specifies that observations whose value matches *category* (formatted, if a format is applied) are designated as the reference.

FIRST designates the first ordered category as the reference

LAST designates the last ordered category as the reference.

By default, REF=LAST.

Spline Effect Options

Spline effect options control how each spline term forms basis expansions.

You can specify the following *spline-effects* inside the parentheses of a SPLINE( ) term:

DETAILS
requests a detailed spline specification information table.

DF=*number*
specifies a fixed degrees of freedom. When you specify this option, no smoothing parameter selection is performed on the spline term. If *number* is not an integer, then *number* is truncated to an integer.

INITSMOOTH=*number*
specifies the starting value for a smoothing parameter. The *number* must be nonnegative.

KNOTS=*method*
specifies the *method* for supplying user-defined knot values instead of using data values for constructing basis expansions. You can use the following *methods* for supplying the knots:

LIST(*list-of-values***)**
specifies a list of values as knots for the spline construction. For a multivariate spline term, the listed values are taken as multiple row vectors, where each vector has values that are ordered by specified variables. If the last row vector of knots contains fewer values than the number of variables, then the last row vector is ignored. For example, the following specification of a spline term produces two actual knot vectors ($\boldsymbol{k}_1$ and $\boldsymbol{k}_2$) and the value 5 is ignored.

```
spline(x1 x2/knots=list(1 2 3 4 5))
```

Table 12.7 Knot Values for a Bivariate Spline with a Supplied List

	x1	x2
$\boldsymbol{k}_1$	1	2
$\boldsymbol{k}_2$	3	4

EQUAL(*n***)**
specifies the number of equally spaced interior knots for every variable in a spline term. Two boundary knots are automatically added to the knot list for each variable such that the total number of knots is $(n + 2)^d$, where d is the number of variables in the spline term. For a multivariate spline term, knot values for each variable are determined independently from the corresponding boundary values. For example, if the boundary points for x1 are 1 and 5 and the boundary points for x2 are 2 and 6, then the following specification of a spline term produces nine actual knots ($\boldsymbol{k}_1$ through $\boldsymbol{k}_9$), which consist of two boundary knots and one interior knot for each variable.

```
spline(x1 x2/knots=equal(1))
```

Table 12.8 Knot Values for a Bivariate Spline with One Interior Knot

	x1	x2
$\boldsymbol{k}_1$	1	2
$\boldsymbol{k}_2$	1	4
$\boldsymbol{k}_3$	1	6
$\boldsymbol{k}_4$	3	2
$\boldsymbol{k}_5$	3	4
$\boldsymbol{k}_6$	3	6
$\boldsymbol{k}_7$	5	2
$\boldsymbol{k}_8$	5	4
$\boldsymbol{k}_9$	5	6

M=*number*

specifies the order of the derivative in the penalty term. The *number* must be a positive integer. The default is $\max(2, \text{int}(d/2) + 1)$, where d is the number of variables in the spline term.

MAXDF=*number*

specifies the maximum *number* of degrees of freedom. When a thin-plate regression spline is formed, the specified *number* is used for constructing a low-rank penalty matrix to approximate the penalty matrix via the truncated eigendecomposition. The *number* must be greater than $\binom{m+d-1}{d}$, where m is the derivative order that is specified in the M= option, and d is the number of variables in the spline term. The default is $10 \times d$. For more information, see the section "Thin-Plate Regression Splines" on page 608.

MAXKNOTS=*number*

specifies the maximum *number* of knots if data points are used to form knots. If KNOTS=LIST(*list-of-values*) is not specified, PROC GAMMOD forms knots from unique data points. If the number of unique data points is greater than *number*, a subset of size *number* is formed by random sampling from all unique data points. The *number* cannot exceed the largest integer that can be stored on the CAS server. By default, MAXKNOTS=2000.

MAXSMOOTH=*number*

specifies the upper bound for the smoothing parameter. The default is the largest double-precision value.

MINSMOOTH=*number*

specifies the lower bound for the smoothing parameter. By default, MINSMOOTH=0.

SMOOTH=*number*

specifies a fixed smoothing parameter. When you specify this option, no smoothing parameter selection is performed on the spline term.

Model Options

You can specify the following *model-options* in the MODEL statement after a slash (/):

ALLOBS
requests that all nonmissing values of the variables be used in a spline term for constructing the spline basis functions, regardless of whether other model variables are missing.

CRITERION=*criterion*
specifies the model evaluation criterion for selecting smoothing parameters for *spline-effects*. You can specify the following values:

GACV< (FACTOR=*number* | **GAMMA=***number*) >
uses the generalized approximate cross validation (GACV) criterion to evaluate models.

GCV< (FACTOR=*number* | **GAMMA=***number*) >
uses the generalized cross validation (GCV) criterion to evaluate models.

UBRE< (FACTOR=*number* | **GAMMA=***number*) >
uses the unbiased risk estimator (UBRE) criterion to evaluate models.

The default *criterion* depends on the value of the DISTRIBUTION= option. For distributions that involve dispersion parameters, GCV is the default. For distributions without dispersion parameters, UBRE is the default. For all three criteria, you can optionally use the FACTOR= option to specify an extra tuning parameter in order to penalize more for model roughness. The value of *number* must be greater than or equal to 1. For more information about the model evaluation criteria, see the section "Model Evaluation Criteria" on page 612.

DISPERSION=*number*
PHI=*number*
specifies a fixed dispersion parameter for distributions that have a dispersion parameter. The dispersion parameter that is used in all computations is fixed at *number*; it is not estimated.

DISTRIBUTION=*keyword*
specifies the response distribution for the model. The *keywords* and their associated distributions are shown in Table 12.9.

Table 12.9 Built-In Distribution Functions

DISTRIBUTION=	Distribution Function
BINARY | BERNOULLI	Binary
BINOMIAL	Binary or binomial
GAMMA	Gamma
INVGAUSS | IG | IGAUSSIAN	Inverse Gaussian
NB | NEGBIN | NEGBINOMIAL	Negative binomial
NORMAL | GAUSSIAN | GAUSS	Normal
POISSON | POI	Poisson
TWEEDIE< (*Tweedie-options***) >**	Tweedie

When DISTRIBUTION=TWEEDIE, you can specify the following *Tweedie-options*:

INITIALP=
specifies a starting value for iterative estimation of the Tweedie power parameter.

P=
requests a fixed Tweedie power parameter.

If you do not specify a link function in the LINK= option, a default link function is used. The default link function for each distribution is shown in Table 12.10. You can use any link function shown in Table 12.11 by specifying the LINK= option. Other commonly used link functions for each distribution are shown in Table 12.10.

Table 12.10 Default and Commonly Used Link Functions

DISTRIBUTION=	Default Link Function	Other Commonly Used Link Functions
BINARY | BERNOULLI	Logit	Probit, complementary log-log, log-log
BINOMIAL	Logit	Probit, complementary log-log, log-log
GAMMA	Log	Reciprocal
INVGAUSS | IG | IGAUSSIAN	Log	Reciprocal square
NB | NEGBIN | NEGBINOMIAL	Log	
NORMAL | GAUSSIAN | GAUSS	Identity	Log
POISSON | POI	Log	
TWEEDIE	Log	

FDHESSIAN
requests that the second-order derivatives (Hessian) be computed using finite-difference approximations based on evaluation of the first-order derivatives (gradient). This option might be useful if the analytical Hessian takes a long time to compute.

INITIALPHI=*number*
specifies a starting value for iterative maximum likelihood estimation of the dispersion parameter for distributions that have a dispersion parameter.

LINK=*keyword*
specifies the link function for the model. The *keywords* and the associated link functions are shown in Table 12.11. Default and commonly used link functions for the available distributions are shown in Table 12.10.

Table 12.11 Built-In Link Functions

LINK=	Link Function	$g(\mu) = \eta =$
CLOGLOG | CLL	Complementary log-log	$\log(-\log(1-\mu))$
IDENTITY | ID	Identity	μ
INVERSE | RECIP | RECIPROCAL	Reciprocal	$1/\mu$
INV2 | POWERMINUS2 | POWMINUS2	Reciprocal square	$1/\mu^2$
LOG	Logarithm	$\log(\mu)$
LOGIT	Logit	$\log(\mu/(1-\mu))$
LOGLOG	Log-log	$-\log(-\log(\mu))$
PROBIT | NORMIT	Probit	$\Phi^{-1}(\mu)$

$\Phi^{-1}(\cdot)$ denotes the quantile function of the standard normal distribution.

MAXPHI=*number*

specifies an upper bound for maximum likelihood estimation of the dispersion parameter for distributions that have a dispersion parameter.

METHOD=OUTER | PERFORMANCE

specifies the algorithm for selecting smoothing parameters for *spline-effects*. You can specify the following values:

OUTER specifies the outer iteration method for selecting smoothing parameters. For more information about this method, see the section "Outer Iteration" on page 613.

PERFORMANCE specifies the performance iteration method for selecting smoothing parameters. For more information about this method, see the section "Performance Iteration" on page 614.

By default, METHOD=PERFORMANCE.

MINPHI=*number*

specifies a lower bound for maximum likelihood estimation of the dispersion parameter for distributions that have a dispersion parameter.

NORMALIZE

requests normalized spline basis functions for model fitting. After the regression spline basis functions are computed, each column is standardized to have a unit standard error. The corresponding penalty matrix is also scaled accordingly. This option might be helpful when you have badly scaled data.

OFFSET=*variable*

specifies a *variable* to be used as an offset to the linear predictor. An offset plays the role of an effect whose coefficient is known to be 1. The offset variable cannot appear in the CLASS statement or elsewhere in the MODEL statement. Observations that have missing values for the offset variable are excluded from the analysis.

RIDGE=*number*
allows a ridge parameter such that a diagonal matrix $\mathbf{H} : \mathbf{H}_{ii} = number$ is added to the optimization problem with respect to regression parameters:

$$\min(\mathbf{y} - \mathbf{X}\boldsymbol{\beta})'(\mathbf{y} - \mathbf{X}\boldsymbol{\beta}) + \boldsymbol{\beta}'\mathbf{S}_{\boldsymbol{\lambda}}\boldsymbol{\beta} + \boldsymbol{\beta}'\mathbf{H}\boldsymbol{\beta} \quad \text{with respect to} \quad \boldsymbol{\beta}$$

By default, RIDGE=0. Specifying a small ridge parameter might be helpful if the model matrix $\mathbf{X}'\mathbf{X} + \mathbf{S}_{\boldsymbol{\lambda}}$ is close to singular.

SCALE=DEVIANCE | MLE | PEARSON
specifies the method for estimating the scale and dispersion parameters. You can specify the following values:

DEVIANCE
estimates the dispersion parameter by using the deviance statistic.

MLE
computes the dispersion parameter by maximizing the likelihood or penalized likelihood.

PEARSON
estimates the dispersion parameter by using Pearson's statistic.

By default, SCALE=MLE.

OUTPUT Statement

OUTPUT OUT=*libref.data-table*
< **ALPHA=***number* > < **COMPONENT** > < **COPYVARS=***(variables)* >
< *keyword* < **=***name* > >. . . < *keyword* < **=***name* > > **;**

The OUTPUT statement creates a data table that contains observationwise statistics that PROC GAMMOD computes after fitting the model. In order to avoid data duplication for large data tables, the variables in the input data table are *not* included in the output data table unless you specify them in the COPYVARS= option.

The computation of the output statistics is based on the final parameter estimates. If the model fit does not converge, missing values are produced for the quantities that depend on the estimates.

You must specify the following option:

OUT=*libref.data-table*
names the output data table for PROC GAMMOD to use. You must specify this option before any other options. *libref.data-table* is a two-level name, where

libref refers to a collection of information that is defined in the LIBNAME statement and includes the library, which includes a path to where the data table is to be stored, and a session identifier, which defaults to the active session but which can be explicitly defined in the LIBNAME statement. For more information about *libref*, see the section "Using CAS Sessions and CAS Engine Librefs" on page 583.

data-table specifies the name of the output data table.

You can also specify the following syntax elements:

ALPHA=*number*

specifies the significance level for the construction of confidence intervals in the output data table. The confidence level is $1 - number$. The value of *number* must be between 0 and 1. By default, *number* is equal to the value of the ALPHA= option in the PROC GAMMOD statement, or 0.05 if that option is not specified.

COMPONENT

requests componentwise statistics for all spline terms if LINP, LOWER, STD, or UPPER is specified as a *keyword*.

COPYVAR=*variable*

COPYVARS=(*variables***)**

transfers one or more *variables* from the input data table to the output data table.

keyword **<=***name***>**

specifies a statistic to include in the output data table and optionally assigns a *name* to the variable. If you do not provide a *name*, the GAMMOD procedure assigns a default name based on the *keyword*.

You can specify the following *keywords* for adding statistics to the OUTPUT data table:

LINP | XBETA

requests the linear predictor $\eta = \mathbf{x}'\boldsymbol{\beta}$. For observations in which only the response variable is missing, values of the linear predictor are computed even though these observations do not affect the model fit. The default *name* is Xbeta.

LOWER

requests a lower Bayesian confidence band value for the predicted value. The default *name* is Lower.

PEARSON | PEARS | RESCHI

requests the Pearson residual, $(y - \mu)/\sqrt{\mathrm{V}(\mu)}$, where μ is the estimate of the predicted response mean and $\mathrm{V}(\mu)$ is the response distribution variance function. The default *name* is Pearson.

PREDICTED | PRED | P

requests predicted values for the response variable. For observations in which only the response variable is missing, the predicted values are computed even though these observations do not affect the model fit. The default *name* is Pred.

RESIDUAL | RESID | R

requests the raw residual, $y - \mu$, where μ is the estimate of the predicted mean. The default *name* is Residual.

STD

requests a standard error for the linear predictor. The default *name* is Std.

UPPER

requests an upper Bayesian confidence band value for the predicted value. The default *name* is Upper.

STORE Statement

STORE < **OUT=** >*libref.data-table* **;**

The STORE statement saves the context and results of the statistical analysis. The resulting analytic store has a binary file format that cannot be modified. An example of analytic store technology is to perform a time-consuming analysis and to store its results by using the STORE statement. Later you can perform specific statistical analysis tasks based on the saved results of the previous analysis, without having to fit the model again. The contents of the analytic store that PROC GAMMOD produces can be processed by the ASTORE procedure, the **`gamScore`** action in the **`gam`** action set, and the **`score`** action in the **`aStore`** action set.

libref.data-table is a two-level name, where *libref* refers to the library, and *data-table* specifies the name of the output data table. For more information about this two-level name, see the section "Using CAS Sessions and CAS Engine Librefs" on page 583.

WEIGHT Statement

WEIGHT *variable* **;**

The *variable* in the WEIGHT statement is used as a weight to perform a weighted analysis of the data. Observations that have nonpositive or missing weights are not included in the analysis. If a WEIGHT statement is not included, then all observations that are used in the analysis are assigned a weight of 1.

Details: GAMMOD Procedure

Missing Values

Any observation that has missing values for the response, frequency, weight, offset, or explanatory variables is excluded from the analysis; however, missing values are valid for response and explanatory variables if you specify the MISSING option in the CLASS statement. Observations that have a nonpositive weight or a frequency less than 1 are also excluded. For Poisson, negative binomial, and Tweedie distributions, observations that have a negative response value are excluded. For gamma and inverse Gaussian distributions, observations that have a nonpositive response value are excluded.

The estimated linear predictor and the fitted means are not computed for any observation that has missing offset or explanatory variables. However, if only the response value is missing, the linear predictor and the fitted means can be computed and output to a data table by using the OUTPUT statement.

Thin-Plate Regression Splines

The GAMMOD procedure uses thin-plate regression splines (Wood 2003) to construct spline basis expansions. The thin-plate regression splines are based on thin-plate smoothing splines (Duchon 1976, 1977). Compared to thin-plate smoothing splines, thin-plate regression splines produce fewer basis expansions and thus make direct fitting of generalized additive models possible.

Thin-Plate Smoothing Splines

Consider the problem of estimating a smoothing function f of $\mathbf{x}$ with d covariates from n observations. The model assumes

$$y_i = f(\mathbf{x}_i) + \epsilon_i, i = 1, \ldots, n$$

Then the thin-plate smoothing splines estimate the smoothing function f by minimizing the penalized least squares function:

$$\sum_{i=1}^{n}(y_i - f(\mathbf{x}_i))^2 + \lambda J_{m,d}(f)$$

The penalty term $\lambda J_{m,d}(f)$ includes the function that measures roughness on the f estimate:

$$J_{m,d}(f) = \int \cdots \int \sum_{\alpha_1+\cdots+\alpha_d=m} \frac{m!}{\alpha_1! \cdots \alpha_d!} \left(\frac{\partial^m f}{\partial {x_1}^{\alpha_1} \cdots \partial {x_d}^{\alpha_d}} \right)^2 \mathrm{d}x_1 \cdots \mathrm{d}x_d$$

The parameter m (which corresponds to the M= option for a spline effect) specifies how the penalty is applied to the function roughness. Function derivatives whose order is less than m are not penalized. The relation $2m > d$ must be satisfied.

The penalty term also includes the smoothing parameter $\lambda \in [0, \infty)$, which controls the trade-off between the model's fidelity to the data and the function smoothness of f. When $\lambda = 0$, the function estimate corresponds to an interpolation. When $\lambda \to \infty$, the function estimate becomes the least squares fit. By using the defined penalized least squares criterion and a fixed λ value, you can explicitly express the estimate of the smooth function f in the following form:

$$f_\lambda(\mathbf{x}) = \sum_{j=1}^{M} \theta_j \phi_j(\mathbf{x}) + \sum_{i}^{n} \delta_i \eta_{m,d}(\|\mathbf{x} - \mathbf{x}_i\|)$$

In the expression of $f_\lambda(\mathbf{x})$, δ_i and θ_j are coefficients to be estimated. The functions $\phi_j(\mathbf{x})$ correspond to unpenalized polynomials of $\mathbf{x}$ with degrees up to $m - 1$. The total number of these polynomials is $M = \binom{m+d-1}{d}$. The function $\eta_{m,d}$ models the extra nonlinearity besides the polynomials and is a function of the Euclidean distance r between any $\mathbf{x}$ value and an observed $\mathbf{x}_i$ value:

$$\eta_{m,d}(r) = \begin{cases} \frac{(-1)^{m+1+d/2}}{2^{2m-1}\pi^{d/2}(m-1)!(m-d/2)!} r^{2m-d} \log(r) & \text{if } d \text{ is even} \\ \frac{\Gamma(d/2-m)}{2^{2m}\pi^{d/2}(m-1)!} r^{2m-d} & \text{if } d \text{ is odd} \end{cases}$$

Define the penalty matrix $\mathbf{E}$ such that each entry $E_{ij} = \eta_{m,d}(\|\mathbf{x}_i - \mathbf{x}_j\|)$, let $\mathbf{y}$ be the vector of the response, let $\mathbf{T}$ be the matrix where each row is formed by $\phi_j(\mathbf{x})$, and let $\boldsymbol{\theta}$ and $\boldsymbol{\delta}$ be vectors of coefficients θ_j and δ_i. Then you can obtain the function estimate f_λ from the following minimization problem:

$$\min \|\mathbf{y} - \mathbf{T}\boldsymbol{\theta} - \mathbf{E}\boldsymbol{\delta}\|^2 + \lambda \boldsymbol{\delta}'\mathbf{E}\boldsymbol{\delta} \quad \text{subject to} \quad \mathbf{T}'\boldsymbol{\delta} = \mathbf{0}$$

Low-Rank Approximation

Given the representation of the thin-plate smoothing spline, the estimate of f involves as many parameters as the number of unique data points. Solving $(\boldsymbol{\theta}, \boldsymbol{\delta})$ with an optimum λ becomes difficult for large problems.

Because the matrix $\mathbf{E}$ is symmetric and nonnegative definite, the eigendecomposition can be taken as $\mathbf{E} = \mathbf{U}\mathbf{D}\mathbf{U}'$, where $\mathbf{D}$ is the diagonal matrix of eigenvalues d_i of $\mathbf{E}$, and $\mathbf{U}$ is the matrix of eigenvectors that corresponds to d_i. The truncated eigendecomposition forms $\tilde{\mathbf{E}}_k$, which is an approximation to $\mathbf{E}$ such that

$$\tilde{\mathbf{E}}_k = \mathbf{U}_k \mathbf{D}_k \mathbf{U}_k'$$

where $\mathbf{D}_k$ is a diagonal matrix that contains the k most extreme eigenvalues in descending order of absolute values: $|\tilde{d}_1| > \cdots > |\tilde{d}_k|$. $\mathbf{U}_k$ is the matrix that is formed by columns of eigenvectors that correspond to the eigenvalues in $\mathbf{D}_k$.

The approximation $\tilde{\mathbf{E}}_k$ not only reduces the dimension from $n \times n$ of $\mathbf{E}$ to $n \times k$ but also is optimal in two senses. First, $\tilde{\mathbf{E}}_k$ minimizes the spectral norm $\|\mathbf{E} - \mathbf{F}_k\|_2$ between $\mathbf{E}$ and all rank k matrices $\mathbf{F}_k$. Second, $\tilde{\mathbf{E}}_k$ also minimizes the worst possible change that is introduced by the eigenspace truncation as defined by

$$\max_{\boldsymbol{\delta} \neq \mathbf{0}} \frac{\boldsymbol{\delta}'(\mathbf{E} - \mathbf{G}_k)\boldsymbol{\delta}}{\|\boldsymbol{\delta}\|^2}$$

where $\mathbf{G}_k$ is formed by any k eigenvalues and corresponding eigenvectors. For more information, see Wood (2003).

Now given $\mathbf{E} \approx \tilde{\mathbf{E}}_k$ and $\tilde{\mathbf{E}}_k = \mathbf{U}_k \mathbf{D}_k \mathbf{U}_k'$, and letting $\boldsymbol{\delta}_k = \mathbf{U}_k' \boldsymbol{\delta}$, the minimization problem becomes

$$\min \|\mathbf{y} - \mathbf{T}\boldsymbol{\theta} - \mathbf{U}_k \mathbf{D}_k \boldsymbol{\delta}_k\|^2 + \lambda \boldsymbol{\delta}_k' \mathbf{D}_k \boldsymbol{\delta}_k \quad \text{subject to} \quad \mathbf{T}'\mathbf{U}_k \boldsymbol{\delta}_k = \mathbf{0}$$

You can turn the constrained optimization problem into an unconstrained one by using any orthogonal column basis $\mathbf{Z}$. One way to form $\mathbf{Z}$ is via the QR decomposition of $\mathbf{U}_k'\mathbf{T}$:

$$\mathbf{U}_k'\mathbf{T} = [\mathbf{Q}_1 \mathbf{Q}_2] \begin{bmatrix} \mathbf{R} \\ \mathbf{0} \end{bmatrix}$$

Let $\mathbf{Z} = \mathbf{Q}_2$. Then it is verified that

$$\mathbf{T}'\mathbf{U}_k \mathbf{Z} = \mathbf{R}'\mathbf{Q}_1'\mathbf{Q}_2 = \mathbf{0}$$

So for $\boldsymbol{\delta}_k$ such that $\mathbf{T}'\mathbf{U}_k \boldsymbol{\delta}_k = \mathbf{0}$, it is true that $\boldsymbol{\delta}_k = \mathbf{Z}\tilde{\boldsymbol{\delta}}$. Now the problem becomes the unconstrained optimization,

$$\min \|\mathbf{y} - \mathbf{T}\boldsymbol{\theta} - \mathbf{U}_k \mathbf{D}_k \mathbf{Z}\tilde{\boldsymbol{\delta}}\|^2 + \lambda \tilde{\boldsymbol{\delta}}' \mathbf{Z}' \mathbf{D}_k \mathbf{Z} \tilde{\boldsymbol{\delta}}$$

Let

$$\boldsymbol{\beta} = \begin{bmatrix} \boldsymbol{\theta} \\ \tilde{\boldsymbol{\delta}} \end{bmatrix}, \quad \mathbf{X} = [\mathbf{T} : \mathbf{U}_k \mathbf{D}_k \mathbf{Z}], \quad \text{and} \quad \mathbf{S} = \begin{bmatrix} \mathbf{0} & \mathbf{0} \\ \mathbf{0} & \mathbf{Z}'\mathbf{D}_k\mathbf{Z} \end{bmatrix}$$

The optimization is simplified as

$$\min \|\mathbf{y} - \mathbf{X}\boldsymbol{\beta}\|^2 + \lambda \boldsymbol{\beta}' \mathbf{S} \boldsymbol{\beta} \quad \text{with respect to} \quad \boldsymbol{\beta}$$

Generalized Additive Models

Generalized Linear Models

All probability distributions that the GAMMOD procedure fits are members of an exponential family of distributions. For the specification of an exponential family, see the section "Exponential Family Distributions" in Chapter 14, "GENSELECT Procedure."

Table 12.12 lists and defines some common notation that is used in the context of generalized linear models and generalized additive models.

Table 12.12 Common Notation

Notation	Meaning
ℓ	Log-likelihood
ℓ_p	Penalized log-likelihood
D	Deviance
D_p	Penalized deviance
g	Link function
g^{-1}	Inverse link function
$\boldsymbol{\mu}$	Response mean $\boldsymbol{\mu} = g^{-1}(\boldsymbol{\eta})$
$\boldsymbol{\eta}$	Linear predictor $\boldsymbol{\eta} = \mathbf{X}\boldsymbol{\beta}$
ϕ	Dispersion parameter
$\mathbf{z}$	Column of adjusted response variable
$\boldsymbol{\nu}$	Column of response variance
ω_i	Prior weight for each observation
w_i	Adjusted weight for each observation
$\mathbf{W}$	Diagonal matrix of adjusted weights

The GAMMOD procedure supports the following distributions: binary, binomial, gamma, inverse Gaussian, negative binomial, normal (Gaussian), Poisson, and Tweedie.

For forms of log likelihood functions for each of the probability distributions, see the section "Log-Likelihood Functions" in Chapter 14, "GENSELECT Procedure."

Generalized Additive Models

Generalized additive models are extensions of generalized linear models (Nelder and Wedderburn 1972). For each observation that has a response Y_i and a row vector of the model matrix $\mathbf{x}_i$, both generalized additive models and generalized linear models assume the model additivity,

$$g(\mu_i) = f_1(\mathbf{x}_{i1}) + \cdots + f_p(\mathbf{x}_{ip})$$

where $\mu_i = E(Y_i)$ and Y_i is independently distributed in some exponential family. Generalized linear models further assume model linearity by $f_j(\mathbf{x}_{ij}) = \mathbf{x}_{ij}\beta_j$ for $j = 1, \ldots, p$. Generalized additive models relax the linearity assumption by allowing some smoothing functions f_j to characterize the dependency. The GAMMOD procedure constructs the smoothing functions by using thin-plate regression splines.

Consider a generalized additive model that has some linear terms $\mathbf{X}_L$ with coefficients $\boldsymbol{\beta}_L$ and p smoothing functions f_j. Each smoothing function can be constructed by thin-plate regression splines with a smoothing

parameter λ_j. Using the notations described in the section "Low-Rank Approximation" on page 609, you can characterize each smoothing function by

$$\boldsymbol{\beta}_j = \begin{bmatrix} \boldsymbol{\theta}_j \\ \tilde{\boldsymbol{\delta}}_j \end{bmatrix}, \quad \mathbf{X}_j = [\mathbf{T}_j : \mathbf{U}_{kj}\mathbf{D}_{kj}\mathbf{Z}_j], \quad \text{and} \quad \mathbf{S}_j = \begin{bmatrix} \mathbf{0} & \mathbf{0} \\ \mathbf{0} & \mathbf{Z}_j'\mathbf{D}_{kj}\mathbf{Z}_j \end{bmatrix}$$

Notice that each smoothing function representation contains a zero-degree polynomial that corresponds to a constant. Having multiple constant terms makes the smoothing functions unidentifiable. The solution is to include a global constant term (that is, the intercept) in the model and enforce the centering constraint to each smoothing function. You can write the constraint as

$$\mathbf{1}'\mathbf{X}_j\boldsymbol{\beta}_j = 0$$

By using a similar approach as the linear constraint for thin-plate regression splines, you obtain the orthogonal column basis $\mathbf{V}_j$ via the QR decomposition of $\mathbf{X}_j'\mathbf{1}$ such that $\mathbf{1}'\mathbf{X}_j\mathbf{V}_j = 0$. Each smoothing function can be reparameterized as $\tilde{\mathbf{X}}_j = \mathbf{X}_j\mathbf{V}_j$.

Let $\mathbf{X} = [\mathbf{X}_L : \tilde{\mathbf{X}}_1 : \cdots : \tilde{\mathbf{X}}_p]$ and $\boldsymbol{\beta}' = [\boldsymbol{\beta}_L' : \boldsymbol{\beta}_1' : \cdots : \boldsymbol{\beta}_p']$. Then the generalized additive model can be represented as $g(\boldsymbol{\mu}) = \mathbf{X}\boldsymbol{\beta}$. The roughness penalty matrix is represented as a block diagonal matrix:

$$\mathbf{S}_{\boldsymbol{\lambda}} = \begin{bmatrix} \mathbf{0} & \mathbf{0} & \cdots & \mathbf{0} \\ \mathbf{0} & \lambda_1\mathbf{S}_1 & \cdots & \mathbf{0} \\ & & \ddots & \\ \vdots & \vdots & \lambda_j\mathbf{S}_j & \vdots \\ & & & \ddots \\ \mathbf{0} & \mathbf{0} & \cdots & \lambda_p\mathbf{S}_p \end{bmatrix}$$

Then the roughness penalty is measured in the quadratic form $\boldsymbol{\beta}'\mathbf{S}_{\boldsymbol{\lambda}}\boldsymbol{\beta}$.

Penalized Likelihood Estimation

Given a fixed vector of smoothing parameters, $\boldsymbol{\lambda} = [\lambda_i \ldots \lambda_p]'$, you can fit the generalized additive models by the penalized likelihood estimation. In contrast to the maximum likelihood estimation, penalized likelihood estimation obtains an estimate for $\boldsymbol{\beta}$ by maximizing the penalized log likelihood,

$$\ell_p(\boldsymbol{\beta}) = \ell(\boldsymbol{\beta}) - \frac{1}{2}\boldsymbol{\beta}'\mathbf{S}_{\boldsymbol{\lambda}}\boldsymbol{\beta}$$

Any optimization technique that you can use for maximum likelihood estimation can also be used for penalized likelihood estimation. If first-order derivatives are required for the optimization technique, you can compute the gradient as

$$\frac{\partial \ell_p}{\partial \boldsymbol{\beta}} = \frac{\partial \ell}{\partial \boldsymbol{\beta}} - \mathbf{S}_{\boldsymbol{\lambda}}\boldsymbol{\beta}$$

If second-order derivatives are required for the optimization technique, you can compute the Hessian as

$$\frac{\partial^2 \ell_p}{\partial \boldsymbol{\beta}\partial \boldsymbol{\beta}'} = \frac{\partial^2 \ell}{\partial \boldsymbol{\beta}\partial \boldsymbol{\beta}'} - \mathbf{S}_{\boldsymbol{\lambda}}$$

In the gradient and Hessian forms, $\partial\ell/\partial\boldsymbol{\beta}$ and $\partial^2\ell/(\partial\boldsymbol{\beta}\partial\boldsymbol{\beta}')$ are the corresponding gradient and Hessian, respectively, for the log likelihood for generalized linear models. For more information about optimization techniques, see the section "Optimization Options" on page 57 in Chapter 2, "Shared Concepts."

Model Evaluation Criteria

Given a fixed set of smoothing parameters $\boldsymbol{\lambda}$ in which each λ_i controls the smoothness of each spline term, you can fit a generalized additive model by penalized likelihood estimation. There are infinitely many sets of smoothing parameters. In order to search optimum models, some model evaluation criteria need to be defined to quantify the model's goodness of fit. The GAMMOD procedure uses the following model evaluation criteria:

- generalized cross validation (GCV), $\mathcal{V}_g$ (Craven and Wahba 1979)
- unbiased risk estimator (UBRE), $\mathcal{V}_u$ (Craven and Wahba 1979)
- generalized approximate cross validation (GACV), $\mathcal{V}_a$ (Xiang and Wahba 1996)

Consider the optimization problem

$$\min(\mathbf{y}-\mathbf{X}\boldsymbol{\beta})'(\mathbf{y}-\mathbf{X}\boldsymbol{\beta})+\boldsymbol{\beta}'\mathbf{S}_{\boldsymbol{\lambda}}\boldsymbol{\beta} \quad \text{with respect to} \quad \boldsymbol{\beta}$$

The parameter estimate for $\boldsymbol{\beta}$ can be represented as

$$\hat{\boldsymbol{\beta}}=(\mathbf{X}'\mathbf{X}+\mathbf{S}_{\boldsymbol{\lambda}})^{-1}\mathbf{X}'\mathbf{y}$$

And the smoothing matrix (also called the influence matrix or hat matrix) is thus represented as

$$\mathbf{H}_{\boldsymbol{\lambda}}=\mathbf{X}(\mathbf{X}'\mathbf{X}+\mathbf{S}_{\boldsymbol{\lambda}})^{-1}\mathbf{X}'$$

With the defined smoothing matrix, you can form the model evaluation criteria as follows:

$$\begin{aligned}
\mathcal{V}_g(\boldsymbol{\lambda}) &= \frac{n\|\mathbf{y}-\mathbf{H}_{\boldsymbol{\lambda}}\mathbf{y}\|^2}{(\mathrm{tr}(\mathbf{I}-\gamma\mathbf{H}_{\boldsymbol{\lambda}}))^2} \\
\mathcal{V}_u(\boldsymbol{\lambda}) &= \frac{1}{n}\|\mathbf{y}-\mathbf{H}_{\boldsymbol{\lambda}}\mathbf{y}\|^2-\frac{2}{n}\sigma^2\mathrm{tr}(\mathbf{I}-\gamma\mathbf{H}_{\boldsymbol{\lambda}})+\sigma^2 \\
\mathcal{V}_a(\boldsymbol{\lambda}) &= \frac{1}{n}\|\mathbf{y}-\mathbf{H}_{\boldsymbol{\lambda}}\mathbf{y}\|^2\left(1+2\gamma\frac{\mathrm{tr}(\mathbf{H}_{\boldsymbol{\lambda}})}{\mathrm{tr}(\mathbf{I}-\mathbf{H}_{\boldsymbol{\lambda}})}\right)
\end{aligned}$$

In the equations, $\gamma \geq 1$ (which corresponds to the GAMMA= suboption of the CRITERION= option) is the tuning parameter that is sometimes used to enforce smoother models.

The GAMMOD procedure uses fitting algorithms that involve minimizing the model evaluation criterion with respect to unknown smoothing parameters $\boldsymbol{\lambda}$.

Fitting Algorithms

For models that assume a normally distributed response variable, you can minimize the model evaluation criteria directly by searching for optimal smoothing parameters. For models that have nonnormal distributions, you cannot use the model evaluation criteria directly because the involved statistics keep changing between iterations. The GAMMOD procedure enables you to use either of two fitting approaches to search for optimum models: the outer iteration method and the performance iteration method. The outer iteration method modifies the model evaluation criteria so that a global objective function can be minimized in order to find the best smoothing parameters. The performance iteration method minimizes a series of objective functions in an iterative fashion and then obtains the optimum smoothing parameters at convergence. For large data tables, the performance iteration method usually converges faster than the outer iteration method.

Outer Iteration

The outer iteration method is outlined in Wood (2006). The method uses modified model evaluation criteria, which are defined as follows:

$$
\begin{aligned}
\mathcal{V}_g^o(\boldsymbol{\lambda}) &= \frac{n D_{\boldsymbol{\lambda}}(\boldsymbol{\mu})}{(n-\gamma \mathrm{tr}(\mathbf{H}_{\boldsymbol{\lambda}}))^2} \\
\mathcal{V}_u^o(\boldsymbol{\lambda}) &= \frac{D_{\boldsymbol{\lambda}}(\boldsymbol{\mu})}{n} - \frac{2}{n}\sigma^2 \mathrm{tr}(\mathbf{I}-\gamma\mathbf{H}_{\boldsymbol{\lambda}}) + \sigma^2 \\
\mathcal{V}_a^o(\boldsymbol{\lambda}) &= \frac{D_{\boldsymbol{\lambda}}(\boldsymbol{\mu})}{n} + \frac{2\gamma \mathrm{tr}(\mathbf{H}_{\boldsymbol{\lambda}}) P_{\boldsymbol{\lambda}}}{n \mathrm{tr}(\mathbf{I}-\mathbf{H}_{\boldsymbol{\lambda}})}
\end{aligned}
$$

By replacing $\|\mathbf{y}-\mathbf{H}_{\boldsymbol{\lambda}}\mathbf{y}\|^2$ with model deviance $D_{\boldsymbol{\lambda}}(\boldsymbol{\mu})$, the modified model evaluation criteria relate to the smoothing parameter $\boldsymbol{\lambda}$ in a direct way such that the analytic gradient and Hessian are available in explicit forms. Pearson's statistic $P_{\boldsymbol{\lambda}}$ is used in the GACV criterion $\mathcal{V}_a^o(\boldsymbol{\lambda})$ (Wood 2008). The algorithm for the outer iteration is thus as follows:

1. Initialize smoothing parameters by taking one step of performance iteration based on adjusted response and adjusted weight except for spline terms whose initial values are specified in the INITSMOOTH= option.
2. Search for the best smoothing parameters by minimizing the modified model evaluation criteria. The optimization process stops when any of the convergence criteria that are specified in the SMOOTHOPTIONS option is met. At each optimization step:
   a) Initialize by setting initial regression parameters $\boldsymbol{\beta} = \{g(\hat{\mathbf{y}}), 0, \ldots, 0\}'$. Set the initial dispersion parameter if necessary.
   b) Search for the best regression parameters $\boldsymbol{\beta}$ by minimizing the penalized deviance D_p (or maximizing the penalized likelihood ℓ_p for negative binomial distribution). The optimization process stops when any of the convergence criteria that are specified in the PLIKEOPTIONS option is met.
   c) At convergence, evaluate derivatives of the model evaluation criteria with respect to $\boldsymbol{\lambda}$ by using $\partial D_p/\partial\boldsymbol{\beta}$, $\partial^2 D_p/(\partial\boldsymbol{\beta}\partial\boldsymbol{\beta}')$, $\partial\boldsymbol{\beta}/\partial\lambda_j$, and $\partial^2\boldsymbol{\beta}/(\partial\lambda_j\partial\lambda_k)$.

Step 2b usually converges quickly because it is essentially penalized likelihood estimation given that $D_p = 2\phi(\ell_{\max} - \ell) + \boldsymbol{\beta}\mathbf{S}_{\boldsymbol{\lambda}}\boldsymbol{\beta}'$. Step 2c contains involved computation by using the chain rule of derivatives. For more information about computing derivatives of $\mathcal{V}_g^o$ and $\mathcal{V}_u^o$, see Wood (2008, 2011).

Performance Iteration

The performance iteration method is proposed by Gu and Wahba (1991). Wood (2004) modifies and stabilizes the algorithm for fitting generalized additive models. The algorithm for the performance iteration method is as follows:

1. Initialize smoothing parameters $\boldsymbol{\lambda} = \{1, \ldots, 1\}$, except for spline terms whose initial values are specified in the INITSMOOTH= option. Set the initial regression parameters $\boldsymbol{\beta} = \{g(\bar{\mathrm{y}}), 0, \ldots, 0\}'$. Set the initial dispersion parameter if necessary.
2. Repeat the following steps until any of these three conditions is met: (1) the absolute function change in penalized likelihood is sufficiently small; (2) the absolute relative function change in penalized likelihood is sufficiently small; (3) the number of iterations exceeds the maximum iteration limit.
   a) Form the adjusted response and adjusted weight from $\boldsymbol{\mu} = g^{-1}(\boldsymbol{\eta})$. For each observation,
   $$z_i = \eta_i + (y_i - \mu_i)/\mu_i', \quad w_i = \omega_i \mu_i'^2/v_i$$
   b) Search for the best smoothing parameters for the current iteration based on valid adjusted response values and adjusted weight values.
   c) Use the smoothing parameters to construct the linear predictor and the predicted means.
   d) Obtain an estimate for the dispersion parameter if necessary.

In step 2b, you can use different optimization techniques to search for the best smoothing parameters. The Newton-Raphson optimization is efficient in finding the optimum $\boldsymbol{\lambda}$ where the first- and second-order derivatives are available. For more information about computing derivatives of $\mathcal{V}_g$ and $\mathcal{V}_u$ with respect to $\boldsymbol{\lambda}$, see Wood (2004).

Degrees of Freedom

Let $\mathbf{W}$ be the adjusted weight matrix at convergence, and let $\mathbf{S}_{\boldsymbol{\lambda}}$ be the roughness penalty matrix with selected smoothing parameters. The degrees of freedom matrix is defined as in Wood (2006):

$$\mathbf{F} = (\mathbf{X}'\mathbf{W}\mathbf{X} + \mathbf{S}_{\boldsymbol{\lambda}})^{-1}\mathbf{X}'\mathbf{W}\mathbf{X}$$

Given the adjusted response $\mathbf{z}$, the parameter estimate is shown to be $\tilde{\boldsymbol{\beta}} = (\mathbf{X}'\mathbf{W}\mathbf{X})^{-1}\mathbf{X}'\mathbf{W}\mathbf{z}$ for the model without penalization, and the parameter estimate is $\hat{\boldsymbol{\beta}} = (\mathbf{X}'\mathbf{W}\mathbf{X} + \mathbf{S}_{\boldsymbol{\lambda}})^{-1}\mathbf{X}'\mathbf{W}\mathbf{z} = \mathbf{F}\tilde{\boldsymbol{\beta}}$ with penalization. $\mathbf{F}$ is thus the matrix that projects or maps the unpenalized parameter estimates to the penalized ones.

The model degrees of freedom is given as

$$\mathrm{df} = \mathrm{tr}(\mathbf{F})$$

And the degrees of freedom for error is given as

$$\mathrm{df}_r = n - 2\mathrm{df} + \mathrm{tr}(\mathbf{FF})$$

For the *j*th spline term, the degrees of freedom for the component is defined to be the trace of the submatrix of $\mathbf{F}$ that corresponds to parameter estimates $\boldsymbol{\beta}_j$:

$$\mathrm{df}_j = \mathrm{tr}(\mathbf{F}_j)$$

The degrees of freedom for the smoothing component test of the *j*th term is defined similarly as

$$\mathrm{df}_j^t = 2\mathrm{df}_j - \mathrm{tr}((\mathbf{FF})_j)$$

Model Inference

Wahba (1983) proposes a Bayesian covariance matrix for parameter estimates $\boldsymbol{\beta}$ by interpreting a smoothing spline as a posterior mean. Nychka (1988) shows that the derived Bayesian posterior confidence limits work well from frequentist viewpoints. The Bayesian posterior covariance matrix for the parameters is

$$\mathbf{V}_{\boldsymbol{\beta}} = (\mathbf{X}'\mathbf{W}\mathbf{X} + \mathbf{S}_{\boldsymbol{\lambda}})^{-1}\sigma^2$$

The posterior distribution for $\boldsymbol{\beta}$ is thus

$$\boldsymbol{\beta}|\mathbf{y} \sim N(\hat{\boldsymbol{\beta}}, \mathbf{V}_{\boldsymbol{\beta}})$$

For a particular point whose design row is vector $\mathbf{x}$, the prediction is $\mathbf{x}\hat{\boldsymbol{\beta}}$ and the standard error is $\sqrt{\mathbf{x}\mathbf{V}_{\boldsymbol{\beta}}\mathbf{x}'}$. The Bayesian posterior confidence limits are thus

$$\left(\mathbf{x}\hat{\boldsymbol{\beta}} \pm z_{\alpha/2}\sqrt{\mathbf{x}\mathbf{V}_{\boldsymbol{\beta}}\mathbf{x}'}\right)$$

where $z_{\alpha/2}$ is the $1 - \alpha/2$ quantile of the standard normal distribution.

For the *j*th spline term, the prediction for the component is formed by $\mathbf{x}_j\hat{\boldsymbol{\beta}}$, where $\mathbf{x}_j$ is a row vector of zeros except for columns that correspond to basis expansions of the *j*th spline term. And the standard error for the component is $\sqrt{\mathbf{x}_j\mathbf{V}_{\boldsymbol{\beta}}\mathbf{x}_j'}$.

Dispersion Parameter

Some distribution families (Gaussian, gamma, inverse Gaussian, negative binomial, and Tweedie) have a dispersion parameter that you can specify in the DISPERSION= option in the MODEL statement or that you can estimate from the data. The following three suboptions for the SCALE= option in the MODEL statement correspond to three ways to estimate the dispersion parameter:

DEVIANCE
estimates the dispersion parameter by the deviance, given the regression parameter estimates:

$$\hat{\phi} = \frac{\sum_i D_i(y_i, \mu_i)}{n - \mathrm{df}}$$

MLE
estimates the dispersion parameter by maximizing the penalized likelihood, given the regression parameter estimates:

$$\hat{\phi} = \underset{\phi}{\operatorname{argmax}}\, \ell_p(\hat{\boldsymbol{\beta}}, \phi)$$

The MLE option is the only option that you can use to estimate the dispersion parameter for the negative binomial and Tweedie distributions.

PEARSON
estimates the dispersion parameter by Pearson's statistic, given the regression parameter estimates:

$$\hat{\phi} = \frac{\sum_i \omega_i (y_i - \mu_i)^2 / v_i}{n - \mathrm{df}}$$

If the dispersion parameter is estimated, it contributes one additional degree of freedom to the fitted model.

Tests for Smoothing Components

The GAMMOD procedure performs a smoothing component test on the null hypothesis $f_j = 0$ for the jth component. In contrast to the analysis of deviance that is used in the GAM procedure (which tests existence of nonlinearity for each smoothing component), the smoothing component test used in PROC GAMMOD tests for the existence of a contribution for each smoothing component.

The hypothesis test is based on the Wald statistic. Define $\mathbf{X}_j$ as the matrix of all zeros except for columns that correspond to basis expansions of the jth spline term. Then the column vector of predictions is $\hat{\mathbf{f}}_j = \mathbf{X}_j \hat{\boldsymbol{\beta}}$, and the covariance matrix for the predictions is $\mathbf{V}_j = \mathbf{X}_j \mathbf{V}_{\boldsymbol{\beta}} \mathbf{X}_j'$. The Wald statistic for testing is

$$T_r = \hat{\mathbf{f}}_j' \mathbf{V}_j^{r-} \hat{\mathbf{f}}_j = \hat{\boldsymbol{\beta}}' \mathbf{X}_j' (\mathbf{X}_j \mathbf{V}_{\boldsymbol{\beta}} \mathbf{X}_j')^{r-} \mathbf{X}_j \hat{\boldsymbol{\beta}}$$

where $\mathbf{V}_j^{r-}$ is the rank-r pseudo-inverse of $\mathbf{V}_j$. If $\mathbf{R}_j$ is the Cholesky root for $\mathbf{X}_j' \mathbf{X}_j$ such that $\mathbf{R}_j' \mathbf{R} = \mathbf{X}_j' \mathbf{X}_j$, then the test statistic can be written as

$$T_r = \hat{\boldsymbol{\beta}}' \mathbf{R}_j' (\mathbf{R}_j \mathbf{V}_{\boldsymbol{\beta}} \mathbf{R}_j')^{r-} \mathbf{R}_j \hat{\boldsymbol{\beta}}$$

Wood (2012) proposes using the df_j^t degrees of freedom for test (which is defined in the section "Degrees of Freedom" on page 614) as the rank r. Because spline terms in fitted models often have noninteger degrees of freedom, the GAMMOD procedure uses a rounded value of df_j^t as the rank:

$$r = \begin{cases} \lfloor \mathrm{df}_j^t \rfloor & \text{if } \mathrm{df}_j^t - \lfloor \mathrm{df}_j^t \rfloor <= 0.05 \text{ or } \mathrm{df}_j^t < 1 \\ \lceil \mathrm{df}_j^t \rceil & \text{otherwise} \end{cases}$$

Let K be a symmetric and nonnegative definite matrix, and let its eigenvalues be sorted as $d_1 > d_2 > \cdots$; then the rank-r pseudo-inverse of K is formed by

$$K^{r-} = U_k \begin{bmatrix} d_1^{-1} & & \\ & \ddots & \\ & & d_r^{-1} \end{bmatrix} U_k'$$

where U_k are formed by columns of eigenvectors that correspond to the r eigenvalues.

Under the null hypothesis, the Wald statistic T_r approximately follows the chi-square distribution $T_r \sim \chi_r^2$. For an observed test statistic t_r, the p-value for rejecting the null hypothesis is computed as $P(\chi_r^2 > t_r)$ if the dispersion parameter is constant, or $P(F_{r,\mathrm{df}_r} > t_r)$ with df_r error degrees of freedom if the dispersion parameter is estimated.

Be cautious when you interpret the results of the smoothing component test because p-values are computed by approximation and the test does not take the smoothing parameter selection process into account.

Multithreading

The GAMMOD procedure allocates data to different threads and calculates the likelihood function, gradient, and Hessian by accumulating the values from all threads. For more information about how PROC GAMMOD uses threads, see the section "Multithreading" on page 102 in Chapter 2, "Shared Concepts."

Optimization Algorithms

Several optimization techniques are available in PROC GAMMOD. You can choose a particular optimizer by using the TECHNIQUE= option in the PROC GAMMOD statement. Table 12.13 summarizes the optimization techniques available in PROC GAMMOD.

Table 12.13 Optimization Techniques

TECHNIQUE=	Algorithm
TRUREG	Trust region method
NEWRAP	Newton-Raphson method with line search
NRRIDG	Newton-Raphson method with ridging
QUANEW	Quasi-Newton methods
DBLDOG	Double-dogleg method
CONGRA	Conjugate gradient methods
NMSIMP	Nelder-Mead simplex method

There is no algorithm for optimizing general nonlinear functions that always finds the global optimum for a general nonlinear optimization problem in a reasonable amount of time. Because no single optimization technique is always superior to others, PROC GAMMOD provides a variety of optimization techniques that work well in various circumstances. However, you can devise problems for which none of the techniques in PROC GAMMOD can find the correct solution. Moreover, nonlinear optimization can be computationally expensive in terms of time and memory, so you must be careful when matching an algorithm to a problem. The section "Choosing an Optimization Algorithm" on page 103 in Chapter 2, "Shared Concepts," is helpful in choosing a suitable optimization algorithm.

Displayed Output

The following sections describe the output that the GAMMOD procedure produces by default. The output is organized into various tables, which are discussed in the order of their appearance.

Model Information

The "Model Information" table displays basic information about the model, such as the response variable, frequency variable, link function, and model category that the GAMMOD procedure determines based on your input and options. The "Model Information" table also displays the distribution of the data that PROC GAMMOD assumes. For information about the supported response distributions, see the DISTRIBUTION= option.

Number of Observations

The "Number of Observations" table displays the number of observations that are read from the input data table and the number of observations that are used in the analysis. If a FREQ statement is present, the sum of the frequencies read and used is displayed. If the events/trials syntax is used, the number of events and trials is also displayed.

Response Profile

The "Response Profile" table displays the ordered values from which the GAMMOD procedure determines the probability that is modeled as an event in binary models. For each response category level, the frequency that is used in the analysis is reported. You can affect the ordering of the response values by specifying *response-options* in the MODEL statement. For binary models, the note that follows the "Response Profile" table indicates which outcome is modeled as the event in binary models and which value serves as the reference category.

The "Response Profile" table is not produced for binomial (events/trials) data. You can find information about the number of events and trials in the "Number of Observations" table.

Class Level Information

The "Class Level Information" table lists the levels of every variable that is specified in the CLASS statement. You should check this information to make sure that the data are correct. You can adjust the order of the CLASS variable levels by specifying the ORDER= option in the CLASS statement. You can suppress the "Class Level Information" table completely or partially by specifying the NOCLPRINT= option in the PROC GAMMOD statement.

If the classification variables use reference parameterization, the "Class Level Information" table also displays the reference value for each variable.

Specifications for Spline(*spline-variables*)

The "Specifications for Spline(*spline-variables*)" table displays basic information (such as the number of variables, specified degrees of freedom, search range for the smoothing parameter, and so on) about how to construct a spline term that the GAMMOD procedure uses to construct basis expansions and search for the smoothing parameter. PROC GAMMOD generates the "Specifications for Spline(*spline-variables*)" table only when you specify the DETAILS option for a spline term.

Optimization Iteration History

For each iteration of the optimization, the "Iteration History" table displays the number of function evaluations (including gradient and Hessian evaluations), the value of the objective function, the change in the objective function from the previous iteration, and the absolute value of the largest (projected) gradient element. The objective function that PROC GAMMOD uses in the optimization is normalized by default to enable comparisons across data tables that have different sampling intensity.

If you specify the ITDETAILS option in the PROC GAMMOD statement, information about the parameter estimates and gradients in the course of the optimization is added to the "Iteration History" table.

For a parametric generalized linear model or for a generalized additive model that has fixed smoothing parameters, the "Iteration History" table displays information about regression parameter estimates and gradients. For a generalized additive model that has unknown smoothing parameters, the "Iteration History" table displays information about smoothing parameter estimates and gradients. If the performance iteration method is used, a column of performance iteration steps is added to the table.

Convergence Status

The convergence status table is a small ODS table that follows the "Iteration History" table in the default output. In the listing, this table appears as a message that indicates whether the optimization succeeded and which convergence criterion was met. If the optimization fails, the message indicates the reason for the failure. If you save the convergence status table to an output data table, a numeric Status variable is added that enables you to programmatically assess convergence. The values of the Status variable encode the following:

0 Convergence was achieved, or an optimization was not performed because TECHNIQUE=NONE was specified.

1 The objective function could not be improved.

2 Convergence was not achieved because of a user interrupt or because a limit (such as the maximum number of iterations or the maximum number of function evaluations) was reached. To modify these limits, see the MAXITER=, MAXFUNC=, and MAXTIME= options in the PROC GAMMOD statement.

3 Optimization failed to converge because function or derivative evaluations failed at the starting values or during the iterations or because a feasible point that satisfies the parameter constraints could not be found in the parameter space.

Fit Statistics

The "Fit Statistics" table displays a variety of likelihood-based measures of fit in addition to the model roughness measurement. All information criteria are presented in "smaller is better" form.

The calculation of the information criteria uses the following formulas, where df denotes the model degrees of freedom, f denotes the number of frequencies used, and ℓ is the log likelihood that is evaluated at the converged estimates:

$$\mathrm{AIC} = -2\ell + 2\mathrm{df}$$

$$\mathrm{AICC} = \begin{cases} -2\ell + 2\mathrm{df}\, f/(f - \mathrm{df} - 1) & \text{when } f > \mathrm{df} + 2 \\ -2\ell + 2\mathrm{df}(\mathrm{df} + 2) & \text{otherwise} \end{cases}$$

$$\mathrm{BIC} = -2\ell + \mathrm{df}\log(f)$$

If no FREQ statement is specified, then f equals n, the number of observations that are used.

Parameter Estimates

The "Parameter Estimates" table displays the regression parameter estimates, their estimated (asymptotic) standard errors, chi-square statistics, and p-values for the hypothesis that the parameter is 0.

Estimates for Smoothing Components

The "Estimates for Smoothing Components" table displays a summary of the fitted spline terms, including effective degrees of freedom, smoothing parameters, roughness penalty values, number of parameters, rank of penalty matrix, and number of knots.

Tests for Smoothing Components

The "Tests for Smoothing Components" table displays effective degrees of freedom, effective degrees of freedom for test, F/χ_2 statistics, and p-values for rejecting the hypothesis that the smoothing component has zero contribution.

Timing

The "Timing" table displays the amount of time (in seconds) that PROC GAMMOD required to perform different tasks in the analysis.

OutputCasTables Table

The OutputCasTables table is a special table that has information about each CAS table that is created during a CAS action execution. The information for each CAS table consists of the CAS table name, the caslib in which the table resides, and the number of columns and rows in the CAS table. Because this table is not a typical ODS table that contains analytical results, you cannot include it in the *table-spec-list* in the DISPLAYOUT statement.

ODS Table Names

Each table that the GAMMOD procedure creates has a name that is associated with it, and you must use this name to refer to the table when you use ODS statements. These names are listed in Table 12.14.

Table 12.14 ODS Tables Produced by PROC GAMMOD

Table Name	Description	Statement	Option
ClassInfo	Level information from the CLASS statement	CLASS	
ConvergenceStatus	Status of optimization at conclusion of optimization	Default output	
FitStatistics	Fit statistics	Default output	
LikelihoodHist	Iteration history for maximum likelihood estimation or penalized likelihood estimation	PROC GAMMOD	ITDETAILS
ModelInfo	Information about the modeling environment	Default output	
NObs	Number of observations read and used, and number of events and trials, if applicable	Default output	
OutputCasTables	See the section "OutputCasTables Table" on page 620	OUTPUT DISPLAYOUT	OUT=
ParameterEstimates	Solutions for the parameter estimates that are associated with parametric effects in the MODEL statement	Default output	
ResponseProfile	Response categories and the category that is modeled in models for binary data	Default output	
SmoothingEstimates	Information for spline terms after model fitting	Default output	
SmoothingHist	Iteration history for smoothing parameter estimation	PROC GAMMOD	ITDETAILS
SmoothingTests	Smoothing components test result	Default output	
SplineDetails	Information about spline construction and smoothing parameter search	MODEL	SPLINE(*variables* / DETAILS)
Timing	Absolute and relative times for tasks performed by the procedure	Default output	

ODS Graphics

Statistical procedures use ODS Graphics to create graphs as part of their output. ODS Graphics is described in detail in the "Statistical Graphics Using ODS" chapter in *SAS/STAT User's Guide*.

Before you create graphs, ODS Graphics must be enabled (for example, by using the ODS GRAPHICS ON statement). For more information about enabling and disabling ODS Graphics, see the section "Enabling and Disabling ODS Graphics" in that chapter.

The overall appearance of graphs is controlled by ODS styles. Styles and other aspects of using ODS Graphics are discussed in the section "A Primer on ODS Statistical Graphics" in that chapter.

When ODS Graphics is enabled, the GAMMOD procedure by default produces plots of the partial predictions for each spline term in the model. Use the PLOTS option in the PROC GAMMOD statement to control aspects of these plots.

PROC GAMMOD assigns a name to each graph that it creates by using ODS. You can use these names to refer to the graphs when using ODS. The names are listed in Table 12.15.

Table 12.15 Graphs Produced by PROC GAMMOD

ODS Graph Name	Plot Description	PLOTS= Option
SmoothingComponentPanel	Panel of multiple prediction curves	Default COMPONENTS
SmoothingComponentPlot	Unpacked prediction curves	PLOTS(UNPACK) PLOTS=COMPONENTS(UNPACK)

By default, prediction plots for each spline component are displayed in panels that contain at most six plots. If you specify more than six smoothing components, multiple panels are used. Use the PLOTS(UNPACK) option in the PROC GAMMOD statement to display these plots individually.

Examples: GAMMOD Procedure

The examples in this chapter are available in the GitHub repository located at https://github.com/sascommunities/doc-supplement-casstat.

Example 12.1: Scatter Plot Smoothing

(View the complete code for this example (gammodex1.sas) in the example repository.)

This example shows how you can use PROC GAMMOD to perform scatter plot smoothing.

The example uses the LIDAR data set (Ruppert, Wand, and Carroll 2003). This data set is used in many books and journals to illustrate different smoothing techniques. Scientists use a technique known as LIDAR (light detection and ranging), which uses laser reflections to detect chemical compounds in the atmosphere. The following DATA step creates the data table Lidar. This DATA step assumes that your CAS engine libref is named mylib, but you can substitute any appropriately defined CAS engine libref.

```
title 'Scatter Plot Smoothing';
data mylib.Lidar;
   input Range LogRatio @@;
   datalines;

;
```

In this data table, Range records the distance that light travels before it is reflected back to the source. LogRatio is the logarithm of the ratio of light that is received from two laser sources. The objective is to use scatter plot smoothing to discover the nonlinear pattern in the data. SAS provides different methods (for example, local regression) for scatter plot smoothing. You can perform scatter plot smoothing by using the SGPLOT procedure, as shown in the following statements:

```
proc sgplot data=mylib.Lidar;
   scatter  x=Range y=LogRatio;
   loess    x=Range y=LogRatio / nomarkers;
   pbspline x=Range y=LogRatio / nomarkers;
run;
```

Output 12.1.1 shows the scatter plot of Range and LogRatio and the smoothing curves that are fitted by the local regression and penalized B-splines smoothing techniques.

Output 12.1.1 Scatter Plot Smoothing

Both scatter plot smoothing techniques show a significant nonlinear structure between Range and LogRatio that cannot be easily modeled by ordinary polynomials. You can also use the GAMMOD procedure to perform scatter plot smoothing on these data, as in the following statements:

```
proc gammod data=mylib.Lidar seed=12345;
   model LogRatio = spline(Range/details);
   output out=mylib.LidarOut pred=p;
run;
```

The "Specifications for Spline(Range)" table in Output 12.1.2 displays the specifications for constructing the spline term for Range. The maximum degrees of freedom is 10, which sets the upper limit of effective degrees of freedom for the spline term to be 9 after one degree of freedom is absorbed in the intercept. The order of the derivative in the penalty is 2, which means that the unpenalized portion of the spline term involves polynomials with degrees up to 2.

Output 12.1.2 Spline Specification

Scatter Plot Smoothing

The GAMMOD Procedure

Specifications for Spline(Range)	
Number of Variables	1
Rank of Penalty Approximation	10
Order of Derivative in the Penalty	2
Maximum Number of Knots	2000

The "Fit Statistics" table in Output 12.1.3 shows the summary statistics for the fitted model.

Output 12.1.3 Fit Statistics

Fit Statistics	
Penalized Log Likelihood	251.44124
Roughness Penalty	0.00000385
Effective Degrees of Freedom	9.99989
Effective Degrees of Freedom for Error	211.00000
AIC (smaller is better)	-482.88271
AICC (smaller is better)	-481.83512
BIC (smaller is better)	-448.90148
GCV (smaller is better)	0.00654

The "Estimates for Smoothing Components" table in Output 12.1.4 shows that the effective degrees of freedom for the spline term of Range is approximately 8 after the GCV criterion is optimized with respect to the smoothing parameter. The roughness penalty is small, suggesting that there is an important contribution from the penalized part of thin-plate regression splines beyond nonpenalized polynomials.

Output 12.1.4 Estimates for Smoothing Components

Estimates for Smoothing Components						
Component	Effective DF	Smoothing Parameter	Roughness Penalty	Number of Parameters	Rank of Penalty Matrix	Number of Knots
Spline(Range)	7.99989	1.0000	3.85E-6	9	10	221

Because the optimal model is obtained by searching in a functional space that is constrained by the maximum degrees of freedom for a spline term, you might wonder whether PROC GAMMOD produces a much different model if you increase the value. The following statements fit another model in which the maximum degrees of freedom is increased to 20:

```
proc gammod data=mylib.Lidar seed=12345;
   model LogRatio = spline(Range/maxdf=20);
   output out=mylib.LidarOut2 pred=p2;
run;
```

Output 12.1.5 displays fit summary statistics for the second model. The model fit statistics from the second model are very close to the ones from the first model, indicating that the second model is not much different from the first model.

Output 12.1.5 Fit Statistics

Scatter Plot Smoothing

The GAMMOD Procedure

Fit Statistics	
Penalized Log Likelihood	250.96488
Roughness Penalty	0.05315
Effective Degrees of Freedom	10.06143
Effective Degrees of Freedom for Error	209.02182
AIC (smaller is better)	-481.86006
AICC (smaller is better)	-480.79981
BIC (smaller is better)	-447.66969
GCV (smaller is better)	0.00657

Output 12.1.6 shows that the effective degrees of freedom for the spline term of Range is slightly larger than 8, which is understandable because increasing the maximum degrees of freedom expands the functional space for model searching. Functions in the expanded space can provide a better fit to the data, but they are also penalized more because the roughness penalty value for the second model is much larger than the one for the first model. This suggests that functions in the expanded space do not help much, given the nonlinear relationship between Range and LogRatio.

Output 12.1.6 Estimates for Smoothing Components

Estimates for Smoothing Components						
Component	Effective DF	Smoothing Parameter	Roughness Penalty	Number of Parameters	Rank of Penalty Matrix	Number of Knots
Spline(Range)	8.06143	23032.9	0.0532	19	20	221

The two fitted models are both based on thin-plate regression splines, in which polynomials that have degrees higher than 2 are penalized. You might wonder whether allowing higher-order polynomials yields a much different model. The following statements fit a third spline model by penalizing polynomials that have degrees higher than 3:

```
proc gammod data=mylib.Lidar seed=12345;
   model LogRatio = spline(Range/m=3);
   output out=mylib.LidarOut3 pred=p3;
run;
```

The fit summary statistics shown in Output 12.1.7 are close to the ones from the previous two models, albeit slightly smaller.

Output 12.1.7 Fit Statistics

Scatter Plot Smoothing

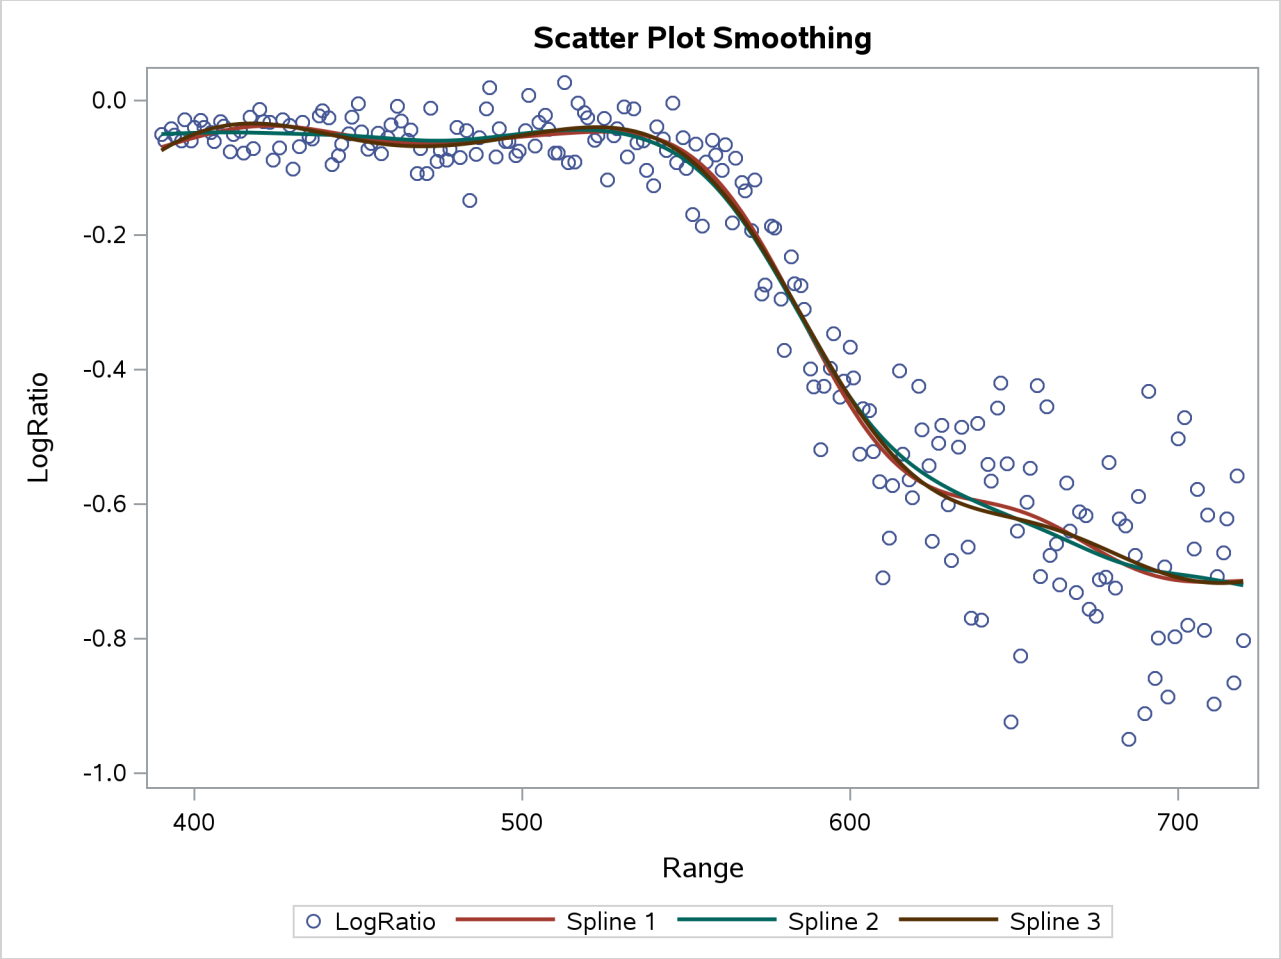
The GAMMOD Procedure

Fit Statistics	
Penalized Log Likelihood	249.79779
Roughness Penalty	9.440383E-9
Effective Degrees of Freedom	10.00000
Effective Degrees of Freedom for Error	211.00000
AIC (smaller is better)	-479.59559
AICC (smaller is better)	-478.54797
BIC (smaller is better)	-445.61397
GCV (smaller is better)	0.00664

As shown in Output 12.1.8, the effective degrees of freedom for the spline term where polynomials with degrees less than 4 are allowed without penalization is 8. The roughness penalty is quite small compared to the previous two fits. This also suggests that there are important contributions from the penalized part of the thin-plate regression splines even after the nonpenalized polynomials are raised to order 3.

Output 12.1.8 Estimates for Smoothing Components

Estimates for Smoothing Components



Component	Effective DF	Smoothing Parameter	Roughness Penalty	Number of Parameters	Rank of Penalty Matrix	Number of Knots
Spline(Range)	8.00000	1.0000	9.44E-9	9	10	221

The following statements use the DATA step to merge the predictions from the three scatter plot smoothing fits by PROC GAMMOD and use the SGPLOT procedure to visualize them:

```
data LidarPred;
   merge mylib.Lidar mylib.LidarOut mylib.LidarOut2 mylib.LidarOut3;
run;
proc sort data=LidarPred; by Range;run;
proc sgplot data=LidarPred;
   scatter x=Range y=LogRatio / markerattrs=GraphData1(size=7);
   series  x=Range y=p        / lineattrs  =GraphData2(thickness=2)
                               legendlabel="Spline 1";
   series  x=Range y=p2       / lineattrs  =GraphData3(thickness=2)
                               legendlabel="Spline 2";
   series  x=Range y=p3       / lineattrs  =GraphData4(thickness=2)
                               legendlabel="Spline 3";
run;
```

Output 12.1.9 displays the scatter plot smoothing fits by PROC GAMMOD under three different spline specifications.

Output 12.1.9 Scatter Plot Smoothing

Example 12.2: Nonparametric Logistic Regression

(View the complete code for this example (gammodex2.sas) in the example repository.)

This example shows how you can use PROC GAMMOD to build a nonparametric logistic regression model for a data set that contains a binary response and then use that model to classify observations.

The example uses the Pima Indians Diabetes data set, which can be obtained from the UCI Machine Learning Repository (Lichman 2013). It is extracted from a larger database that was originally owned by the National Institute of Diabetes and Digestive and Kidney Diseases. Data are for female patients who are at least 21 years old, are of Akimel O'otham (Pima Indian) heritage, and live near Phoenix, Arizona. The objective of this study is to investigate the relationship between a diabetes diagnosis and variables that represent physiological measurements and medical attributes. Some missing or invalid observations are removed from the analysis. The reduced data set contains 532 records. The following DATA step creates the data set DiabetesStudy:

```
title 'Diabetes Study';
data DiabetesStudy;
   input NPreg Glucose Pressure Triceps BMI Pedigree Age Diabetes Test@@;
   datalines;
 6  148   72   35   33.6  0.627  50  1  1    1   85   66   29   26.6  0.351  31  0  1
 1   89   66   23   28.1  0.167  21  0  0    3   78   50   32    31  0.248  26  1  0
 2  197   70   45   30.5  0.158  53  1  0    5  166   72   19   25.8  0.587  51  1  1
 0  118   84   47   45.8  0.551  31  1  1    1  103   30   38   43.3  0.183  33  0  1
 3  126   88   41   39.3  0.704  27  0  0    9  119   80   35    29  0.263  29  1  0

   ... more lines ...

 1  128   48   45   40.5  0.613  24  1  0    2  112   68   22   34.1  0.315  26  0  0
 1  140   74   26   24.1  0.828  23  0  1    2  141   58   34   25.4  0.699  24  0  1
 7  129   68   49   38.5  0.439  43  1  1    0  106   70   37   39.4  0.605  22  0  0
 1  118   58   36   33.3  0.261  23  0  1    8  155   62   26    34  0.543  46  1  0
;
```

The data set contains nine variables, including the binary response variable Diabetes. Table 12.16 describes the variables.

Table 12.16 Variables in the DiabetesStudy Data Set

Variable	Description
NPreg	Number of pregnancies
Glucose	Two-hour plasma glucose concentration in an oral glucose tolerance test
Pressure	Diastolic blood pressure (mm Hg)
Triceps	Triceps skin fold thickness (mm)
BMI	Body mass index (weight in kg/(height in m)^2)
Pedigree	Diabetes pedigree function
Age	Age (years)
Diabetes	0 if test negative for diabetes, 1 if test positive
Test	0 for training role, 1 for test

The Test variable splits the data set into training and test subsets. The training observations (whose Test value is 0) hold approximately 59.4% of the data. To build a model that is based on the training data and evaluate its performance by predicting the test data, you use the following statements to create a new variable, Result, whose value is the same as that of the Diabetes variable for a training observation and is missing for a test observation:

```
data mylib.DiabetesStudy;
   set DiabetesStudy;
   Result = Diabetes;
   if Test=1 then Result=.;
run;
```

A typical starting point of your analysis for modeling the binary response might be a parametric logistic regression model. But it is restricted in the sense that all variables affect the response in strictly linear fashion. If you are uncertain that a variable is an important factor and its contribution is linear in predicting the response, you might want to choose a nonparametric logistic regression model to fit the data. You can use

PROC GAMMOD to form a nonparametric model by including the spline transformation of each explanatory variable, as shown in the following statements:

```
proc gammod data=mylib.DiabetesStudy seed=12345;
   model Result(event='1') = spline(NPreg)    spline(Glucose)
                             spline(Pressure) spline(Triceps)
                             spline(BMI)      spline(Pedigree)
                             spline(Age) / dist=binary;
run;
```

Because the response variable Result is binary, the DIST=BINARY option in the MODEL statement specifies a binary distribution for the response variable. By default, PROC GAMMOD models the probability of the first ordered response category, which is a negative diabetes testing result in this case. The EVENT= option specifically requests that PROC GAMMOD model the probability of positive diabetes testing results. The "Response Profile" table in Output 12.2.1 shows the frequencies of the response in both categories.

Output 12.2.1 Response Profile

Diabetes Study

The GAMMOD Procedure

Response Profile

Ordered Value	Result	Total Frequency
1	0	208
2	1	122

Probability modeled is Result = 1.

Output 12.2.2 lists the summary statistics from the nonparametric logistic regression model, which include spline transformations of all variables.

Output 12.2.2 Fit Statistics

Fit Statistics	
Penalized Log Likelihood	-138.57851
Roughness Penalty	1.208734E-8
Effective Degrees of Freedom	16.00000
Effective Degrees of Freedom for Error	314.28286
AIC (smaller is better)	309.15702
AICC (smaller is better)	310.89504
BIC (smaller is better)	369.94250
UBRE (smaller is better)	0.02357

The "Tests for Smoothing Components" table in Output 12.2.3 shows approximate tests results. Although some spline terms are significant, others are not. The null testing hypothesis is whether the total contribution from a variable is 0. So you can form a reduced model by removing those nonsignificant spline terms from the model. In this case, spline transformations for NPreg, Pressure, BMI, and Triceps are dropped from the model because their p-values are larger than the 0.1 nominal level.

Output 12.2.3 Tests for Smoothing Components

Tests for Smoothing Components				
Component	Effective DF	Effective DF for Test	Chi-Square	Pr > ChiSq
Spline(NPreg)	1.00000	1	0.0186	0.8916
Spline(Glucose)	1.00000	1	44.5949	<.0001
Spline(Pressure)	1.00000	1	2.8310	0.0925
Spline(Triceps)	1.00000	1	1.2128	0.2708
Spline(BMI)	1.00000	1	5.8112	0.0159
Spline(Pedigree)	1	1	6.1108	0.0134
Spline(Age)	9	9	19.0721	0.0246

The following statements use PROC GAMMOD to fit a reduced nonparametric logistic regression model. The OUTPUT statement requests predicted probabilities for both training and test data. The COPYVARS option in the OUTPUT statement requests that the Diabetes and Test variables also be included in the output data table so that you can use them to identify test observations and compute misclassification errors.

```
ods graphics on;
proc gammod data=mylib.DiabetesStudy plots seed=12345;
   model Result(event='1') = spline(Glucose)
                             spline(Pedigree) spline(Age) / dist=binary;
   output out=mylib.DiabetesStudyOut copyvars=(Diabetes Test);
run;
```

Output 12.2.4 shows the summary statistics from the reduced nonparametric logistic regression model. The values of the information criteria are better than those of the parametric logistic regression model.

Output 12.2.4 Fit Statistics

Diabetes Study

The GAMMOD Procedure

Fit Statistics	
Penalized Log Likelihood	-149.85766
Roughness Penalty	2.85613
Effective Degrees of Freedom	8.05241
Effective Degrees of Freedom for Error	320.61183
AIC (smaller is better)	312.96402
AICC (smaller is better)	313.41826
BIC (smaller is better)	343.55588
UBRE (smaller is better)	-0.00230

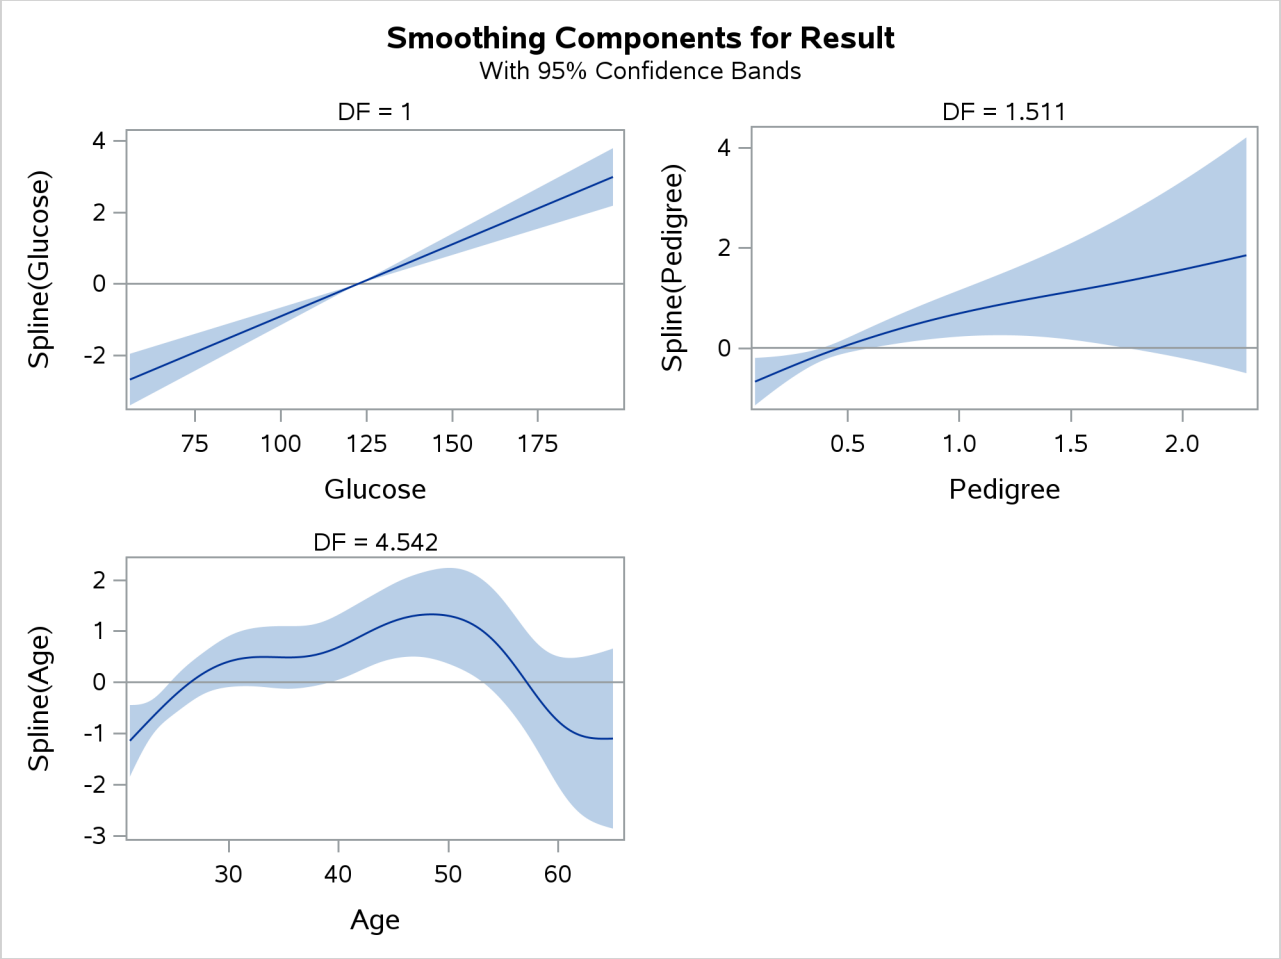
In the "Estimates for Smoothing Components" table in Output 12.2.5, PROC GAMMOD reports that the effective degrees of freedom value for spline transformations of Glucose is quite close to 1. This suggests a strictly linear form for Glucose. For Pedigree, the degrees of freedom value demonstrates a moderate amount of nonlinearity. For Age, the degrees of freedom value is much larger than 1. The measure suggests a nonlinear pattern in the dependency of the response on Age.

Output 12.2.5 Estimates for Smoothing Components

Estimates for Smoothing Components

Component	Effective DF	Smoothing Parameter	Roughness Penalty	Number of Parameters	Rank of Penalty Matrix	Number of Knots
Spline(Glucose)	1.00000	9.636E17	2.66E-14	9	10	110
Spline(Pedigree)	1.51071	0.4383	0.5086	9	10	283
Spline(Age)	4.54170	69.8812	2.3475	9	10	42

The "Tests for Smoothing Components" table in Output 12.2.6 shows that all spline transformations are significant in predicting diabetes testing results.



Output 12.2.6 Tests for Smoothing Components

Tests for Smoothing Components

Component	Effective DF	Effective DF for Test	Chi-Square	Pr > ChiSq
Spline(Glucose)	1.00000	1	53.0363	<.0001
Spline(Pedigree)	1.51071	2	9.9354	0.0070
Spline(Age)	4.54170	6	23.0661	0.0008

The smoothing component panel (which is produced by the PLOTS option and is shown in Output 12.2.7) visualizes the spline transformations for the four variables in addition to 95% Bayesian curvewise confidence bands. For Glucose, the spline transformation is almost a straight line. For Pedigree, the spline transformation shows a slightly nonlinear trend. For Age, the dependency is obviously nonlinear.

Output 12.2.7 Smoothing Components Panel

The following statements compute the misclassification error on the test data from the reduced nonparametric logistic regression model that PROC GAMMOD produces:

```
data test;
   set mylib.DiabetesStudyOut(where=(Test=1));
   if ((Pred>0.5 & Diabetes=1) | (Pred<0.5 & Diabetes=0))
   then Error=0;
   else Error=1;
run;

proc freq data=test;
   tables Diabetes*Error/nocol norow;
run;
```

Output 12.2.8 shows the misclassification errors for observations in the test set and observations of each response category.

Output 12.2.8 Crosstabulation Table for Test Set Prediction

Diabetes Study

The FREQ Procedure

Frequency Percent	Table of Diabetes by Error		
		Error	
Diabetes	0	1	Total
0	130 64.36	17 8.42	147 72.77
1	35 17.33	20 9.90	55 27.23

Example 12.3: Nonparametric Tweedie Regression

(View the complete code for this example (gammodex4.sas) in the example repository.)

This example illustrates how you can use the GAMMOD procedure to fit a nonparametric regression model with spline effects for a response variable that has a Tweedie distribution.

You can view this model as a generalized linear model because the Tweedie distribution belongs to the exponential family. The Tweedie distribution is particularly useful for modeling response variables that are continuous for positive values and take the value 0 with a positive probability. For example, in the insurance industry the Tweedie distribution is often assumed for claims, which are positive for customers who have filed claims and are 0 for other customers. You can use the Tweedie distribution to model such response variables without special transformations.

The GENSELECT procedure can fit Tweedie regression models that incorporate linear effects for the covariates. However, as demonstrated in this example, the assumption of linearity can be too restrictive, and you might want to use the GAMMOD procedure to explore the nonlinear dependency structures in the data.

The following DATA step simulates a response variable Y by using a Tweedie distribution and four continuous predictors. Each continuous predictor is sampled independently from the uniform distribution $U(0,1)$. The linear predictor η for the true model is formed by applying additive nonlinear transformations to x_1, x_2, and x_3:

$$\eta = \frac{2\sin(\pi x_1) + 0.8\exp(2x_2) + 0.2x_3^{11}(10(1-x_3))^6 + 10(10x_3)^3(1-x_3)^{10}}{20}$$

The predictor x_4 is a nuisance parameter that does not enter the model. The parameters for the Tweedie distribution are $\phi = 0.4$ and $p = 1.5$, and the link function is $\log\mu = \eta$, where the expected value is $\mathrm{E}(Y) = \mu$ and the variance is $\mathrm{Var}(Y) = \phi\mu^p$. The power parameter p controls the variance of the distribution. When p is between 1 and 2, as in this example, a Tweedie random variable can be generated from a compound Poisson distribution (Smyth 1996).

```
title 'Nonparametric Tweedie Model';
%let phi=0.4;
%let power=1.5;
```

```
data mylib.one;
   do i=1 to 1000;

      /* Sample the predictors */
      x1=ranuni(1);
      x2=ranuni(1);
      x3=ranuni(1);
      x4=ranuni(1);

      /* Apply nonlinear transformations to predictors */
      f1=2*sin(3.14159265*x1);
      f2=exp(2*x2)*0.8;
      f3=0.2*x3**11*(10*(1-x3))**6+10*(10*x3)**3*(1-x3)**10;
      xb=f1+f2+f3;
      xb=xb/20;
      mu=exp(xb);

      /* Compute parameters of compound Poisson distribution */
      lambda=mu**(2-&power)/(&phi*(2-&power));
      alpha=(2-&power)/(&power-1);
      gamma=&phi*(&power-1)*(mu**(&power-1));

      /* Simulate the response */
      rpoi=ranpoi(1,lambda);
      if rpoi=0 then y=0;
      else do;
         y=0;
         do j=1 to rpoi;
            y=y+rangam(1,alpha);
         end;
         y=y*gamma;
      end;
      output;
   end;
run;
```

You can use PROC GENSELECT to fit a parametric model for Y by using the following statements:

```
proc genselect data=mylib.one;
   model y=x1 x2 x3 x4/dist=tweedie;
run;
```

Equivalently, you can also use PROC GAMMOD to fit a parametric linear model by using the PARAM option in the MODEL statement, as shown in the following statements.

```
proc gammod data=mylib.one seed=1234;
   model y=param(x1 x2 x3 x4)/dist=tweedie;
run;
```

The "Fit Statistics" table in Output 12.3.1 shows the summary statistics for the fitted parametric Tweedie model.

Output 12.3.1 Fit Statistics

Nonparametric Tweedie Model

The GAMMOD Procedure

Fit Statistics	
Penalized Log Likelihood	-1178.69507
Roughness Penalty	0
Effective Degrees of Freedom	7.00000
Effective Degrees of Freedom for Error	993.00000
AIC (smaller is better)	2371.39014
AICC (smaller is better)	2371.50305
BIC (smaller is better)	2405.74443

The "Parameter Estimates" table in Output 12.3.2 shows the estimates for regression parameters in addition to dispersion and power parameters (ϕ and p).

Output 12.3.2 Parameter Estimates

Parameter Estimates					
Parameter	DF	Estimate	Standard Error	Chi-Square	Pr > ChiSq
Intercept	1	0.441832	0.067334	43.0565	<.0001
x1	1	-0.043725	0.064965	0.4530	0.5009
x2	1	0.202242	0.064216	9.9188	0.0016
x3	1	-0.253920	0.066625	14.5250	0.0001
x4	1	-0.061098	0.066040	0.8559	0.3549
Dispersion	1	0.416001	0.016987		
Power	1	1.524596	0.048675		

If you are uncertain about the relationship between the linked mean for the fitted Tweedie model and the covariates, you can add spline terms to the model to explore possible nonlinear dependence. The following statements fit a nonparametric Tweedie model and produce a plot of fitted smoothing components.

```
proc gammod data=mylib.one seed=1234 plots;
   model y=spline(x1) spline(x2) spline(x3) spline(x4)/dist=tweedie;
run;
```

The "Fit Statistics" table in Output 12.3.3 shows the summary statistics for the fitted nonparametric Tweedie model. Compared to the parametric model, the nonparametric model has more effective degrees of freedom, but smaller AIC and AICC values. The penalized likelihood value is larger for the nonparametric model. These statistics indicate that the nonparametric model provides a better fit.

Output 12.3.3 Fit Statistics

Nonparametric Tweedie Model

The GAMMOD Procedure

Fit Statistics	
Penalized Log Likelihood	-1157.17502
Roughness Penalty	2.62230
Effective Degrees of Freedom	14.11920
Effective Degrees of Freedom for Error	983.62098
AIC (smaller is better)	2339.96615
AICC (smaller is better)	2340.39965
BIC (smaller is better)	2409.25974
GCV (smaller is better)	0.39845

The "Regression Parameter Estimates" table in Output 12.3.4 lists the estimate for the intercept, in addition to the estimates for the dispersion and power parameters for the Tweedie model. Both variance parameters are close to the true values.

Output 12.3.4 Regression Parameter Estimates

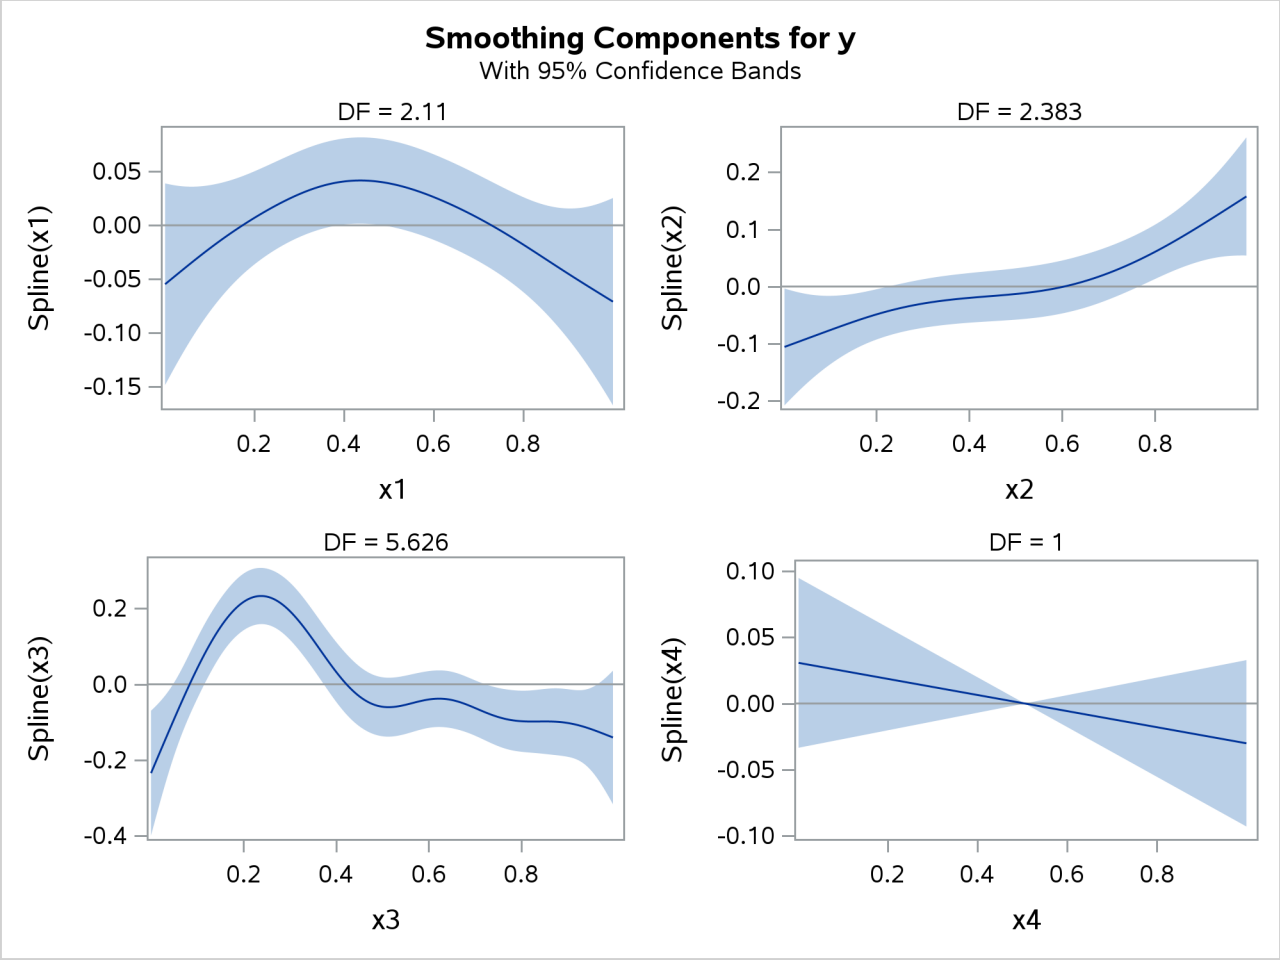
Parameter Estimates					
Parameter	DF	Estimate	Standard Error	Chi-Square	Pr > ChiSq
Intercept	1	0.356825	0.018329	379.0079	<.0001
Dispersion	1	0.400459	0.518084		
Power	1	1.501771	1.514454		

The "Estimates for Smoothing Components" table in Output 12.3.5 shows the fitted information for the spline terms in the model. The degrees of freedom value and the roughness penalty value suggest some moderate nonlinear relationship between the linked mean and the three covariates x_1, x_2, and x_3. The spline term for the nuisance parameter x_4 has a linear form.

Output 12.3.5 Estimates for Smoothing Components

Estimates for Smoothing Components						
Component	Effective DF	Smoothing Parameter	Roughness Penalty	Number of Parameters	Rank of Penalty Matrix	Number of Knots
Spline(x1)	2.10969	0.9560	0.5659	9	10	1000
Spline(x2)	2.38340	0.5604	0.3814	9	10	1000
Spline(x3)	5.62608	0.0145	1.6750	9	10	1000
Spline(x4)	1.00002	133078	3.662E-6	9	10	1000

The "Tests for Smoothing Components" table in Output 12.3.6 shows the approximate Wald test for the four spline terms. The spline term for the nuisance predictor x_4 is not significant.



Output 12.3.6 Tests for Smoothing Components

Tests for Smoothing Components

Component	Effective DF	Effective DF for Test	F Value	Pr > F
Spline(x1)	2.10969	3	4.76	0.0027
Spline(x2)	2.38340	3	13.64	<.0001
Spline(x3)	5.62608	7	49.02	<.0001
Spline(x4)	1.00002	1	0.88	0.3484

Output 12.3.7 displays the "Smoothing Component Panel" for all the spline terms used in the model. For x_1, x_2, and x_3, the fitted curves are reasonably smooth and close to the true functions. For x_4, the spline plot shows a strictly linear fit, with 95% Bayesian confidence bands covering the horizontal line at 0. This reinforces the conclusion that x_4 does not contribute to the model and can be removed from further analysis.

Output 12.3.7 Smoothing Component Panel

Overview: GAMSELECT Procedure

The GAMSELECT procedure fits and performs model selection for generalized additive models in SAS Viya.

Generalized additive models are extensions of generalized linear models. They relax the generalized linear models' assumption of linearity by allowing spline terms that characterize nonlinear dependency structures. PROC GAMSELECT supports model selection by componentwise functional gradient descent (Friedman 2001; Bühlmann and Hothorn 2007) and the shrinkage method by using the penalized likelihood with sparsity-inducing penalties (Meier, Van de Geer, and Bühlmann 2009). It fits models for standard distributions in the exponential family, such as the normal, Poisson, gamma, and binary distributions.

PROC GAMSELECT Features

PROC GAMSELECT offers the following basic features:

- estimates the regression parameters of a generalized additive model by using penalized likelihood estimation or componentwise functional gradient descent
- enables model building (variable selection) through the SELECTION statement
- provides model-building syntax in the CLASS statement and effect-based parametric effects in the MODEL statement, which are used in other SAS/STAT analytic procedures (in particular, the GLM, LOGISTIC, GLIMMIX, and MIXED procedures)
- provides response-variable options
- provides control options for constructing a spline term
- provides multiple link functions for any distribution
- provides a WEIGHT statement for weighted analysis
- provides a FREQ statement for grouped analysis
- provides an OUTPUT statement to produce a data table that contains predicted values and other observationwise statistics
- provides a PARTITION to divide data into training, validation, and test data roles
- produces graphs via ODS Graphics
- allows programming statements so that you can create variables on the fly for model effects and splines, frequency, offset, response, and weight

Because the GAMSELECT procedure runs on SAS Cloud Analytic Services (CAS), it also does the following:

- enables you to run on a cluster of machines that distribute the data and the computations
- enables you to run in single-machine mode
- exploits all the available cores and concurrent threads (for information about how PROC GAMSELECT uses threads, see the section "Multithreading" on page 102 in Chapter 2, "Shared Concepts")

PROC GAMSELECT Compared with Other SAS Procedures

In SAS Viya, both the GAMSELECT and GAMMOD procedures fit generalized additive models. The GAMSELECT procedure and the GRADBOOST procedure both fit predictive models by using methods that are based on a generic functional gradient descent, or boosting, algorithm (Friedman 2001).

PROC GAMSELECT Compared with the GAMMOD Procedure

Both the GAMSELECT and GAMMOD procedures in SAS Visual Statistics have been developed specifically for SAS Viya. Both procedures are designed to run on a cluster of machines that distribute the data and the computations. Both procedures perform computations in multiple threads. However, the GAMMOD and GAMSELECT procedures use different approaches for constructing spline basis expansions and fitting generalized additive models. PROC GAMSELECT fits and performs model selection for generalized additive models but does not support model inference. In general, you should not expect similar results from these two procedures. Table 13.1 summarizes the main differences.

Table 13.1 PROC GAMSELECT Compared with PROC GAMMOD

Functionality	PROC GAMSELECT	PROC GAMMOD
Constructing spline basis expansions	Uses B-spline basis expansions for the boosting method and natural cubic splines for the shrinkage method. The boosting method supports univariate and bivariate spline terms with nonnegative degrees.	Uses thin-plate regression splines to construct basis expansions for each spline term, and each term allows multiple variables
Fitting generalized additive models	Fits models and performs model selection by boosting and shrinkage methods. The boosting method uses a componentwise functional gradient descent algorithm for models with parametric effects and spline terms. The shrinkage method optimizes a penalized likelihood with sparsity-inducing penalties to control model complexity and smoothness. Penalty terms can be either fixed or varied.	Fits models that have fixed smoothness terms by optimizing penalized likelihood. For models that have varying smoothness terms, PROC GAMMOD estimates smoothing parameters simultaneously by optimizing global model fit criteria such as generalized cross validation (GCV).

Table 13.1 *continued*

Functionality	PROC GAMSELECT	PROC GAMMOD
Model degrees of freedom and inference	Does not compute model degrees of freedom or perform inference	Uses the trace of the global degrees-of-freedom matrix. A global Bayesian posterior covariance matrix is available. The confidence limits for each observation's prediction are available, in addition to componentwise confidence limits.
Multithreading scheme	Specifically designed to operate in SAS Viya and performs computations in multiple threads	Specifically designed to operate in SAS Viya and performs computations in multiple threads

PROC GAMSELECT Compared with the GRADBOOST Procedure

Both the GAMSELECT and GRADBOOST procedures fit predictive models by using a generic functional gradient descent, or boosting, algorithm (Friedman 2001). However, how the procedures implement the boosting algorithms and the types of predictive models that they fit differ substantially.

The GAMSELECT procedures uses a componentwise implementation of the generic functional gradient descent algorithm. The effects in the model can be parametric effects, univariate spline terms, or bivariate spline terms. The parameter estimates for each component are additive across the iterations of the boosting algorithm. As a result, the predictive model that is fit by the boosting method in PROC GAMSELECT is a generalized additive model that consists of parametric effects and spline terms selected at the boosting iterations. For more information about the componentwise boosting algorithm that PROC GAMSELECT implements, see the section "Boosting" on page 674.

The boosting algorithm that is implemented by the GRADBOOST procedure fits a decision tree at each iteration. The tree can consist of both interval and nominal predictors. The decision trees that are fit at each iteration are not additive in the estimated parameters. As a result, the predictive model that is fit by PROC GRADBOOST is a tree ensemble. For more information about the boosting algorithm that PROC GRADBOOST implements, see the section "Boosting" (Chapter 17, *SAS Viya: Machine Learning Procedures*).

Using CAS Sessions and CAS Engine Librefs

SAS Cloud Analytic Services (CAS) is the analytic server and associated cloud services in SAS Viya. This section describes how to create a CAS session and set up a CAS engine libref that you can use to connect to the CAS session. It assumes that you have a CAS server already available; contact your system administrator if you need help starting and terminating a server. This CAS server is identified by specifying the host on which it runs and the port on which it listens for communications. To simplify your interactions with this CAS server, the host information and port information for the server are stored as SAS option values that are retrieved automatically whenever this CAS server needs to be accessed. You can examine the host and port values for the server at your site by using the following statements:

```
proc options option=(CASHOST CASPORT);
run;
```

In addition to starting a CAS server, your system administrator might also have created a CAS session and a CAS engine libref for your use. You can define your own sessions and CAS engine librefs that connect to the CAS server as shown in the following statements:

```
cas mysess;
libname mylib cas sessref=mysess;
```

The CAS statement creates the CAS session named mysess, and the LIBNAME statement creates the mylib CAS engine libref that you use to connect to this session. It is not necessary to explicitly name the CASHOST and CASPORT of the CAS server in the CAS statement, because these values are retrieved from the corresponding SAS option values.

If you have created the mysess session, you can terminate it by using the TERMINATE option in the CAS statement as follows:

```
cas mysess terminate;
```

For more information about the CAS and LIBNAME statements, see the section "Introduction to Shared Concepts" on page 6 in Chapter 2, "Shared Concepts."

Getting Started: GAMSELECT Procedure

(View the complete code for this example at https://github.com/sascommunities/doc-supplement-casstat/tree/main/Examples/gamselectgs1.sas.)

NOTE: Input data must be in a CAS table that is accessible in your CAS session. You must refer to this table by using a two-level name. The first level must be a CAS engine libref, and the second level must be the table name. For more information, see the sections "Using CAS Sessions and CAS Engine Librefs" on page 7 and "Loading a SAS Data Set onto a CAS Server" on page 7 in Chapter 2, "Shared Concepts."

Given a response with many potential predictors, this example shows how you can use the GAMSELECT procedure not only to find which are the few predictors that really do affect the response, but also to determine what functional form that effect takes.

The following DATA step creates the data table getStarted, which consists of 20,000 observations on a continuous response variable (y) and 90 continuous variables (x1–x90) in the current CAS engine libref named mylib:

```
data mylib.getStarted;
  drop i j w;

  array x{90};
  call streaminit(4321);
  pi=constant("pi");

  do i=1 to 20000;
      u = ranuni(12345);
      do j=1 to dim(x);
         w    = ranuni(12345);
         x{j} = (w + u)/2;
      end;
      f1 = x1;
      f2 = (2*x2-1)**2;
      f3 = sin(2 * pi * x3)/(2-sin(2*pi*x3));
      f4 = 0.1*sin(2*pi*x4) + 0.2*cos(2*pi*x4)+0.3*sin(2*pi*x4)**2
         + 0.4*cos(2*pi*x4)**3+0.5*sin(2*pi*x4)**3;
      linp = 5*f1+3*f2+4*f3+6*f4;
      y =  linp + 1.32 * rand("Normal");
      output;
   end;
run;
```

These statements assume that your CAS engine libref is named mylib, but you can substitute any appropriately defined CAS engine libref. For the simulation, only the variables x1–x4 affect the outcome y, and the variables x1–x90 are all positively correlated.

The following statements fit a nonparametric model by using spline transformations of the variables x1–x10:

```
ods graphics on;
proc gamselect data= mylib.getStarted plots=all;
   model y = spline(x1 ) spline(x2 ) spline(x3 ) spline(x4 ) spline(x5 )
             spline(x6 ) spline(x7 ) spline(x8 ) spline(x9 ) spline(x10)
             ;
```

```
   selection method=boosting;
run;
```

The MODEL statement and the SELECTION statement are required when you use PROC GAMSELECT. The output from this analysis is presented in Figure 13.1 through Figure 13.6.

Figure 13.1 displays the "Model Information" table. The GAMSELECT procedure uses the boosting method to fit and select the model. For more information about the boosting selection method, see the section "Boosting" on page 674. The response variable y is modeled using a normal distribution whose mean is modeled by an identity link function.

Figure 13.1 Model Information

The GAMSELECT Procedure

Model Information	
Data Source	GETSTARTED
Response Variable	y
Distribution	Normal
Link Function	Identity
Selection Method	Boosting
Random Number Seed	2816737677

Figure 13.2 displays the "Number of Observations" table. All 20,000 observations in the data table are used in the analysis. For data tables that have missing or invalid values, the number of observations that are used might be less than the number of observations that are read.

Figure 13.2 Number of Observations

Number of Observations Read	20000
Number of Observations Used	20000

Figure 13.3 displays the "Iteration Summary" table. The boosting algorithm executed 500 iterations. The selected model corresponds to the final boosting iteration and includes four effects.

Figure 13.3 Iteration Summary

Iteration Summary	
Iterations Executed	500
Selected Iteration	500
Number of Selected Effects	4

Figure 13.4 displays the "Selected Effects" table. The table displays the effects that are included in the selected model, the first iteration at which an effect entered the model, and the number of iterations at which the effect was selected. The four spline terms that are constructed from the variables x1–x4 are selected for the final model.

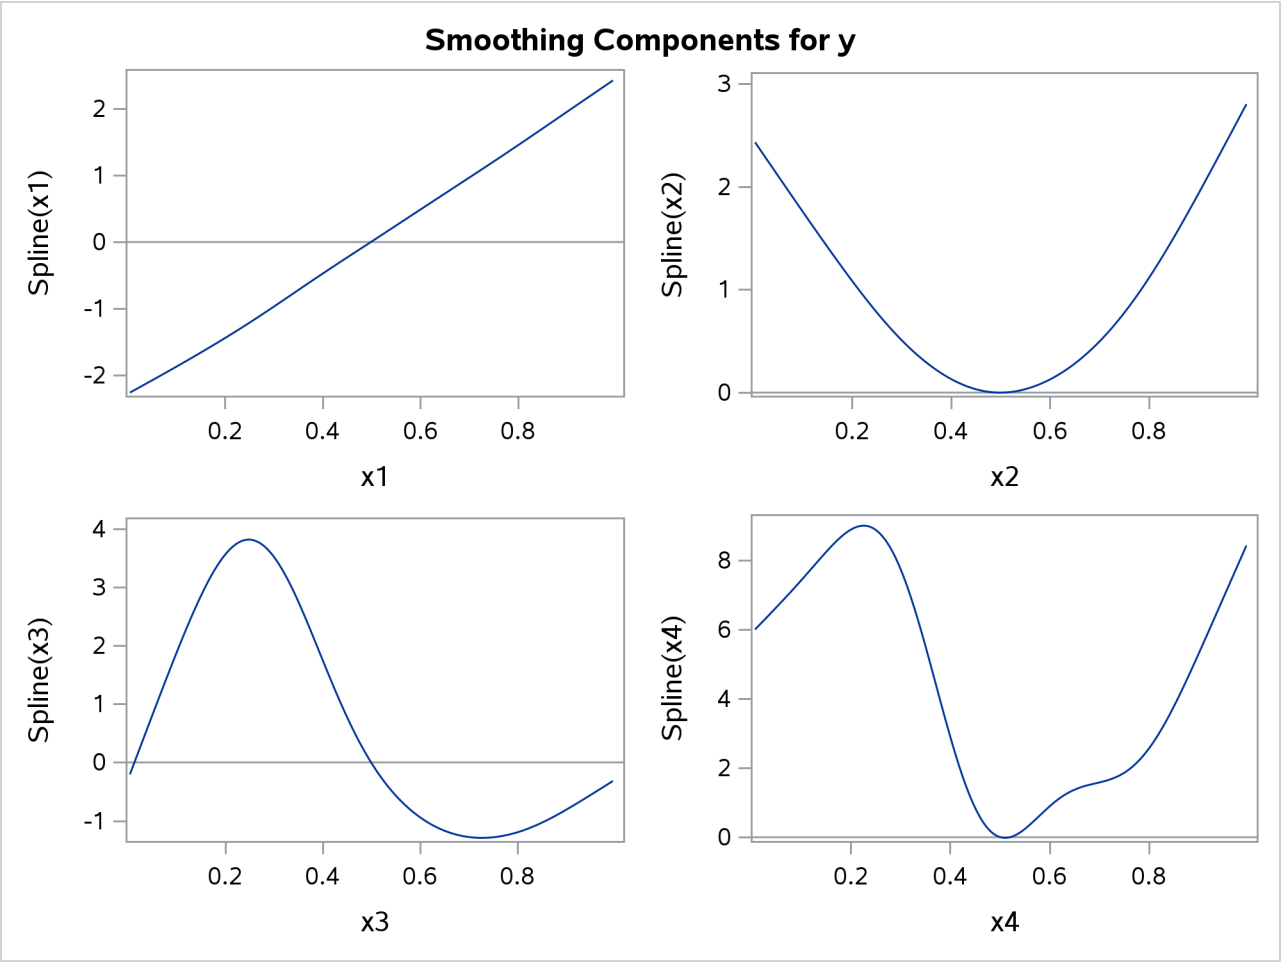

Figure 13.4 Selected Effects

Selected Effects

Effect	Entry Iteration	Times Selected
Spline(x4)	1	293
Spline(x3)	9	113
Spline(x1)	34	54
Spline(x2)	36	40

Figure 13.5 displays the smoothing component panel for the spline terms in the selected model. It displays predicted spline curves for each of the spline terms in the selected model.

Figure 13.5 Smoothing Component Panel

Finally, the procedure displays the table shown in Figure 13.6, which shows the amount of time (in seconds) that PROC GAMSELECT required to perform the various tasks in the analysis.

Figure 13.6 Procedure Timing

Task Timing		
Task	**Seconds**	**Percent**
Parsing	0.02	1.21%
Reading and Levelizing Data	0.01	0.66%
Creating Basis Expansions	0.04	1.77%
Fitting Model	1.99	96.07%
Producing Graphics	0.00	0.05%
Miscellaneous	0.01	0.26%
Cleaning Up	0.00	0.02%
Total	2.07	100.00%

The following code uses the macro function SplinePrefixList to specify a model for the variable y by using spline transformations of all 90 explanatory variables, x1–x90:

```
%macro SplinePrefixList(prefix,n);
   %do i = 1 %to &n;
      spline(&prefix.&i)
      %end;
%mend;

ods graphics on;
proc gamselect data= mylib.getStarted plots=all;
   model y = %SplinePrefixList(x,90);
   selection method=boosting;
run;
```

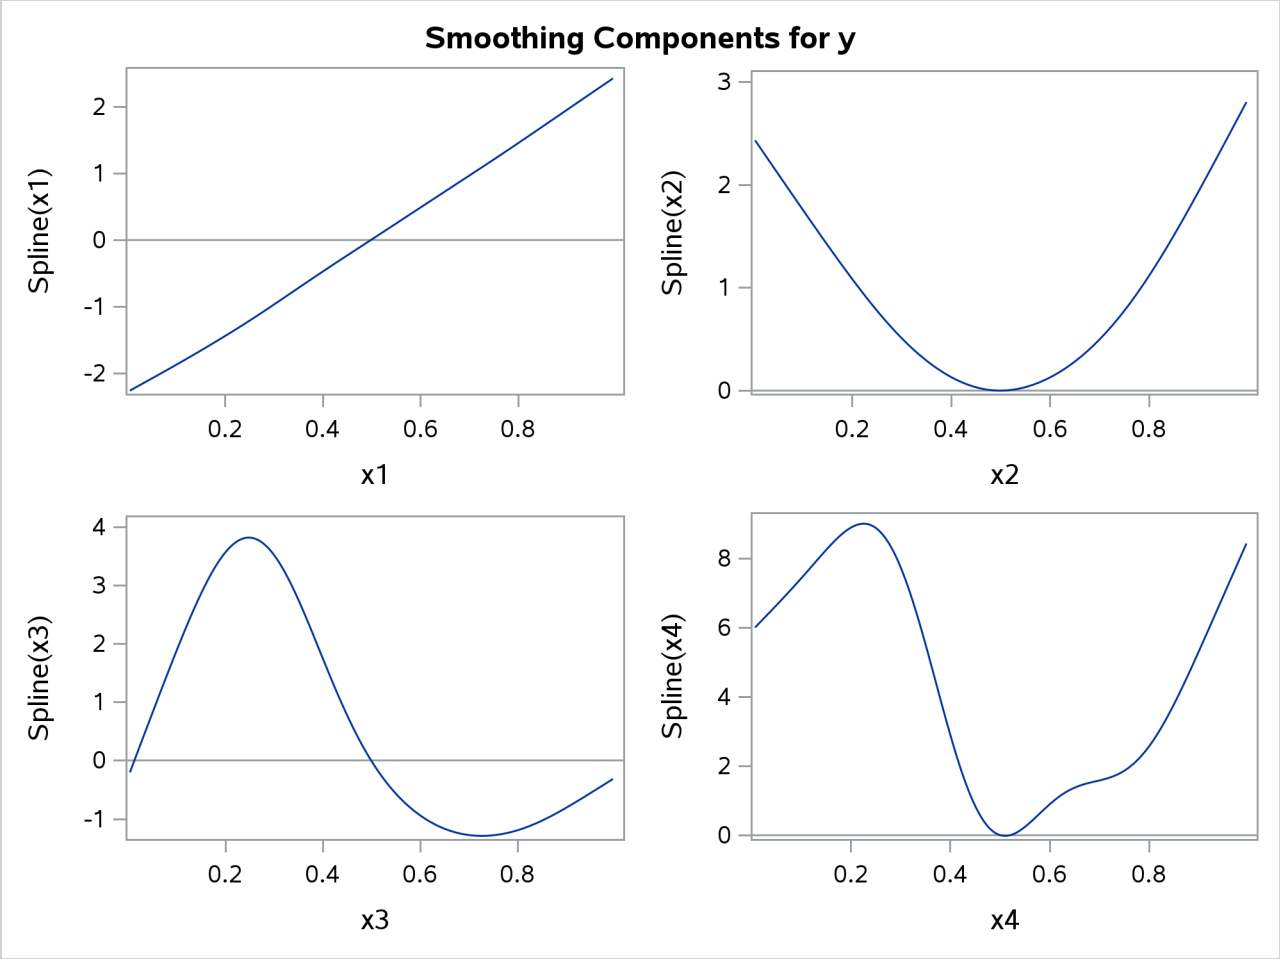

Figure 13.7 and Figure 13.8 show that the analysis that is run using all 90 predictors selects the same model that includes only the four spline terms constructed from the variables x1–x4.

Figure 13.7 Selected Effects

The GAMSELECT Procedure

Selected Effects		
Effect	**Entry Iteration**	**Times Selected**
Spline(x4)	1	293
Spline(x3)	9	113
Spline(x1)	34	54
Spline(x2)	36	40

Figure 13.8 Smoothing Component Panel

Syntax: GAMSELECT Procedure

The following statements are available in the GAMSELECT procedure:

PROC GAMSELECT < *options* > **;**
BY *variables* **;**
CLASS *variable* < **(***options***)** > . . . < *variable* < **(***options***)** > > < / *global-options* > **;**
DISPLAY < *table-list* > < / *options* > **;**
DISPLAYOUT *table-spec-list* < / *options* > **;**
FREQ *variable* **;**
MODEL *response* < **(***response-options***)** > **=** < **PARAM(***effects***)** >
< **SPLINE(***variable* < / *spline-options* >**)** >
< **SPLINE(***variable1 variable2* < / *spline-options* >**)** > < / *model-options* > **;**
MODEL *events* / *trials* **=** < **PARAM(***effects***)** >
< **SPLINE(***variable* < / *spline-options* >**)** >
< **SPLINE(***variable1 variable2* < / *spline-options* >**)** > < / *model-options* > **;**
OUTPUT OUT=*libref.data-table*
< **COMPONENT** >< **COMPVARS=(***variables***)** > < **COPYVARS=(***variables***)** >
< *keyword* < **=***name* > >. . . < *keyword* < **=***name* > > **;**
PARTITION *partition-options* **;**
SELECTION < **METHOD=***method* < **(***method-options***)** > > **;**
STORE < **OUT=** >*libref.data-table* **;**
WEIGHT *variable* **;**
Programming statements **;**

The PROC GAMSELECT statement, one MODEL statement, and one SELECTION statement are required. The CLASS statement can appear multiple times. If a CLASS statement is specified, it must precede the MODEL statement. The following sections describe the PROC GAMSELECT statement and then describe the other statements in alphabetical order.

PROC GAMSELECT Statement

PROC GAMSELECT < *options* > **;**

The PROC GAMSELECT statement invokes the procedure. Table 13.2 summarizes the available options in the PROC GAMSELECT statement by function. The options are then described fully in alphabetical order.

Table 13.2 PROC GAMSELECT Statement Options

Option	Description
Basic Options	
DATA=	Specifies the input data table
SEED=	Sets the seed for pseudorandom number generation
Display Options	
ITDETAILS	Displays the “Iteration Details” table
NOCLPRINT	Limits or suppresses the display of classification variable levels

Table 13.2 *continued*

Option	Description
PLOTS=	Controls plots that are produced through ODS Graphics
Tolerance Options	
SINGCHOL=	Tunes the singularity criterion for Cholesky decompositions
SINGULAR=	Tunes the general singularity criterion

You can specify the following *options* in the PROC GAMSELECT statement.

DATA=*libref.data-table*
names the input data table for PROC GAMSELECT to use. The default is the most recently created data table. *libref.data-table* is a two-level name, where

libref refers to a collection of information that is defined in the LIBNAME statement and includes the library, which includes a path to the data, and a session identifier, which defaults to the active session but which can be explicitly defined in the LIBNAME statement. For more information about *libref*, see the section "Using CAS Sessions and CAS Engine Librefs" on page 645.

data-table specifies the name of the input data table.

ITDETAILS
generates the "Iteration Details" table.

NOCLPRINT< =*number* **>**
suppresses the display of the "Class Level Information" table if you do not specify *number*. If you specify *number*, the values of the classification variables are displayed for only those variables whose number of levels is less than *number*. Specifying a *number* helps reduce the size of the "Class Level Information" table if some classification variables have a large number of levels.

PLOTS < (*global-plot-option***) > < =** *plot-requests* **< (***option***) > >**
controls the plots that are produced through ODS Graphics. When ODS Graphics is enabled, PROC GAMSELECT produces by default a panel of plots of partial prediction curves or surfaces of smoothing components. For example:

```
ods graphics on;

proc gamselect plots;
   model y=spline(x1) spline(x2);
   selection;
run;

ods graphics off;
```

You can specify the following *global-plot-option*, which applies to the smoothing component plots that the GAMSELECT procedure generates:

UNPACK

UNPACKPANEL

suppresses paneling. By default, multiple smoothing component plots can appear in some output panels. Specify this option to display each plot individually.

You can specify the following *plot-requests*:

ALL

produces all default plots.

COMPONENTS < (*component-option***) >**

plots a panel of smoothing components of the fitted model. You can specify the following *component-option*:

COMMONAXES

requests that the smoothing component plots, except for bivariate contour plots, use a common vertical axis. This option enables you to visually judge the relative effect size.

NONE

suppresses all plots.

SEED=*number*

specifies an integer to use to start the pseudorandom number generator for subset sampling from observations to form knots if necessary, for random cross validation if the boosting method is used for model selection, and for random data partitioning if a separate random number seed is not supplied. If you do not specify this option or if *number* ≤ 0, the seed is generated by reading the time of day from the computer's clock. If you specify this option with a nonzero value and you also specify the PARTITION statement without specifying the random number seed there, then the same random number seed is used to partition the input data. Note that the random sampling of observations for cross validation and data partitioning depends on how the data are distributed across machines and threads. Therefore, even if you specify the same seed, results might differ between runs of PROC GAMSELECT.

SINGCHOL=*number*

tunes the singularity criterion in Cholesky decomposition and matrix inversion operations. The default *number* is 1E4 times the machine epsilon; this product is approximately 1E–12 on most computers.

SINGULAR=*number*

tunes the singularity criterion that is used to solve ridge regressions in searching upper bounds of the sparsity parameter and the smoothness parameter, if you specify the shrinkage method of model selection. The default *number* is 1E4 times the machine epsilon; this product is approximately 1E–12 on most computers.

BY Statement

BY *variables* **;**

You can specify a BY statement in PROC GAMSELECT to obtain separate analyses of observations in groups that are defined by the values of the BY variables. If you specify more than one BY statement, only the last one specified is used. For more information, see the discussion of BY-group processing in the "Grouping Data" section of *SAS Programmers Guide: Essentials*.

CLASS Statement

CLASS *variable* < **(***options***)** >. . . < *variable* < **(***options***)** > > < / *global-options* > **;**

The CLASS statement names the classification variables to be used as explanatory variables in the analysis. You can list the response variable for binary models in the CLASS statement, but this is not required. Table 13.3 summarizes the values that you can use for either an *option* or a *global-option*. The options are fully documented in the section "CLASS Statement" on page 9 in Chapter 2, "Shared Concepts."

Table 13.3 CLASS Statement Options

Option	Description
DESCENDING	Reverses the sort order
MISSING	Treats missing values as valid levels
ORDER=	Specifies the sort order for the levels
PARAM=	Specifies the parameterization of the variable
REF=	Specifies the reference level of the variable

DISPLAY Statement

DISPLAY < *table-list* > < / *options* > **;**

The DISPLAY statement enables you to specify a list of display tables to display or exclude. This statement is similar to the ODS SELECT, ODS EXCLUDE, and ODS TRACE statements. However, the DISPLAY statement can improve performance when a large number of tables could be generated (such as in BY-group processing). The procedure processes the DISPLAY statement on a CAS server and thus sends only a subset of ODS tables to the SAS client. Because ODS statements are processed on a SAS client, first all the generated display tables are sent to the client, and then the client creates a subset.

If you use both DISPLAY and ODS statements together, the DISPLAY statement takes precedence over the ODS statements. Note that the ODS EXCLUDE statement processes tables that are sent to the client after they have been filtered by the DISPLAY statement. In some cases, it might appear that the ODS EXCLUDE statement is taking precedence because it can further filter the tables. For more information about ODS, see *SAS Output Delivery System: Procedures Guide*.

You can specify the *table-list* as a list of table names, paths, partial pathnames, and regular expressions.

The table names that you can specify are listed in the section "ODS Table Names" on page 680. A path is a table name that is prefixed with dot-separated grouping information. For example, a SelectionSummary table that a procedure produces during a selection routine might have the path *Bygroup1.Summary.SelectionSummary*. A partial pathname does not include all groups; for example, *SelectionSummary* and *Summary.SelectionSummary* are partial pathnames for *Bygroup1.Summary.SelectionSummary*.

When you specify a table name or partial pathname, all display tables whose paths end in the specified name are selected for display or exclusion. For example, both *SelectionSummary* and *Summary.SelectionSummary* select *Bygroup1.Summary.SelectionSummary*.

A regular expression is enclosed in forward slashes (/). For example, specifying "/tions/" selects all pathnames that contain the substring "tions"; in particular, the *Bygroup1.Summary.SelectionSummary* table is selected. Specifying "!/tions/" selects all pathnames that do not contain the substring "tions"; in particular, the *Bygroup1.Summary.SelectionSummary* table is not selected.

You can specify the following *options* after a slash (/):

CASESENSITIVE
performs a case-sensitive comparison of table names in the *table-list* to display table names when tables are subsetted for display. To preserve case, you must enclose table names in the *table-list* in quotation marks.

EXCLUDE
displays all display tables except those that you specify in the *table-list*.

EXCLUDEALL
suppresses display of all tables. This option takes precedence over the other options.

TRACE
displays the display table names, labels, and paths.

DISPLAYOUT Statement

DISPLAYOUT *table-spec-list* < / *options* > **;**

The DISPLAYOUT statement enables you to create output tables from your displayed output. This statement is similar to the ODS OUTPUT statement. For more information about ODS, see *SAS Output Delivery System: Procedures Guide*.

The *table-spec-list* specifies a list of output tables to create. Each entry in the list has either a *key=value* format or a *key* format:

key=value specifies *key* as the ODS table name, path, or partial pathname, and specifies *value* as the output table name.

key specifies *key* as the ODS table name and also as the output table name.

The ODS table names that you can specify are listed in the section "ODS Table Names" on page 680. You cannot specify the ODS table named OutputCasTables in the *table-spec-list*.

Table names and partial pathnames are discussed under the DISPLAY statement. The DISPLAYOUT statement does not support regular expressions.

You can specify the following *options* after a slash (/):

INCLUDEALL
creates output tables for all display tables. The name of the created output table is the same as the name of the corresponding display table. If you specify this option, the *table-spec-list* specification is ignored.

NOREPLACE
does not replace any existing output table of the same name.

REPEATED
replicates all output tables on all nodes.

FREQ Statement

FREQ *variable* **;**

The *variable* in the FREQ statement identifies a numeric variable in the input data table that contains the frequency of occurrence of each observation. PROC GAMSELECT treats each observation as if it appears f times, where f is the value of the FREQ *variable* for the observation. If f is not an integer, it is truncated to an integer. If f is less than 1 or missing, the observation is not used in the analysis. When you omit the FREQ statement, each observation is assigned a frequency of 1.

MODEL Statement

MODEL *response* < **(***response-options***)** > **=** < **PARAM(***effects***)** >
< **SPLINE(***variable* < / *spline-options* >**)** >
< **SPLINE(***variable1 variable2* < / *spline-options* >**)** > < / *model-options* > **;**

MODEL *events* / *trials* **=** < **PARAM(***effects***)** >
< **SPLINE(***variable* < / *spline-options* >**)** >
< **SPLINE(***variable1 variable2* < / *spline-options* >**)** > < / *model-options* > **;**

The MODEL statement specifies the response (dependent or target) variable and the predictor (independent or explanatory) effects of the model. You can specify the response as a single variable or as a ratio of two variables, which are denoted as *events/trials*. The first form applies to all distribution families; the second form applies only to summarized binomial response data. When you have binomial data, the *events* variable contains the number of positive responses (or events), and the *trials* variable contains the number of trials. The values of both *events* and (*trials* – *events*) must be nonnegative, and the value of *trials* must be positive. If you specify a single *response* variable in a CLASS statement, then the response is assumed to be binary. For more information about the *response-options*, see the section "Response Variable Options" on page 658.

You can use the PARAM(*effects*) option to specify parametric effects that are constructed from variables in the input data; this option can appear multiple times. For information about constructing the model effects, see the section "Specification and Parameterization of Model Effects" on page 64 in Chapter 2, "Shared Concepts."

You can use the SPLINE(*variable*) or SPLINE(*variable1 variable2*) option to specify nonparametric spline effects that are constructed from variables in the input data. Only continuous variables (not classification

variables) can be specified in spline effects. For more information about the options that enable you to control the construction of spline effects, see the section "Spline Effect Options" on page 659.

If only spline effects are present, PROC GAMSELECT builds a nonparametric additive model. If both spline and parametric effects are present, PROC GAMSELECT builds a semiparametric model by using the parametric effects as the linear part of the model. If only parametric effects are present, PROC GAMSELECT uses the boosting method to build a parametric generalized linear model by using the terms inside the parentheses of all PARAM(*effects*) options. The shrinkage method requires spline terms.

Three sets of options are available in the MODEL statement. The *response-options* determine how the GAMSELECT procedure models probabilities for binary data. The *spline-options* controls how each spline term forms basis expansions. The *model-options* control other aspects of model formation and inference. Table 13.4 summarizes these options, and the sections after the table describe them in detail.

Table 13.4 MODEL Statement Options

Option	Description
Response Variable Options	
DESCENDING	Reverses the response categories
EVENT=	Specifies the event category
ORDER=	Specifies the sort order
REF=	Specifies the reference category
Spline Effect Options	
DEGREE=	Specifies the degree of the spline effect
DETAILS	Produces detailed spline information
DF=	Specifies the fixed degrees of freedom
DIFFORDER=	Specifies the order of the difference penalty for a B-spline
KNOTS=	Specifies the knots to use for constructing the spline
LOWEREXKNOTS=	Specifies the lower exterior knots
MAXKNOTS=	Specifies the maximum number of knots to use for constructing the spline
SMOOTH=	Specifies a fixed smoothing parameter
UPPEREXKNOTS=	Specifies the upper exterior knots
WEIGHT1=	Specifies the sparsity penalty strength
WEIGHT2=	Specifies the smoothness penalty strength
Model Options	
ALLOBS	Uses values of spline variables from all data roles to construct spline basis functions
DISPERSION=	Specifies the fixed dispersion parameter
DISTRIBUTION=	Specifies the response distribution
INITIALPHI=	Specifies the starting value of the dispersion parameter
LINK=	Specifies the link function
MAXPHI=	Specifies the upper bound for searching the dispersion parameter
MINPHI=	Specifies the lower bound for searching the dispersion parameter
OFFSET=	Specifies the offset variable

Response Variable Options

Response variable options determine how the GAMSELECT procedure models probabilities for binary data.

You can specify the following *response-options* by enclosing them in parentheses after the *response* variable:

DESCENDING
DESC
reverses the order of the response categories. If you specify both the DESCENDING and ORDER= options, PROC GAMSELECT orders the response categories according to the ORDER= option and then reverses that order.

EVENT='*category***' | FIRST | LAST**
specifies the event category for the binary response model. PROC GAMSELECT models the probability of the event category. This option has no effect when there are more than two response categories.

You can specify any of the following values:

'*category*' specifies that observations whose value matches *category* (formatted, if a format is applied) in quotation marks represent events in the data. For example, the following statements specify that observations that have a formatted value of '1' represent events in the data. The probability that is modeled by the GAMSELECT procedure is thus the probability that the variable def takes the (formatted) value '1'.

```
proc gamselect data=mylib.MyData;
   class A B C;
   model def(event ='1') = param(A B) spline(x1) spline(x2);
   selection;
run;
```

FIRST designates the first ordered category as the event.

LAST designates the last ordered category as the event.

By default, EVENT=FIRST.

ORDER=FORMATTED | FREQ | INTERNAL
specifies the sort order for the levels of the *response* variable. You can specify the following values:

FORMATTED sorts the levels by external formatted value, except for numeric variables that have no explicit format, which are sorted by their unformatted (internal) value. For numeric variables for which you have supplied no explicit format (that is, for which there is no corresponding FORMAT statement in the current PROC GAMSELECT run or in the DATA step that created the data table), the levels are ordered by their internal (numeric) value. The sort order is machine-dependent.

FREQ sorts the levels by descending frequency count (levels that have the most observations come first in the order).

INTERNAL sorts the levels by unformatted value. The sort order is machine-dependent.

By default, ORDER=FORMATTED.

For more information about sort order, see the chapter about the SORT procedure in *Base SAS Procedures Guide* and the discussion of BY-group processing in *SAS Language Reference: Concepts*.

REF='*category***' | FIRST | LAST**
specifies the reference category for the binary response model. Specifying one response category as the reference is the same as specifying the other response category as the event category. You can specify any of the following values:

'*category*'	specifies that observations whose value matches *category* (formatted, if a format is applied) are designated as the reference.
FIRST	designates the first ordered category as the reference.
LAST	designates the last ordered category as the reference.

By default, REF=LAST.

Spline Effect Options

Spline effects are specified by the SPLINE(*variable* / < *spline-options* >) or the SPLINE(*variable1 variable2* / < *spline-options* >) option. Each SPLINE term defines one spline effect. The boosting selection method can take both types of specifications. The shrinkage selection method can only take SPLINE(*variable* / < *spline-options* >). You can specify any number of SPLINE(*variables*) options.

Spline effect options control how each spline term forms basis expansions. For more information about the construction and estimation of spline terms, see the sections "Penalized B-Splines" on page 671 and "Natural Cubic Splines" on page 673.

You can specify the following *spline-options*:

DEGREE=*number*
specifies the degree of the spline transformation, where *number* must be a nonnegative integer. This option is not applicable when the shrinkage method is requested. By default, DEGREE=3.

DETAILS
produces a detailed spline specification information table.

DF=*number*
specifies the fixed degrees of freedom for the spline at each boosting iteration. This option is applicable only when the boosting selection method is requested. The SMOOTH= option is ignored when you specify the degrees of freedom. By default, DF=4 for univariate spline terms and DF=6 for bivariate spline terms.

DIFFORDER=*number*
specifies the order of the difference penalty for a B-spline. This option is applicable only when the boosting selection method is requested. By default, DIFFORDER=2.

KNOTS=*method*
specifies the *method* to use for supplying user-defined knot values for constructing basis expansions. You can specify the following *methods*:

EQUAL(*n*)
specifies the number of equally spaced interior knots to use for every variable in a spline term. Boundary knots are automatically added to the knot list for each variable.

LIST(*list-of-values*)
specifies a list of values as knots for the spline construction. For a multivariate spline term, the listed values are taken as multiple row vectors, where each vector has values that are ordered by specified variables. If the last row vector of knots contains fewer values than the number of variables, then the last row vector is ignored. For example, the following specification of a spline term produces two actual knot vectors ($\boldsymbol{k}_1$ and $\boldsymbol{k}_2$), displayed in Table 13.5, and the value 5 is ignored.

```
spline(x1 x2/knots=list(1 2 3 4 5))
```

Table 13.5 Knot Values for a Bivariate Spline with a Supplied List

	x1	x2
$\boldsymbol{k}_1$	1	2
$\boldsymbol{k}_2$	3	4

By default, the boosting method constructs basis expansions by using 20 evenly spaced interior knots for univariate spline terms, 10 evenly spaced interior knots for each variable in bivariate spline term, and evenly spaced boundary knots. By default, the shrinkage method constructs natural cubic spline basis expansions by using interior knots at unique data points and duplicated exterior knots. You can use the MAXKNOTS= option to specify the maximum number of knots if unique data points are used as interior knots.

LOWEREXKNOTS=*number*
specifies the lower exterior knots.

MAXKNOTS=*number*
specifies the maximum *number* of knots if data points are used to form knots. The boosting method does not support knot construction from unique data points. For the shrinkage method, if KNOTS=LIST(*list-of-values*) is not specified, PROC GAMSELECT forms knots from unique data points. If the number of unique data points is greater than *number*, a subset of size *number* is formed by random sampling from all unique data points. The *number* cannot exceed the largest integer that can be stored on the CAS server. By default, MAXKNOTS=20 if the shrinkage selection method is requested.

SMOOTH=*number*
specifies a fixed smoothing parameter. This option is applicable only when the boosting selection method is requested. This option is ignored when you specify the DF= option.

UPPEREXKNOTS=*number*
specifies the upper exterior knots.

WEIGHT1=*number*
specifies a sparsity penalty strength parameter. When you specify this option, a spline term might receive more or less sparsity penalty than other terms. This option is applicable only when the shrinkage selection method is requested. By default, WEIGHT1=1.

WEIGHT2=*number*
specifies a smoothness penalty strength parameter. When you specify this option, a spline term might receive more or less smoothness penalty than other terms. This option is applicable only when the shrinkage selection method is requested. By default, WEIGHT2=1.

Model Options

You can specify the following *model-options* in the MODEL statement after a slash (/):

ALLOBS
uses values of spline variables from all data roles for constructing the spline basis functions. By default, only observations that have the training data role are used to construct the spline basis functions.

DISPERSION=*number*

PHI=*number*
specifies a fixed dispersion parameter for distributions that have a dispersion parameter. The dispersion parameter that is used in all computations is fixed at *number*; it is not estimated.

DISTRIBUTION=*keyword*
specifies the response distribution for the model. The *keywords* and their associated distributions are shown in Table 13.6.

Table 13.6 Built-In Distribution Functions

DISTRIBUTION=	Distribution Function
BINARY | BERNOULLI	Binary
BINOMIAL	Binary or binomial
GAMMA	Gamma
INVGAUSS | IG | IGAUSSIAN	Inverse Gaussian
NORMAL | GAUSSIAN | GAUSS	Normal
POISSON | POI	Poisson

If you do not specify a link function in the LINK= option, a default link function is used. The default link function for each distribution is shown in Table 13.7. You can use any link function shown in Table 13.8 by specifying the LINK= option. Other commonly used link functions for each distribution are shown in Table 13.7.

Table 13.7 Default and Commonly Used Link Functions

DISTRIBUTION=	Default Link Function	Other Commonly Used Link Functions
BINARY | BERNOULLI	Logit	Probit, complementary log-log, log-log
BINOMIAL	Logit	Probit, complementary log-log, log-log
GAMMA	Log	Reciprocal
INVGAUSS | IG | IGAUSSIAN	Log	Reciprocal square
NORMAL | GAUSSIAN | GAUSS	Identity	Log
POISSON | POI	Log	

INITIALPHI=*number*

specifies a starting value for iterative maximum likelihood estimation of the dispersion parameter for distributions that have a dispersion parameter.

LINK=*keyword*

specifies the link function for the model. The *keywords* and the associated link functions are shown in Table 13.8. Default and commonly used link functions for the available distributions are shown in Table 13.7.

Table 13.8 Built-In Link Functions

LINK=	Link Function	$g(\mu) = \eta =$
CLOGLOG | CLL	Complementary log-log	$\log(-\log(1-\mu))$
IDENTITY | ID	Identity	μ
INVERSE | RECIP | RECIPROCAL	Reciprocal	$1/\mu$
INV2 | POWERMINUS2 | POWMINUS2	Reciprocal square	$1/\mu^2$
LOG	Logarithm	$\log(\mu)$
LOGIT	Logit	$\log(\mu/(1-\mu))$
LOGLOG	Log-log	$-\log(-\log(\mu))$
PROBIT | NORMIT	Probit	$\Phi^{-1}(\mu)$

$\Phi^{-1}(\cdot)$ denotes the quantile function of the standard normal distribution.

MAXPHI=*number*

specifies an upper bound for maximum likelihood estimation of the dispersion parameter for distributions that have a dispersion parameter.

MINPHI=*number*

specifies a lower bound for maximum likelihood estimation of the dispersion parameter for distributions that have a dispersion parameter.

OFFSET=*variable*
specifies a *variable* to use as an offset to the linear predictor. An offset plays the role of an effect whose coefficient is known to be 1. The offset variable cannot appear in the CLASS statement or elsewhere in the MODEL statement. Observations that have missing values for the offset variable are excluded from the analysis. For the boosting method, the offset variable is used to set the initial model estimate.

OUTPUT Statement

OUTPUT OUT=*libref.data-table*
< **COMPONENT** > < **COMPVARS=(***variables***)** > < **COPYVARS=(***variables***)** >
< *keyword* < **=***name* > >. . . < *keyword* < **=***name* > > **;**

The OUTPUT statement creates a data table that contains observationwise statistics that PROC GAMSELECT computes after fitting the model. In order to avoid data duplication for large data tables, the variables in the input data table are *not* included in the output data table unless you specify them in the COPYVARS= option.

The computation of the output statistics is based on the final parameter estimates. If the model fit does not converge, missing values are produced for the quantities that depend on the estimates.

You must specify the following option:

OUT=*libref.data-table*
names the output data table for PROC GAMSELECT to use. You must specify this option before any other options. *libref.data-table* is a two-level name, where

libref refers to a collection of information that is defined in the LIBNAME statement and includes the library, which includes a path to where the data table is to be stored, and a session identifier, which defaults to the active session but which can be explicitly defined in the LIBNAME statement. For more information about *libref*, see the section "Using CAS Sessions and CAS Engine Librefs" on page 645.

data-table specifies the name of the output data table.

You can also specify the following syntax elements:

COMPONENT
produces componentwise statistics for all spline terms if LINP is specified as a *keyword*.

COMPVAR | COMPUTEDVAR=*variable*

COMPVARS | COMPUTEDVARS=(*variables***)**
transfers one or more *variables* that are computed from programming statements to the output data table.

COPYVAR=*variable*

COPYVARS=(*variables***)**
transfers one or more *variables* from the input data table to the output data table.

keyword **<** **=***name* **>**
specifies a statistic to include in the output data table and optionally assigns a *name* to the variable. If you do not provide a *name*, PROC GAMSELECT assigns a default name based on the *keyword*.

You can specify the following *keywords* for adding statistics to the OUTPUT data table:

XBETA< **=***name* **>**

LINP< **=***name* **>**
requests the linear predictor $\eta = \mathbf{x}'\boldsymbol{\beta}$. For observations in which only the response variable is missing, values of the linear predictor are computed even though these observations do not affect the model fit. The default *name* is Xbeta.

PEARSON< **=***name* **>**

PEARS< **=***name* **>**

RESCHI< **=***name* **>**
computes the Pearson residual, $(y-\mu)/\sqrt{\mathrm{V}(\mu)}$, where μ is the estimate of the predicted response mean and $\mathrm{V}(\mu)$ is the response distribution variance function. The default *name* is Pearson.

PRED< **=***name* **>**

PREDICTED< **=***name* **>**

P< **=***name* **>**
computes predicted values for the response variable. For observations in which only the response variable is missing, the predicted values are computed even though these observations do not affect the model fit. The default *name* is Pred.

RESIDUAL< **=***name* **>**

RESID< **=***name* **>**

R< **=***name* **>**
computes the raw residual, $y - \mu$, where μ is the estimate of the predicted mean. The default *name* is Residual.

ROLE< **=***name* **>**
specifies the numeric variable that indicates the role played by each observation in fitting the model. The default *name* is _ROLE_. Table 13.9 shows how this variable is interpreted for each observation.

Table 13.9 Role Interpretation

Value	Observation Role
0	Not used
1	Training
2	Validation
3	Testing

If you do not partition the input data by specifying a PARTITION statement, then the role variable value is 1 for observations that are used in fitting the model and 0 for observations that have at least one missing or invalid value for the response, regressor, frequency, or weight variables.

PARTITION Statement

PARTITION *partition-option* **;**

The PARTITION statement specifies how observations in the input data set are logically partitioned into disjoint subsets for model training, validation, and testing. For more information, see the section "Using Validation and Test Data" on page 101 in Chapter 2, "Shared Concepts." Either you can designate a variable in the input data table and a set of formatted values of that variable to determine the role of each observation, or you can specify proportions to use for randomly assigning observations to each role.

You must specify exactly one of the following *partition-options*:

FRACTION(<TEST=*fraction***> <VALIDATE=***fraction***> <SEED=***number***>)**
randomly assigns specified proportions of the observations in the input data table to the roles. You specify the proportions for testing and validation by using the TEST= and VALIDATE= suboptions. If you specify both the TEST= and VALIDATE= suboptions, then the sum of the specified fractions must be less than 1 and the remaining fraction is the proportion of the observations assigned to the training role. The SEED= option specifies an integer that is used to start the pseudorandom number generator for random partitioning of data for training, testing, and validation. If you do not specify SEED=*number* or if *number* is less than or equal to 0, the seed is generated by reading the time of day from the computer's clock.

ROLE=*variable* **(<TEST='***value***'> <TRAIN='***value***'> <VALIDATE='***value***'>)**
ROLEVAR=*variable* **(<TEST='***value***'> <TRAIN='***value***'> <VALIDATE='***value***'>)**
names the *variable* in the input data table whose values are used to assign roles to each observation. This *variable* cannot also appear as an analysis variable in other statements or options. The TEST=, TRAIN=, and VALIDATE= suboptions specify the formatted values of this variable that are used to assign observation roles. If you do not specify the TRAIN= suboption, then all observations whose role is not determined by the TEST= or VALIDATE= suboption are assigned to the training role.

SELECTION Statement

SELECTION <**METHOD=***method* <**(***method-options***)**>> **;**

The SELECTION statement performs model selection by examining whether spline effects should be kept in the model.

You can specify the following *methods* in the SELECTION statement:

METHOD=*method* **<(***method-options***)>**
specifies the method to use to select the model. You can also specify *method-options* that apply to the specified method by enclosing them in parentheses after the *method*.

The following *methods* are available and are explained in detail in the section "Model Selection Methods" on page 674. By default, METHOD=BOOSTING.

BOOSTING specifies the boosting method.

SHRINKAGE specifies the shrinkage method.

Because of the intrinsic difference between the boosting method and the shrinkage method, the two selection methods have two different sets of options that enable you to control the selection process. You can specify the following *method-options* for the boosting method.

CHOOSE=CV | VALIDATE
specifies the criterion to use to select the final model. If you specify the STOPHORIZON= option, the criterion that you specify in the CHOOSE= option is also used to evaluate early termination of the selection process. If you omit the CHOOSE= option, the average square error for the training data is used to select the final model.

You can specify the following values:

CV | CROSSVALIDATION specifies k-fold cross validation of the average square error. You can use the INDEX= or KFOLD= option to specify the partition folds.

VALIDATE specifies the average square error for the validation data.

INDEX=*variable*
names the *variable* in the input data table whose values are used to assign observations to partition folds for cross validation. This option is applicable only if you specify the CHOOSE=CV option. The number of folds equals the number of unique levels of the *variable*.

KFOLD=*number*
specifies the *number* of partition folds in the random cross validation process. This option is applicable only if you specify the CHOOSE=CV option. The *number* must be greater than 2. By default, KFOLD=5.

LINPINMEM=*number*
specifies the maximum *number* of observations for which the linear predictor values are stored in memory when you are training the model. The *number* must be positive. By default, LINPINMEM=500000.

MAXITER=*number*
specifies the maximum number of iterations for the boosting method. By default, MAXITER=500.

STEPSIZE=*number*
LEARNINGRATE=*number*
specifies the step size to use for the boosting algorithm, where *number* must be between 0 and 1. By default, STEPSIZE=0.1.

STOPHORIZON=*number*
specifies the number of consecutive iterations in which the performance measured by the criterion that you specify in the CHOOSE= option must deteriorate in order to terminate the selection process. If you specify the STOPTOL= option, a relative change in the criterion is evaluated. By default, an absolute difference in this criterion is evaluated. If you omit the CHOOSE= option, the average square error for the training data is used.

STOPTOL=*number*

STOPTOLERANCE=*number*

specifies the *number* to use as the tolerance for evaluating the relative change in the CHOOSE= option. This option is applicable only when you specify the STOPHORIZON= option. The *number* must be nonnegative.

You can specify the following *method-options* for the shrinkage method.

ADMMABSEPS=*number*

specifies the absolute convergence criterion for the alternating direction method of multipliers (ADMM) algorithm that is used to compute the solution. By default, ADMMABSEPS=1E–6.

ADMMMAXITER=*number*

specifies the maximum number of iterations that the ADMM algorithm can take at each step of solving a reweighted additive model. By default, ADMMMAXITER=10000.

ADMMRELEPS=*number*

specifies the relative convergence criterion for the ADMM algorithm that is used to compute the solution. By default, ADMMRELEPS=1E–4.

ADMMRHO=*number*

specifies the tuning parameter to use in the ADMM algorithm to control the balance between the primal residual and the dual residual. By default, *number* is computed from the input data.

ADMMRHOADAPTIVE < =NO | YES >

specifies whether to use an adaptive mechanism to update the ADMM tuning parameter in the first several steps. By default, ADMMRHOADAPTIVE=YES.

DISTRIBUTEDSEARCH < =NO | YES >

specifies whether to use distributed mode to evaluate different regularization parameter candidates in a grid environment. This mode distributes training data to workers so that each worker has a full copy of the training data and performs model fitting independently. Using this option can eliminate the cost of communication over the grid and thus improve performance. However, distributed mode requires more memory space for each worker. This option is not applicable when you are in single-machine mode. By default, DISTRIBUTEDSEARCH=YES.

LAMBDA1=*number*

L1=*number*

sets a fixed nonnegative value to control the sparsity penalty.

LAMBDA2=*number*

L2=*number*

sets a fixed nonnegative value to control the smoothness penalty.

LAMBDA3=*number*

L3=*number*

sets a fixed nonnegative value to control the generalized ridge penalty.

MAXITER=*number*

specifies the maximum number of iterations that generalized additive model fitting can take by solving reweighted additive models at each iteration. By default, MAXITER=500.

MAXLAMBDA1=*number*

MAXL1=*number*

sets the maximum value to start with to search the optimal sparsity penalty parameter. By default, *number* is computed from the input data.

MAXLAMBDA2=*number*

MAXL2=*number*

sets the maximum value to start with to search the optimal smoothness penalty parameter. By default, *number* is computed from the input data.

MAXLAMBDA3=*number*

MAXL3=*number*

sets the maximum value to start with to search the optimal generalized ridge penalty parameter. By default, MAXLAMBDA3=0.

NUMLAMBDA1=*number*

NUML1=*number*

sets the total number of candidates to try in searching the optimal sparsity penalty parameter. By default, NUMLAMBDA1=20.

NUMLAMBDA2=*number*

NUML2=*number*

sets the total number of candidates to try in searching the optimal smoothness penalty parameter. By default, NUMLAMBDA2=10.

NUMLAMBDA3=*number*

NUML3=*number*

sets the total number of candidates to try in searching the optimal generalized ridge parameter. If you specify the MAXLAMBDA3= option but not the LAMBDA3= option, then by default NUMLAMBDA3=10.

RHOLAMBDA1=*number*

RHOL1=*number*

sets the scaling factor for the sparsity penalty parameter when computing a new candidate from its previous candidate attempt. For example, if the maximum sparsity penalty parameter is λ_1^*, then PROC GAMSELECT first computes the solution at λ_1^*, and in the following steps it computes solutions at $\lambda_1^*\rho_1$, $\lambda_1^*\rho_1^2$, and so on. By default, RHOLAMBDA1=0.8.

RHOLAMBDA2=*number*

RHOL2=*number*

sets the scaling factor for the smoothness penalty parameter when computing a new candidate from its previous candidate attempt. For example, if the maximum smoothness penalty parameter is λ_2^*, then PROC GAMSELECT first computes the solution at λ_2^*, and in the following steps it computes solutions at $\lambda_2^*\rho_2$, $\lambda_2^*\rho_2^2$, and so on. By default, RHOLAMBDA2=0.5.

RHOLAMBDA3=*number*

RHOL3=*number*

sets the scaling factor for the generalized ridge penalty parameter when computing a new candidate from its previous candidate attempt. For example, if the maximum generalized ridge penalty parameter is λ_3^*, then PROC GAMSELECT first computes the solution at λ_3^*, and in the following steps it computes solutions at $\lambda_3^*\rho_3$, $\lambda_3^*\rho_3^2$, and so on. If you specify the MAXLAMBDA3= option but not the LAMBDA3= option, then by default RHOLAMBDA3=0.5.

STORE Statement

STORE < **OUT=** >*libref.data-table* **;**

The STORE statement saves the context and results of the statistical analysis. The resulting analytic store has a binary file format that cannot be modified. An example of analytic store technology is to perform a time-consuming analysis and to store its results by using the STORE statement. Later you can perform specific statistical analysis tasks based on the saved results of the previous analysis, without having to fit the model again. The contents of the analytic store can be processed by the ASTORE procedure, the **`gamScore`** action in the **`gam`** action set, and the **`score`** action in the **`aStore`** action set.

libref.data-table is a two-level name, where *libref* refers to the library, and *data-table* specifies the name of the output data table. For more information about this two-level name, see the section "Using CAS Sessions and CAS Engine Librefs" on page 645.

WEIGHT Statement

WEIGHT *variable* **;**

The *variable* in the WEIGHT statement is used as a weight to perform a weighted analysis of the data. Observations that have nonpositive or missing weights are not included in the analysis. The values of the WEIGHT variable can be nonintegral and are not truncated. When you omit the WEIGHT statement, all observations that are used in the analysis are assigned a weight of 1.

Programming Statements

A number of programming statements are available in the GAMSELECT procedure that enable you to create computed variables on the fly. For example, you can compute model effects, weights, frequency, and other variables. This section lists these programming statements and also documents the differences between them and programming statements available in the SAS DATA step. The syntax of programming statements that is used in PROC GAMSELECT is identical to that used in the NLMIXED procedure (see Chapter 89, "The NLMIXED Procedure" (*SAS/STAT User's Guide*) and the MODEL procedure (see the *SAS/ETS User's Guide*). Most of the programming statements available in the DATA step are also available in PROC GAMSELECT. See *SAS DATA Step Statements: Reference* for a description of SAS programming statements.

You can specify the following programming statements:

ARRAY *arrayname* < **[** *dimensions* **]** > < **$** > < *variables-and-constants* >**;**
CALL *name* < **(***expression* < **,** *expression . . .* > **)** >**;**
DO < *variable* **=** *expression* < **TO** *expression* > < **BY** *expression* > >
< **,** *expression* < **TO** *expression* > < **BY** *expression* > > . . .
< **WHILE** *expression* > < **UNTIL** *expression* >**;**
END;
GOTO *statement-label***;**
IF *expression***;**
IF *expression* **THEN** *program-statement***;**
ELSE *program-statement***;**
variable **=** *expression***;**
variable **+** *expression***;**
LINK *statement-label***;**
RETURN;
SELECT < **(***expression***)** >**;**
STOP;
SUBSTR(*variable***,** *index***,** *length***) =** *expression***;**
WHEN (*expression***)** *program-statement***;**
OTHERWISE *program-statement***;**

For the most part, the SAS programming statements available in PROC GAMSELECT work the same as they do in the SAS DATA step, as documented in *SAS Programmers Guide: Essentials*. However, there are several differences:

- The DO statement does not allow a character index variable. Thus

```
do i = 1,2,3;
```

  is supported. However, the following statement is not supported:

```
do i = 'A','B','C';
```

- The LAG function is not supported.
- The WHEN and OTHERWISE statements enable you to specify more than one target statement. That is, DO/END groups are not necessary for multiple WHEN statements. For example, the following syntax is valid:

```
select;
   when (exp1) stmt1;
               stmt2;
   when (exp2) stmt3;
               stmt4;
end;
```

The LINK statement is used in a program to jump immediately to the label *statement_label* and to continue program execution at that point.

When coding your programming statements, you should avoid defining variables that begin with an underscore (_), because they might conflict with internal variables that PROC GAMSELECT creates. You should avoid operations that would directly modify the variables that appear in the input table, because such operations are not supported for the input data.

You cannot use the programming statements to create a computed variable and then add it to the CLASS statement so that it is used as a classification variable. If you have already specified a variable in the CLASS statement, you should also avoid using it in the programming statements to compute variables with the expectation that the computation would use its levelization results.

Details: GAMSELECT Procedure

Missing Values

Any observation that has missing values for the response, frequency, weight, offset, or explanatory variables is excluded from the analysis; however, missing values are valid for response and explanatory variables if you specify the MISSING option in the CLASS statement. Observations that have a nonpositive weight or a frequency less than 1 are also excluded. For Poisson distribution, observations that have a negative response value are excluded. For gamma and inverse Gaussian distributions, observations that have a nonpositive response value are excluded.

The estimated linear predictor and the fitted means are not computed for any observation that has missing offset or explanatory variables. However, if only the response value is missing, the linear predictor and the fitted means can be computed and output to a data table by using the OUTPUT statement.

Penalized B-Splines

You can use penalized B-splines (Eilers and Marx 1996) to fit a smooth curve, $f_j(\mathbf{x}_j)$, through a scatter plot of points (u_i, x_{ij}), $i = 1, \ldots, n$. The penalized B-spline fit applies a difference penalty to coefficients for adjacent elements of a B-spline basis expansion $\mathbf{B}_j$ of $\mathbf{x}_j$. For more information about B-spline basis expansions, see the section "B-Spline Basis" on page 30 in Chapter 2, "Shared Concepts" and also see De Boor (1978).

Let $\boldsymbol{\beta}$ denote the coefficients for the basis expansion $\mathbf{B}$. The first-order difference for the ℓth element of $\boldsymbol{\beta}$ is $\Delta\beta_\ell = \beta_\ell - \beta_{\ell-1}$. Higher-order differences are defined recursively by $\Delta^o\beta_\ell = \Delta\left(\Delta^{o-1}\beta_\ell\right)$. For a B-spline expansion with degree d and k interior knots, the penalized B-spline fit is obtained by solving

$$\min_{\boldsymbol{\beta}} \frac{1}{2}\sum_{i=1}^{n} w_i(u_i - \mathbf{B}_{ij}\boldsymbol{\beta})^2 + \frac{\lambda}{2}\sum_{\ell=o+1}^{d+k+1}\left(\Delta^o\beta_\ell\right)^2$$

where λ is a nonnegative smoothing parameter and w_i are observation weights.

As described in Eilers and Marx (1996), a second-order difference penalty is related to a penalty on the second derivative of the estimated function. Compared to penalties on the derivatives of a function, the difference

penalty leads to a simpler minimization problem by omitting terms that involve overlapping elements of the B-spline basis functions.

The difference penalty can be written in terms of a $(d + 1 + k - o) \times (d + 1 + k)$ matrix $\mathbf{D}$. The nonzero elements of $\mathbf{D}$, order 1, are (1 –1); $\mathbf{D}$, order 2 are (1 –2 1); $\mathbf{D}$, order 3 (the default) are (1 –3 3 –1); $\mathbf{D}$, order 4 are (1 –4 6 –4 1); and so on. The nonzero elements for each order are made from the nonzero elements from the preceding order by subtraction: $\mathbf{d}'_{i+1} = (\mathbf{d}'_i \;\; 0) - (0 \;\; \mathbf{d}'_i)$. For example, the nonzero elements for the order 3 penalty are obtained as follows:

$$
\begin{array}{rcccc}
 & 1 & -1 & 0 & \\
- & 0 & 1 & -1 & \\
\hline
 & 1 & -2 & 1 & 0 \\
- & 0 & 1 & -2 & 1 \\
\hline
 & 1 & -3 & 3 & -1
\end{array}
$$

Within an order, the first nonzero element of row i is in column i—that is, each row of $\mathbf{D}$ is made from the preceding row by shifting the nonzero elements to the right by one position. For example, when $k = 4$ knots, order $o = 3$, and degree $d = 3$, $\mathbf{D}$ is the following matrix:

$$
\begin{bmatrix}
1 & -3 & 3 & -1 & 0 & 0 & 0 & 0 \\
0 & 1 & -3 & 3 & -1 & 0 & 0 & 0 \\
0 & 0 & 1 & -3 & 3 & -1 & 0 & 0 \\
0 & 0 & 0 & 1 & -3 & 3 & -1 & 0 \\
0 & 0 & 0 & 0 & 1 & -3 & 3 & -1
\end{bmatrix}
$$

The penalized B-spline transformation $\hat{\mathbf{u}}$ of $\mathbf{u}$ is a linear smoother $\hat{\mathbf{u}} = \mathbf{H_j u}$, where the hat matrix $\mathbf{H_j}$ is defined as

$$\mathbf{H_j} = \mathbf{B}_j \left(\mathbf{B}_j^T \mathbf{W} \mathbf{B}_j + \lambda \mathbf{D}^T \mathbf{D} \right)^{-1} \mathbf{B}_j^T \mathbf{W}$$

where $\mathbf{W}$ is a diagonal matrix of the observation weights w_i. The degrees of freedom for the penalized B-spline equals the trace of $\mathbf{H_j}$.

You can extend penalized B-splines to bivariate spline terms by using the approach described in Marx and Eilers (2005). A two-dimensional surface is created by taking the outer product of the B-spline basis expansions for each variable. The boosting method uses the same degree d and number of interior knots k for each B-spline basis expansion. A vectorized representation of the outer product leads to a spline expansion $\mathbf{B}_{ij}$ of dimension $1 \times (d + k + 1)^2$ for $\mathbf{x}_{ij}$.

For the bivariate spline term, the penalty matrix $\mathbf{P}$ is of the form

$$\mathbf{P} = \mathbf{I} \otimes \mathbf{D}^T \mathbf{D} + \mathbf{D}^T \mathbf{D} \otimes \mathbf{I}$$

where $\otimes$ denotes the Kronecker product, $\mathbf{I}$ denotes the identity matrix, and $\mathbf{D}$ is the $(d+1+k-o) \times (d+1+k)$ difference matrix for order o. The matrices $\mathbf{I} \otimes \mathbf{D}^T \mathbf{D}$ and $\mathbf{D}^T \mathbf{D} \otimes \mathbf{I}$ apply the difference penalty to the coefficients $\boldsymbol{\beta}$ that correspond to the rows and columns of the two-dimensional representation of the spline basis surface. The boosting method assumes that the same difference order o is used in both components of the penalty matrix $\mathbf{P}$.

The penalized B-spline fit for a bivariate spline with nonnegative smoothing parameter λ is also a linear smoother with hat matrix $\mathbf{H_j}$ defined as

$$\mathbf{H_j} = \mathbf{B}_j \left(\mathbf{B}_j^T \mathbf{W} \mathbf{B}_j + \lambda \mathbf{P} \right)^{-1} \mathbf{B}_j^T \mathbf{W}$$

Natural Cubic Splines

A natural cubic spline is the function $f(\cdot)$ that minimizes the penalized residual sum of squares

$$\mathbf{RSS}(f,\lambda) = \sum_{i=1}^{n}(y_i - f(x_i))^2 + \lambda \int (f''(t))^2 \mathrm{d}t$$

where λ is the smoothing parameter that controls the trade-off between a model's goodness of fit and its complexity. The unknown smooth function $f(x)$ is constructed by using cubic polynomials that are smoothly connected at all unique data points. Additional constraints at the boundaries enforce linear functions beyond the boundary knots. Natural cubic splines can be represented by both the truncated power function basis and the B-spline basis. For more information, see the section "Natural Cubic Spline Basis" on page 32 in Chapter 2, "Shared Concepts."

For the shrinkage selection method, the GAMSELECT procedure uses a similar spline representation to approximate the unknown smooth function *f*, but with fewer interior knots, so that its computation is more efficient for models that have multiple spline terms. The results are still close to natural cubic splines. This technique is introduced in O'Sullivan (1986). Because of this resemblance, the technique is referred to as natural cubic splines hereafter in this chapter.

On the basis of the B-spline representation, Wand and Ormerod (2008) derive the explicit formula for the penalty matrix

$$\mathbf{\Omega} = \mathbf{B}_L^T \mathbf{W} \mathbf{B}_L$$

where $\mathbf{B}_L$ is the linear B-spline basis based on the same set of knots and evaluated at an augmented set of points constructed from the used knots, and $\mathbf{W}$ is a diagonal matrix with diagonal values that is constructed from the same augmented set of points. For more information, see Wand and Ormerod (2008).

Generalized Additive Models

All probability distributions that the GAMSELECT procedure fits are members of the exponential family of distributions. For the specification of an exponential family, see the section "Exponential Family Distributions" on page 747 in Chapter 14, "GENSELECT Procedure." The GAMSELECT procedure supports the binary, binomial, gamma, inverse Gaussian, normal (Gaussian), and Poisson distributions.

For forms of log-likelihood functions for each of the probability distributions, see the section "Log-Likelihood Functions" on page 754 in Chapter 14, "GENSELECT Procedure."

Generalized additive models (GAMs) are extensions of generalized linear models (Nelder and Wedderburn 1972). For each observation that has a response Y_i and a row vector of the model matrix $\mathbf{x}_i$, both GAMs and generalized linear models assume the model additivity,

$$g(\mu_i) = f_1(\mathbf{x}_{i1}) + \cdots + f_p(\mathbf{x}_{ip})$$

where $\mu_i = E(Y_i)$ and Y_i is independently distributed in some exponential family. Generalized linear models further assume model linearity by $f_j(\mathbf{x}_{ij}) = \mathbf{x}_{ij}\beta_j$ for $j = 1, \ldots, p$. GAMs relax the linearity assumption by allowing spline functions.

For the boosting method, PROC GAMSELECT fits the model by performing a series of boosting iterations. At each iteration, a separate fit is obtained for each effect and one effect is selected for an update. The final model is composed of the effects that are selected across the boosting iterations.

For the shrinkage method, PROC GAMSELECT fits models by estimating all parameters simultaneously. Based on the spline basis construction mechanism, the model is unidentifiable in general because each spline term contains an intercept. To address this, PROC GAMSELECT transforms each spline design matrix into $\tilde{\mathbf{B}}_j$ to satisfy $\mathbf{1}'\mathbf{B}_j\boldsymbol{\beta}_j = 0$. The penalty matrix that corresponds to each spline term is also transformed. For simplicity, hereafter in the chapter the transformed spline design matrix is referred to as $\mathbf{B}_j$, and the transformed penalty matrix is referred to as $\boldsymbol{\Omega}_j$. For more information, see the section "Generalized Additive Models" on page 610 in Chapter 12, "GAMMOD Procedure."

Model Selection Methods

The model selection methods are specified using the METHOD= option in the SELECTION statement. The following methods are available. By default, the boosting method is used.

Boosting

The boosting selection method uses a componentwise implementation of a generic functional gradient descent, or boosting, algorithm (Friedman, Hastie, and Tibshirani 2000; Friedman 2001; Bühlmann and Hothorn 2007). Component functions f_j are defined for each parametric effect and spline term in the MODEL statement. Spline terms can have at most two variables for the boosting selection method.

Table 13.10 defines some notation that is used here to describe the componentwise boosting algorithm that PROC GAMSELECT implements.

Table 13.10 Boosting Notation

Notation	Meaning
ℓ	Log likelihood
$\hat{f}^m$	Estimate for f at mth boosting iteration
$\hat{f}_j^m$	Estimate for jth component function f_j at mth boosting iteration
$\mathbf{x}_j$	Predictors for the jth component function f_j
γ_j^m	Fit for jth component at mth boosting iteration
ν	Step size for the boosting algorithm
m_{end}	Number of boosting iterations executed
M	Maximum number of boosting iterations

The componentwise boosting algorithm is as follows:

1. Initialize $\hat{f}^0$ and $m = 1$.
2. Repeat the following steps until the maximum number of iterations M has been reached or an early stopping criterion is met:
   a) Compute $u_i = -\frac{\partial}{\partial f}\ell(y_i, f)|_{\hat{f}^{m-1}(\mathbf{x}_i)}, i = 1\ldots, n.$

b) For each component function f_j, $j = 1, \ldots, p$, obtain an estimated fit $\hat{\gamma}_j^m$ for the data $(u_i, \mathbf{x}_{ij})$, $i = 1 \ldots, n$.

c) Select the component $j^* = \underset{j=1,\ldots,p}{\operatorname{argmin}} \sum_{i=1}^{n} w_i \left(u_i - \hat{\gamma}_j^m(\mathbf{x}_{ij})\right)^2$.

d) Update the component functions by

$$\hat{f}_j^m = \begin{cases} \hat{f}_j^{m-1} + \nu\gamma_j^m & \text{if } j = j^* \\ \hat{f}_j^{m-1} & \text{if } j \neq j^* \end{cases}$$

e) Set $m = m + 1$ and check the stopping criterion.

3. Choose an iteration $m^* \leq m_{\text{end}}$ and set $\hat{f} = \hat{f}^{m^*}$.

The initial function $\hat{f}^0$ is set to the value of the offset variable that you specify in the OFFSET= option or by fitting an intercept-only model to the response y if no offset variable is specified. You can use the MAXITER= option in the SELECTION statement to specify the maximum number of boosting iterations. By default, MAXITER=500.

For component functions f_j that correspond to parametric effects, the functions γ_j^m are linear models that are estimated by solving

$$\min_{\boldsymbol{\beta}_j} \sum_{i=1}^{n} w_i \left(u_i - \mathbf{x}_{ij}\boldsymbol{\beta}_j\right)^2$$

Each linear model $\gamma_j^m = \mathbf{x}_{ij}\boldsymbol{\beta}_j$ includes an intercept term.

For component functions f_j that correspond to spline terms, the functions γ_j^m are estimated using penalized B-splines. For more information about penalized B-splines, see the section "Penalized B-Splines" on page 671.

By default, the penalized B-splines are of degree 3, and a difference penalty of order 2 is used. The smoothing parameter values are selected by default, so a univariate spline term has 4 degrees of freedom and a bivariate spline has 6 degrees of freedom. For more information about options that enable you to control how each spline term is constructed, see the section "Spline Effect Options" on page 659. Note that the degrees of freedom are defined for the penalized B-spline γ_j^m fit at each boosting iteration m. The degrees of freedom do not apply to the component functions f_j^m.

If you specify a value in the STOPHORIZON=*number* option in the SELECTION statement, then PROC GAMSELECT uses the criterion specified in the CHOOSE= option in the same statement to evaluate early termination of the selection process. Let CR_m denote the value of the criterion at iteration m. The selection process terminates early if $\mathrm{CR}_{m-1} < \mathrm{CR}_m$ for *number* consecutive iterations. If you specify the STOPTOL=*number* option in the SELECTION statement, a relative change in the criterion is evaluated and the selection process terminates early if

$$\left|\frac{\mathrm{CR}_{m-1} - \mathrm{CR}_m}{\mathrm{CR}_{m-1}}\right| < \tau$$

for *number* consecutive iterations, where $\tau =$*number*. By default, the average square error for the training data is used as the criterion.

When the boosting iterations finish, there are $m_{\text{end}}+1$ models $\hat{f}^m$. If you specify a criterion in the CHOOSE= option, PROC GAMSELECT selects the model $\hat{f} = \hat{f}^{m^*}$ that minimizes the criterion. By default, the procedure returns the model that minimizes the average square error on the training data. The effects in the final model are effects that were selected for at least one boosting iteration $m < m^*$.

Shrinkage

This section discusses the shrinkage selection method.

Sparsity-inducing norms have been explored by many authors as a technique for selecting generalized additive models. Because nonlinear terms in additive models are typically represented by splines and thus are naturally grouped, the L_2 norm used in group LASSO (Yuan and Lin 2006) and its generalizations are often used to perform additive model selection. For different approaches, see Lin and Zhang (2006), Cantoni, Flemming, and Ronchetti (2006), Ravikumar et al. (2009), Meier, Van de Geer, and Bühlmann (2009), Marra and Wood (2011), Raskutti, Wainwright, and Yu (2012), Suzuki and Sugiyama (2013), and Chouldechova and Hastie (2015). For a review of this field, see Amato, Antoniadis, and De Feis (2016).

Based on ideas in Meier, Van de Geer, and Bühlmann (2009), Suzuki and Sugiyama (2013), and Amato, Antoniadis, and De Feis (2016), the shrinkage method that is used in the GAMSELECT procedure performs a grid search of tuning parameters $\boldsymbol{\lambda} = (\lambda_1, \lambda_2, \lambda_3)$ and evaluates different models on the basis of their fits, given any fixed $\boldsymbol{\lambda}$ value. For each fixed $\boldsymbol{\lambda}$, PROC GAMSELECT fits the model by minimizing the penalized negative log-likelihood function

$$-\frac{\ell(\boldsymbol{\beta})\phi_d}{n} + \lambda_1 \sum_j \phi_j \sqrt{\boldsymbol{\beta}_j' \mathbf{K}_j \boldsymbol{\beta}_j} + \lambda_2 \sum_j \psi_j \sqrt{\boldsymbol{\beta}_j' \boldsymbol{\Omega}_j \boldsymbol{\beta}_j} + \lambda_3 \sum_j \boldsymbol{\beta}_j' \boldsymbol{\Omega}_j \boldsymbol{\beta}_j$$

where $\mathbf{K}_j = \mathbf{B}_j' \mathbf{B}_j / n$, and $\boldsymbol{\Omega}_j = \int (f_j'')^2 \mathrm{d}x$. The two terms $\lambda_1 \sum_j \phi_j \sqrt{\boldsymbol{\beta}_j' \mathbf{K}_j \boldsymbol{\beta}_j}$ and $\lambda_2 \sum_j \psi_j \sqrt{\boldsymbol{\beta}_j' \boldsymbol{\Omega}_j \boldsymbol{\beta}_j}$ are sparsity-inducing norms, which are generalizations of the L_2 norm. ϕ_j and ψ_j are two sets of control parameters that you can use to enforce stronger or weaker penalties for each individual spline term. ϕ_d is the dispersion parameter for the appropriate distribution in the exponential family. Because ϕ_d cancels out the denominator in the likelihood function, the optimization can focus on regression parameters only.

The first term can force $\boldsymbol{\beta}_j = \mathbf{0}$ if λ_1 is sufficiently large, and the second term can force $\boldsymbol{\beta}_j$ to be equivalent to a parametric solution ($\boldsymbol{\beta}_j' \boldsymbol{\Omega}_j \boldsymbol{\beta}_j = \mathbf{0}$) if λ_2 is sufficiently large. The third term, $\lambda_3 \sum_j \boldsymbol{\beta}_j' \boldsymbol{\Omega}_j \boldsymbol{\beta}_j$, serves as an optional penalty (similar to ridge regression) to make the solution smoother.

The solution for a fixed set of tuning parameters can be found by iteratively minimizing penalized weighted additive models that are based on pseudo-response z_i and pseudo-weights w_i. This is similar to the performance iteration algorithm used in the GAMMOD procedure. For more information, see "Performance Iteration" on page 614 in Chapter 12, "GAMMOD Procedure." The objective function for the minimization problem at each performance iteration is

$$\begin{aligned} O_{\boldsymbol{\lambda}}(\boldsymbol{\beta}|z, \mathbf{W}) = \frac{1}{2n}(z - \sum_j \mathbf{B}_j \boldsymbol{\beta}_j)' \mathbf{W} (z - \sum_j \mathbf{B}_j \boldsymbol{\beta}_j) &+ \lambda_1 \sum_j \phi_j \sqrt{\boldsymbol{\beta}_j' \mathbf{K}_j \boldsymbol{\beta}_j} \\ &+ \lambda_2 \sum_j \psi_j \sqrt{\boldsymbol{\beta}_j' \boldsymbol{\Omega}_j \boldsymbol{\beta}_j} \\ &+ \lambda_3 \sum_j \boldsymbol{\beta}_j' \boldsymbol{\Omega}_j \boldsymbol{\beta}_j \end{aligned}$$

To solve the optimization problem that involves two nonsmooth convex penalties operating on the same parameter vector, PROC GAMSELECT uses the alternating direction method of multipliers (ADMM) (Boyd et al. 2011) to break it into two subproblems.

Note that the objective function that is controlled by three tuning parameters $(\lambda_1, \lambda_2, \lambda_3)$ provides a general framework for performing additive model selection. Special cases of the objective correspond to different

model selection approaches. For example, $(\lambda_1, 0, 0)$ is close to Ravikumar et al. (2009), $(\lambda_1, \lambda_2, 0)$ is close to Koltchinskii and Yuan (2010), and $(0, \lambda_2, \lambda_3)$ is close to Tomioka and Suzuki (2009). The shrinkage selection method in PROC GAMSELECT enables you to specify a fixed value for any of the three tuning parameters while performing a grid search on the rest.

The shrinkage selection algorithm is as follows:

1. Pick a candidate $\boldsymbol{\lambda}$ value and perform the following steps:
   a) Initialize $f_j^{(0)} = 0$ for $j = 1, \ldots, p$.
   b) Repeat the following steps until the maximum differences in parameters over all spline terms have been reached or the maximum number of iterations has been reached.
      i. Recompute a pseudo-response $\boldsymbol{z}$ and pseudo-weights $\mathbf{W}$ on the basis of previous fits.
      ii. Use the corresponding partial residual to fit the parametric part, including the intercept.
      iii. Use the corresponding partial residual to optimize $\boldsymbol{O}_{\boldsymbol{\lambda}}(\boldsymbol{\beta}|\boldsymbol{z}_r, \mathbf{W})$.
   c) Obtain an estimate for the dispersion parameter if necessary.
2. Evaluate the model fit from the validation data or the training data. Update the selection if a better model is found.

Displayed Output

The following sections describe the output that PROC GAMSELECT produces. The output is organized into various tables, which are discussed in order of their appearance.

Model Information

The "Model Information" table displays basic information about the model, such as the response variable, the frequency variable, the link function, and the model category that the PROC GAMSELECT selected on the basis of your input and options. The "Model Information" table also displays the distribution of the data that is assumed by the procedure. The selection method and random number seed are also displayed.

Class Level Information

The "Class Level Information" table lists the levels of every variable that is specified in the CLASS statement. You should check this information to make sure that it is correct. You can adjust the order of the CLASS variable levels by specifying the ORDER= option in the CLASS statement. You can suppress the "Class Level Information" table completely or partially by specifying the NOCLPRINT= option in the PROC GAMSELECT statement.

If the classification variables use reference parameterization, the "Class Level Information" table also displays the reference value for each variable.

Number of Observations

The "Number of Observations" table displays the number of observations that are read from the input data table and the number of observations that are used in the analysis. If a FREQ statement is present, the sum of the frequencies that are read and used is displayed. If the events/trials syntax is used, the number of events and trials is also displayed.

Response Profile

The "Response Profile" table displays the ordered values from which PROC GAMSELECT determines the probability that is modeled as an event in binary models. For each response category level, the frequency that is used in the analysis is reported. You can affect the ordering of the response values by specifying *response-options* in the MODEL statement. For binary models, the note that follows this table indicates which outcome is modeled as the event in binary models and which value serves as the reference category.

The "Response Profile" table is not produced for binomial (events/trials) data. You can find information about the number of events and trials in the "Number of Observations" table.

Specifications for Spline(*spline-variables*)

The "Specifications for Spline(*spline-variables*)" table displays basic information (such as the number of variables, specified degrees of freedom, boundary knots and interior knots, and so on) about how to construct a spline term that PROC GAMSELECT uses to construct basis expansions. The procedure generates this table only when you specify the DETAILS option in the MODEL statement for a spline term.

Convergence Status

The convergence status table is a small ODS table that precedes the "Iteration Summary" table in the default output. In the listing, this table appears as a message that indicates whether the selected model that corresponds to the optimal regularization parameter converged. If the selected model fails to converge, the message indicates the reason for the failure. If you save the convergence status table to an output data table, a numeric Status variable is added that enables you to programmatically assess convergence. The values of the Status variable have the following meanings:

0 The selected model converged at the selected regularization parameters. The fitting of all other regularization parameters also succeeded.

1 The selected model converged at the selected regularization parameters. The fitting of some regularization parameters did not succeed.

2 Convergence was not achieved within the specified number of iterations. To modify the limit, see the MAXITER= option in the SELECTION statement.

3 The selected model did not converge.

PROC GAMSELECT generates this table only when you specify the shrinkage selection method.

Iteration Summary

For the boosting selection method, the "Iteration Summary" table displays the number of boosting iterations executed, the iteration that is selected by the criterion specified in the CHOOSE= option as the final model, and the number of effects in the final model.

For the shrinkage selection method, this table displays the number of penalty parameter trials, the number of reweighted iterations for the selected model, and the number of selected effects.

Shrinkage Regularization Parameter Summary

The "Shrinkage Regularization Parameter Summary" table displays the upper bounds of regularization parameters that are determined from the input data or specified by you, and the chosen parameters after PROC GAMSELECT performs the selection. The procedure generates this table only when you specify the shrinkage selection method.

Selected Effects

For the boosting selection method, the "Selected Effects" table displays the effects that are included in the final model, the first iteration at which an effect entered the model, and the number of iterations at which the effect was selected.

For the shrinkage selection method, this table displays which effects or spline components were included in the final model.

Fit Statistics

The "Fit Statistics" table displays the average square errors (ASEs) that are computed on the basis of the final selected model. If you specify a PARTITION statement, the table displays the values for each role along with statistics for comparing the training, validation, and testing results. If you use the boosting selection method and specify cross validation as the model selection criterion, this table also displays the cross validation ASEs for the selected model.

Parameter Estimates

The "Parameter Estimates" table displays the regression parameter estimates.

Iteration Details

For the boosting selection method, the "Iteration Details" table displays the effect that is selected at each iteration and the fit statistic values at each iteration. The table also includes columns for the coefficients of the effect selected at each iteration, scaled by the step size; these columns are not displayed by default but are accessible if you save the table as an output data set by specifying the ODS OUTPUT statement or if you save the table as an output data table by using the DISPLAYOUT statement.

Spline Regularization

The "Spline Regularization" table displays the sparsity penalty, smoothness penalty, and generalized ridge penalty for the selected spline terms in the final model. PROC GAMSELECT generates this table only when you specify the shrinkage selection method.

Timing

The "Timing" table displays the amount of time (in seconds) that PROC GAMSELECT required to perform different tasks in the analysis.

OutputCasTables Table

The OutputCasTables table is a special table that has information about each CAS table that is created during a CAS action execution. The information for each CAS table consists of the CAS table name, the caslib in which the table resides, and the number of columns and rows in the CAS table. Because this table is not a typical ODS table that contains analytical results, you cannot include it in the *table-spec-list* in the DISPLAYOUT statement.

ODS Table Names

Each table that the GAMSELECT procedure creates has a name that is associated with it. You must use this name to refer to the table when you use ODS statements. Table 13.11 lists the name of each table and a short description of its contents.

Table 13.11 ODS Tables Produced by PROC GAMSELECT

Table Name	Description	Statement	Option
ClassInfo	Level information from the CLASS statement	CLASS	
ConvergenceStatus	Status of the regularization parameter search at the conclusion of the optimization	SELECTION	METHOD=SHRINKAGE
FitStatistics	Fit statistics	Default output	
IterationDetails	Detailed information about iterations in the selection process	PROC GAMSELECT	ITDETAILS
IterationSummary	Summary information about iterations in selection methods	Default output	
ModelInfo	Information about the modeling environment	Default output	
NObs	Number of observations read and used, and number of events and trials, if applicable	Default output	
OutputCasTables	See the section "OutputCasTables Table" on page 680	OUTPUT DISPLAYOUT	OUT=

Table 13.11 *continued*

Table Name	Description	Statement	Option
ParameterEstimates	Solutions for the parameter estimates that are associated with parametric effects in the MODEL statement	Default output	
Regularization	Information about range and final choice of regularization parameters	SELECTION	METHOD=SHRINKAGE
ResponseProfile	Response categories and the category that is modeled in models for binary data	Default output	
SelectedEffects	List of effects and spline terms selected for the model	SELECTION	
SplineDetails	Information about spline construction and smoothing parameter search	MODEL	SPLINE(*variables* / DETAILS)
SplineRegularization	List of the spline regularization penalties for the selected model	SELECTION	METHOD=SHRINKAGE
Timing	Absolute and relative times for tasks performed by the procedure	Default output	

ODS Graphics

Statistical procedures use ODS Graphics to create graphs as part of their output. ODS Graphics is described in detail in the "Statistical Graphics Using ODS" chapter in *SAS/STAT User's Guide*.

Before you create graphs, ODS Graphics must be enabled (for example, by using the ODS GRAPHICS ON statement). For more information about enabling and disabling ODS Graphics, see the section "Enabling and Disabling ODS Graphics" in that chapter.

The overall appearance of graphs is controlled by ODS styles. Styles and other aspects of using ODS Graphics are discussed in the section "A Primer on ODS Statistical Graphics" in that chapter.

When ODS Graphics is enabled, the GAMSELECT procedure by default produces plots of the partial predictions for each spline term in the model. Use the PLOTS option in the PROC GAMSELECT statement to control aspects of these plots.

PROC GAMSELECT assigns a name to each graph that it creates by using ODS. You can use these names to refer to the graphs when using ODS. The names are listed in Table 13.12.

Table 13.12 Graphs Produced by PROC GAMSELECT

ODS Graph Name	Plot Description	PLOTS= Option
SmoothingComponentPanel	Panel of multiple prediction curves	Default COMPONENTS
SmoothingComponentPlot	Unpacked prediction curves	PLOTS(UNPACK) PLOTS=COMPONENTS(UNPACK)

By default, prediction plots for each spline component are displayed in panels that contain at most six plots. If you specify more than six smoothing components, multiple panels are used. To display these plots individually, use the PLOTS(UNPACK) option in the PROC GAMSELECT statement.

Examples: GAMSELECT Procedure

The examples in this chapter are available in the GitHub repository located at `https://github.com/sascommunities/doc-supplement-casstat`.

Example 13.1: Testing Model Fit with Partitioned Data

(View the complete code for this example (gamselex1.sas) in the example repository.)

The Sashelp.JunkMail data set comes from a study that classifies whether an email is junk email (coded as 1) or not (coded as 0). The data were collected by Hewlett-Packard Labs and donated by George Forman. The data table, which is specified in the following DATA step, contains 4,601 observations, with 2 binary variables and 57 continuous explanatory variables. The response variable, Class, is a binary indicator of whether an email is considered spam or not. The partitioning variable, Test, is a binary indicator that is used to divide the data into training and testing parts. The 57 explanatory variables are continuous variables that represent frequencies of some common words and characters and lengths of uninterrupted sequences of capital letters in emails.

```
data mylib.JunkMail;
   set Sashelp.JunkMail;
run;
```

In the following program, the PARTITION statement divides the data into two parts. The training data have a Test value of 0 and contain about two-thirds of the data; the rest of the data are used to evaluate the fit. The macro function SplineVList is defined to specify spline terms by using the default construction.

```
%macro SplineVList(vars);
   %let i = 1;
   %do %while (%length(%scan(&vars,&i)));
      spline(%scan(&vars,&i))
      %let i = %eval(&i + 1);
   %end;
%mend;
```

```
proc gamselect data=mylib.JunkMail;
   model Class(event='1')= %SplineVList(Make Address All _3d Our Over Remove
         Internet Order Mail Receive Will People Report Addresses Free Business
         Email You Credit Your Font _000 Money HP HPL George _650 Lab Labs
         Telnet _857 Data _415 _85 Technology _1999 Parts PM Direct CS Meeting
         Original Project RE Edu Table Conference Semicolon Paren Bracket
         Exclamation Dollar Pound CapAvg CapLong CapTotal)
   / dist=binary allobs;
   partition rolevar=Test(train='0' test='1');
   selection method=boosting(maxIter=2000);
run;
```

The ALLOBS option specifies that all observations be used to construct the spline basis functions. By default, only observations that have the training data role are used to construct the spline basis functions. By default, observations with the validation or test role that have spline variable values outside the range of values that is used to construct the spline basis functions are omitted from the analysis.

The "Number of Observations" and "Response Profile" tables in Output 13.1.1 are divided into training and testing columns.

Output 13.1.1 Partitioned Counts

The GAMSELECT Procedure

Number of Observations Read	4601
Number of Observations Used	4601
Number of Observations Used for Training	3065
Number of Observations Used for Validation	0
Number of Observations Used for Testing	1536

Response Profile

Ordered Value	Class	Total Frequency	Training Frequency	Validation Frequency	Test Frequency
1	0	2788	1847	0	941
2	1	1813	1218	0	595

Probability modeled is Class = 1.

The "Iteration Summary" table in Output 13.1.2 shows that the boosting algorithm executed 2,000 iterations and selected the model that corresponds to the final iteration with 26 effects.

Output 13.1.2 Iteration Summary

Iteration Summary	
Iterations Executed	2000
Selected Iteration	2000
Number of Selected Effects	26

The fit statistics for the selected model are displayed in the "Fit Statistics" table in Output 13.1.3.

Output 13.1.3 Partitioned Fit Statistics

Fit Statistics	
ASE (Train)	0.05450
ASE (Test)	0.06042
Misclassification Rate (Train)	0.06623
Misclassification Rate (Test)	0.06771

These statistics are computed for both the training and testing data. The average square error (ASE) and the misclassification rate should be similar between the two groups when the training data are representative of the testing data; for this model, the values of these statistics seem similar between the two disjoint subsets.

The "Selected Effects" table in Output 13.1.4 shows the effects that are included in the selected model, the iteration at which the effect first entered the model, and the number of iterations at which the effect was selected for an update.

Output 13.1.4 Selected Effects

Selected Effects		
Effect	Entry Iteration	Times Selected
Spline(Your)	1	24
Spline(Dollar)	2	127

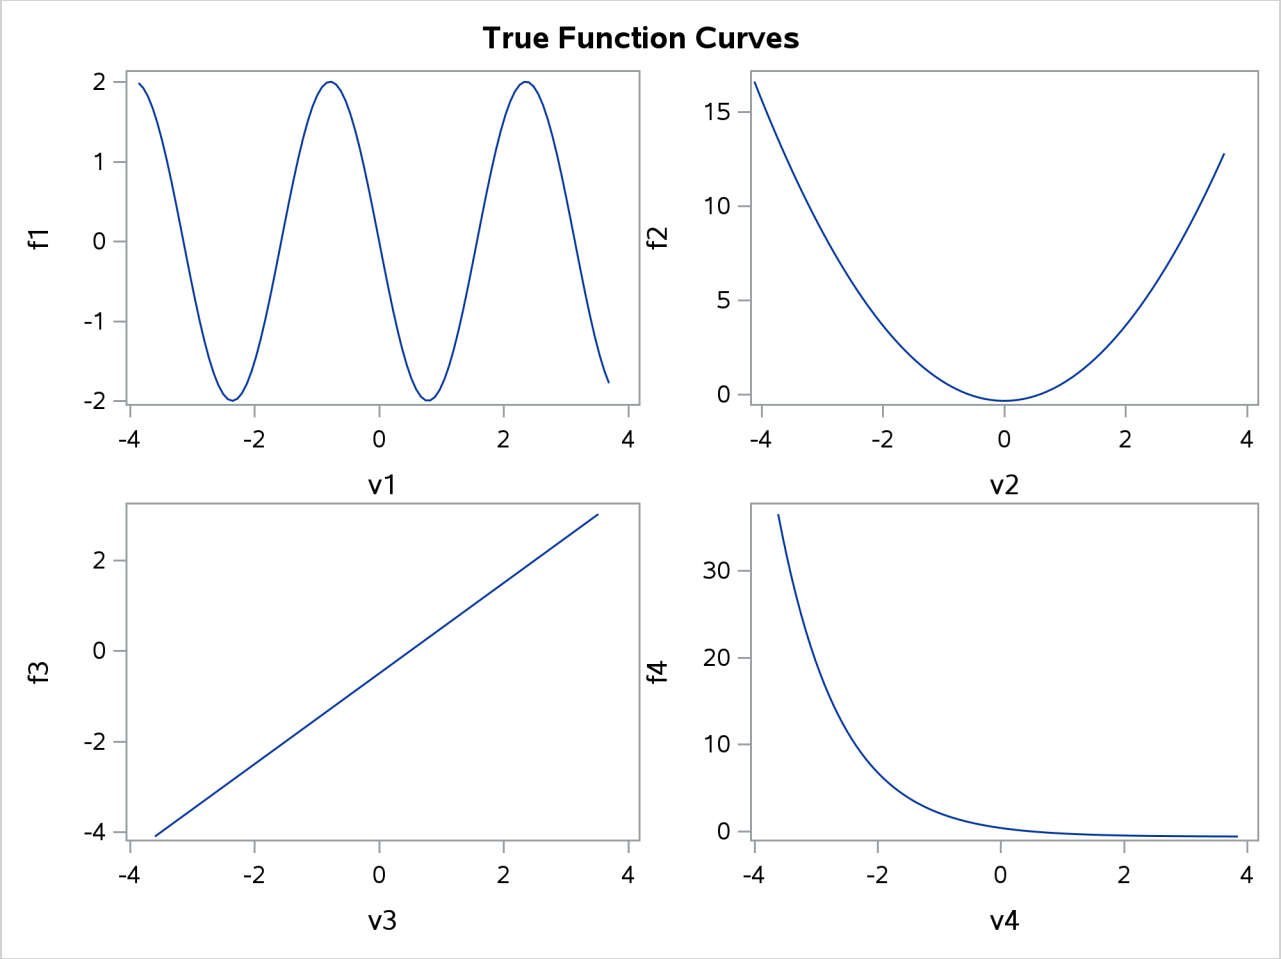
Example 13.2: Options to Control Boosting Model Fit



(View the complete code for this example (gamselex2.sas) in the example repository.)

This example and Example 13.3 demonstrate how you can build an additive model and how you can control the complexity of the model that PROC GAMSELECT fits. The following DATA step creates the data table one in the current CAS engine libref named mylib:

```
data mylib.one;
   call streaminit(1);
   array v{200} v1-v200;
   do i=1 to 10000;
      do j=1 to 200;
          v{j}=rand("normal");
      end;
      f1=-2*sin(2*v1);
      f2=v2*v2-1./3;
      f3=v3-0.5;
      f4=exp(-v4)+exp(-1)-1;
      linp=f1+f2+f3+f4;
      y=rand("normal",linp);
      output;
   end;
 run;
```

The data table one consists of 10,000 observations for a continuous response variable (y) and 200 continuous variables (v1–v200). The model for the mean of response variable y includes a sine function of the variable v1, a quadratic function of the variable v2, an exponential function of the variable v3, and a linear function of the variable v4. Output 13.2.1 shows the true function curves of the four variables that construct the response.

Output 13.2.1 True Function Curves

Without knowing the data generating process, you could form an initial analysis plan by using some basic exploratory tools. A density histogram of the response variable y (not shown) suggests that it follows a normal distribution, and a scatter matrix (not shown) indicates nonlinear relationships between some of the predictors and the response and many possible nuisance predictors. On the basis of these observations, you might decide to first use PROC REGSELECT to perform the selection. This procedure enables you to use the EFFECT statement to construct regression splines to model nonlinear terms. For more information about the procedure, see Chapter 29, "REGSELECT Procedure." For more information about using the EFFECT statement in PROC REGSELECT to construct regression splines, see the section "Spline Effects" on page 25 in Chapter 2, "Shared Concepts." The following program shows how you can start your analysis by performing the stepwise selection on 200 constructed regression splines:

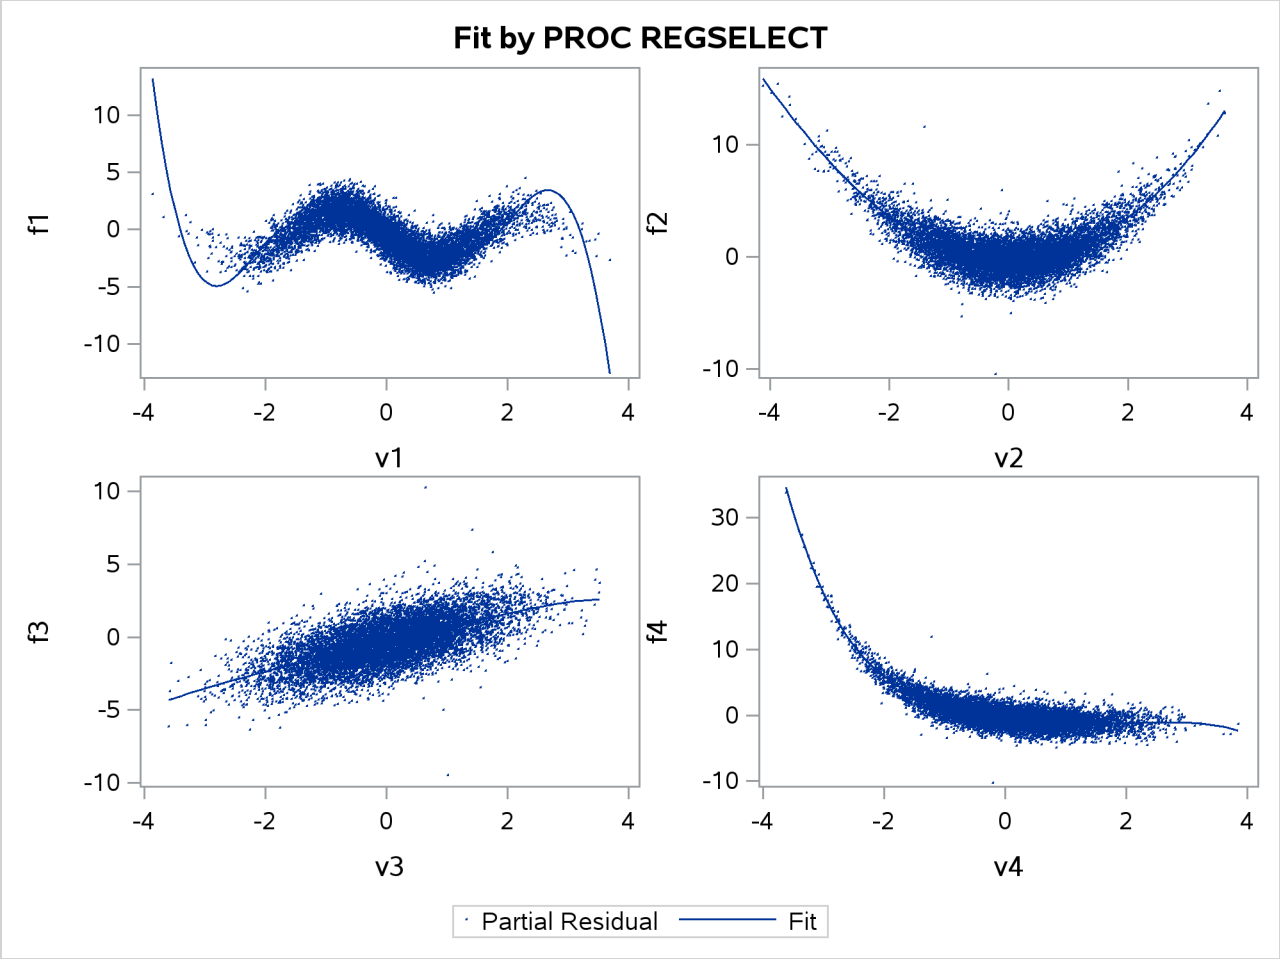
```
proc regselect data=mylib.one;
   effect spl=spline(v1-v200/separate);
   model y=spl;
   selection method=stepwise;
run;
```

The output from PROC REGSELECT (Output 13.2.2) shows that five effects, including the intercept, are selected and shows an average square error (ASE) of about 1.4 for the selected model.

Output 13.2.2 Selected Effects and Fit Statistics

The REGSELECT Procedure

Selection Details



Selected Effects:	Intercept spl_v1 spl_v2 spl_v3 spl_v4

Root MSE	1.18341
R-Square	0.86648
Adj R-Sq	0.86616
AIC	13395
AICC	13395
SBC	3573.31162
ASE	1.39697

For regression modeling of data that have nonlinear structures, it is often necessary to check partial residuals and partial predictions to determine whether the included model effects sufficiently explain the nonlinear structure. Output 13.2.3 displays the partial predictions overlaid with fitted partial prediction curves for the selected model.

In Output 13.2.3, you observe that the fitted curves explain the pattern in the partial residuals reasonably well, except for the first variable, v1. The fitted curve seems to overfit the partial residuals, especially in the tail areas. This suggests that the default regression spline construction is not sufficient for modeling the nonlinear relationship between v1 and y.

Output 13.2.3 PROC REGSELECT Fit

This problem has a few possible solutions. One solution is to construct multiple spline bases at different scales of knot intervals in order to approximate the nonlinear structure at finer scales and plot the partial residuals for the new models. In general, you will have to keep repeating these steps in order to obtain a model that explains the nonlinear structure well. For data that have complicated dependency structures, this might take many iterations. However, you can use PROC GAMSELECT to perform an additive model selection that uses penalized splines. Because of the spline penalty, the fitted splines are less prone to exhibit extreme boundary behaviors. This example and Example 13.3 demonstrate how you can use the procedure to perform the selection and use some options to fine-tune the selection results.

The following PROC SQL statements create a macro variable, splineTerms, which contains the list of spline terms for the variables v1–v200:

```
proc sql noprint;
   select cat("spline(",strip(name),")") into :splineTerms separated by ' '
   from dictionary.columns
   where libname = "MYLIB" and memname = "ONE" and
   upcase(name) like 'V%';
quit;
```

The following PROC GAMSELECT statements use the macro variable splineTerms to specify a model for the variable y by using the boosting method without specifying any options to control the model fit:

```
proc gamselect data=mylib.one plots=all;
   model y = &splineTerms;
   selection method=boosting;
run;
```

Output 13.2.4 shows that the boosting algorithm executed 500 iterations and selected the model that corresponds to the final boosting iteration.

Output 13.2.4 Iteration Summary for Default Model

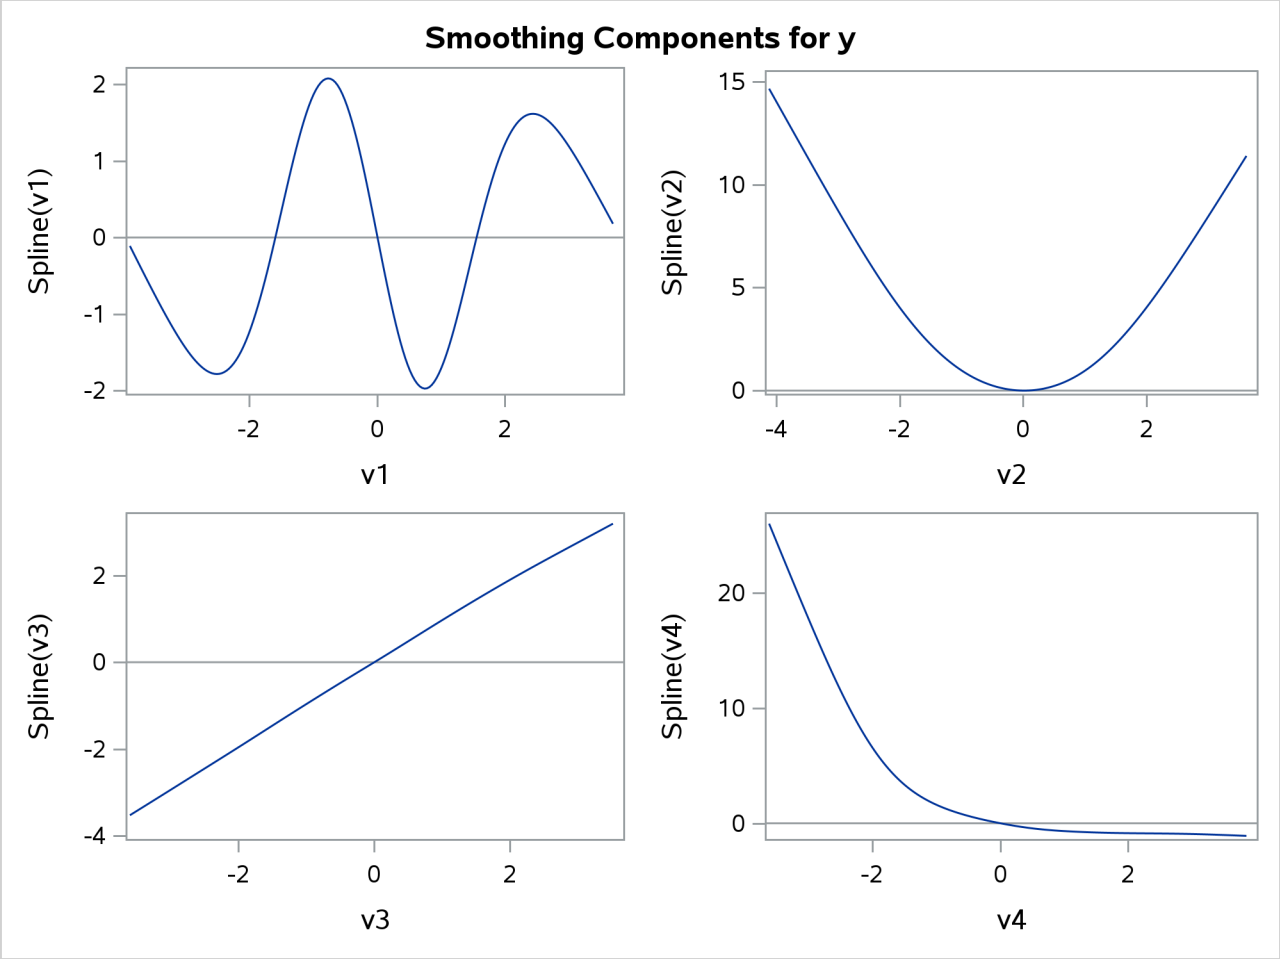
The GAMSELECT Procedure

Iteration Summary	
Iterations Executed	500
Selected Iteration	500
Number of Selected Effects	8

The "Selected Effects" table in Output 13.2.5 shows that the four spline terms that are constructed from the variables v1–v4 are included in the final model and that at most iterations the effect that was selected for an update was one of these four terms.

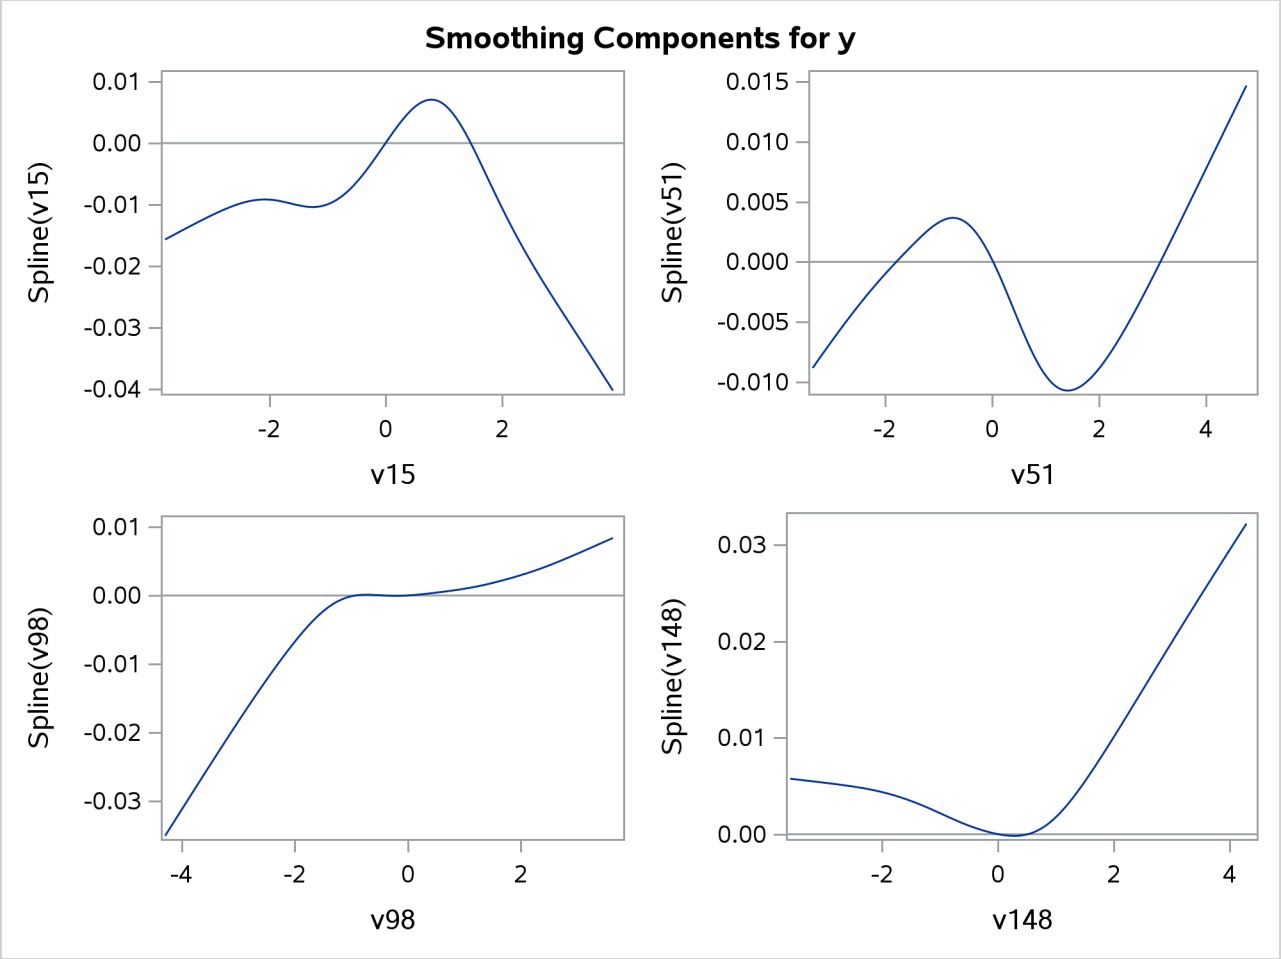
Output 13.2.5 Selected Effects for Default Model

Selected Effects		
Effect	Entry Iteration	Times Selected
Spline(v4)	1	187
Spline(v2)	5	67
Spline(v1)	9	204
Spline(v3)	18	35
Spline(v15)	443	3
Spline(v51)	464	2
Spline(v148)	472	1
Spline(v98)	493	1



The model also includes four effects that do not correspond to any true signal. These effects enter the model at iterations later in the run of the boosting algorithm and are selected for a small number of iterations. Output 13.2.6 shows the fit statistics for the selected model; in this case, there is only one—the ASE.

Output 13.2.6 Fit Statistics for Default Model



Fit Statistics	
Average Square Error	1.03910

The smoothing component plots for the selected effects in Output 13.2.7 show well-reconstructed curves for the splines that are constructed from the variables v1–v4 and show small contributions from the remaining components.

Output 13.2.7 Smoothing Component Panel for Default Model

Output 13.2.7 *continued*

By default, PROC GAMSELECT selects the model $\hat{f}^{m^*}$ that minimizes the ASE for the training data from the set of models that correspond to each boosting iteration. This criterion for selecting the final model might result in overfitting of the training data. To prevent overfitting of the training data, you can use the CHOOSE= option in the SELECTION statement to change the criterion that is used to select the final model. In addition to changing this criterion, you can implement early stopping of the selection process by using the STOPHORIZON= and STOPTOL= options in the SELECTION statement. For more information about how PROC GAMSELECT implements early stopping, see the section "Boosting" on page 674.

To demonstrate the use of early stopping, the model selection process is repeated using k-fold cross validation of the ASE as the selection criterion. PROC GAMSELECT can perform cross validation either by randomly assigning observations to folds or by using an input variable to partition the data into folds. Note that the random sampling of observations for cross validation depends on the initial random number seed and how the data are distributed across machines and threads. Therefore, even if you specify the same seed value by using the SEED= option in the PROC GAMSELECT statement, results might differ between runs of PROC GAMSELECT. The following DATA step adds a variable cvFold that can be used to partition the data into folds for cross validation:

```
data mylib.one / single=yes;
  set mylib.one;
  call streaminit(1848);
  cvFold = rand("table",0.2,0.2,0.2,0.2,0.2);
run;
```

The following PROC GAMSELECT statements perform model selection by using early stopping, k-fold cross validation to select the final model, and the same list of spline terms that is specified in the splineTerms macro variable:

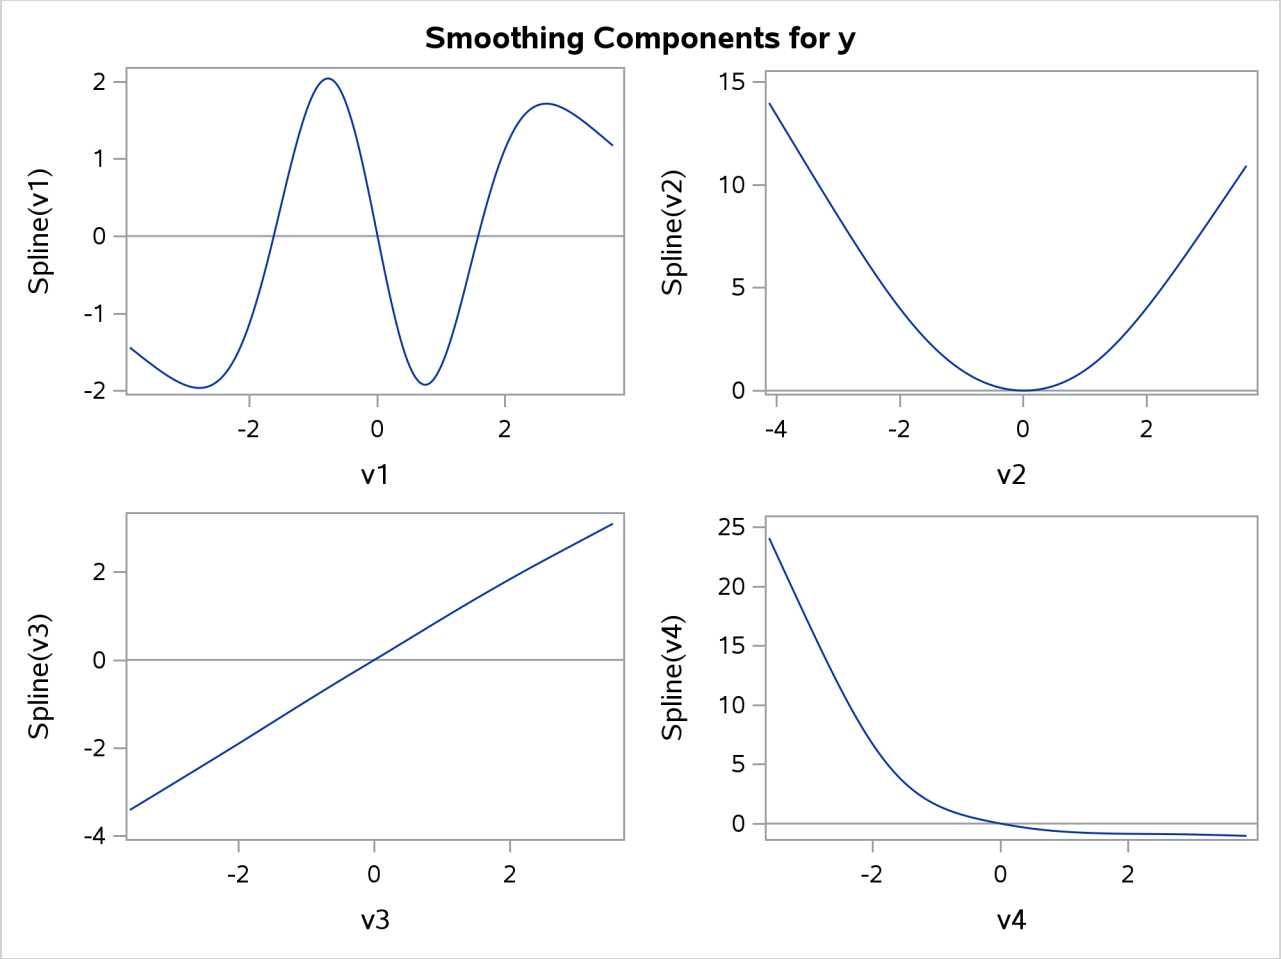
```
proc gamselect data=mylib.one plots=all;
   model y = &splineTerms;
   selection method=boosting(choose=CV index=cvFold
             stopHorizon=10 stopTol = 0.0005);
run;
```

Output 13.2.8 shows that the selection process terminates early, at the 300th boosting iteration, and that the selected model includes four effects.

Output 13.2.8 Iteration Summary Using Cross Validation

The GAMSELECT Procedure

Iteration Summary	
Iterations Executed	300
Selected Iteration	300
Number of Selected Effects	4



The "Fit Statistics" table in Output 13.2.9 shows the ASE for the training data and the k-fold cross validation of the ASE. The two ASE values are similar and are larger than the ASE value for the default model (Output 13.2.6).

Output 13.2.9 Fit Statistics Using Cross Validation

Fit Statistics	
Average Square Error	1.07588
Cross Validation ASE	1.09528

Output 13.2.10 displays the smoothing component panel for the model that is selected using cross validation and early stopping. Compared to the smoothing component panel for the default model (Output 13.2.7), the curve for Spline(v1) in Output 13.2.10 shows a worse reconstruction near the maximum and minimum values of the variable v1. This difference suggests that the fit might benefit from increasing the degrees of freedom for the penalized B-spline for Spline(v1) fit at each boosting iteration. For more information about the construction of penalized B-splines, see the section "Penalized B-Splines" on page 671.

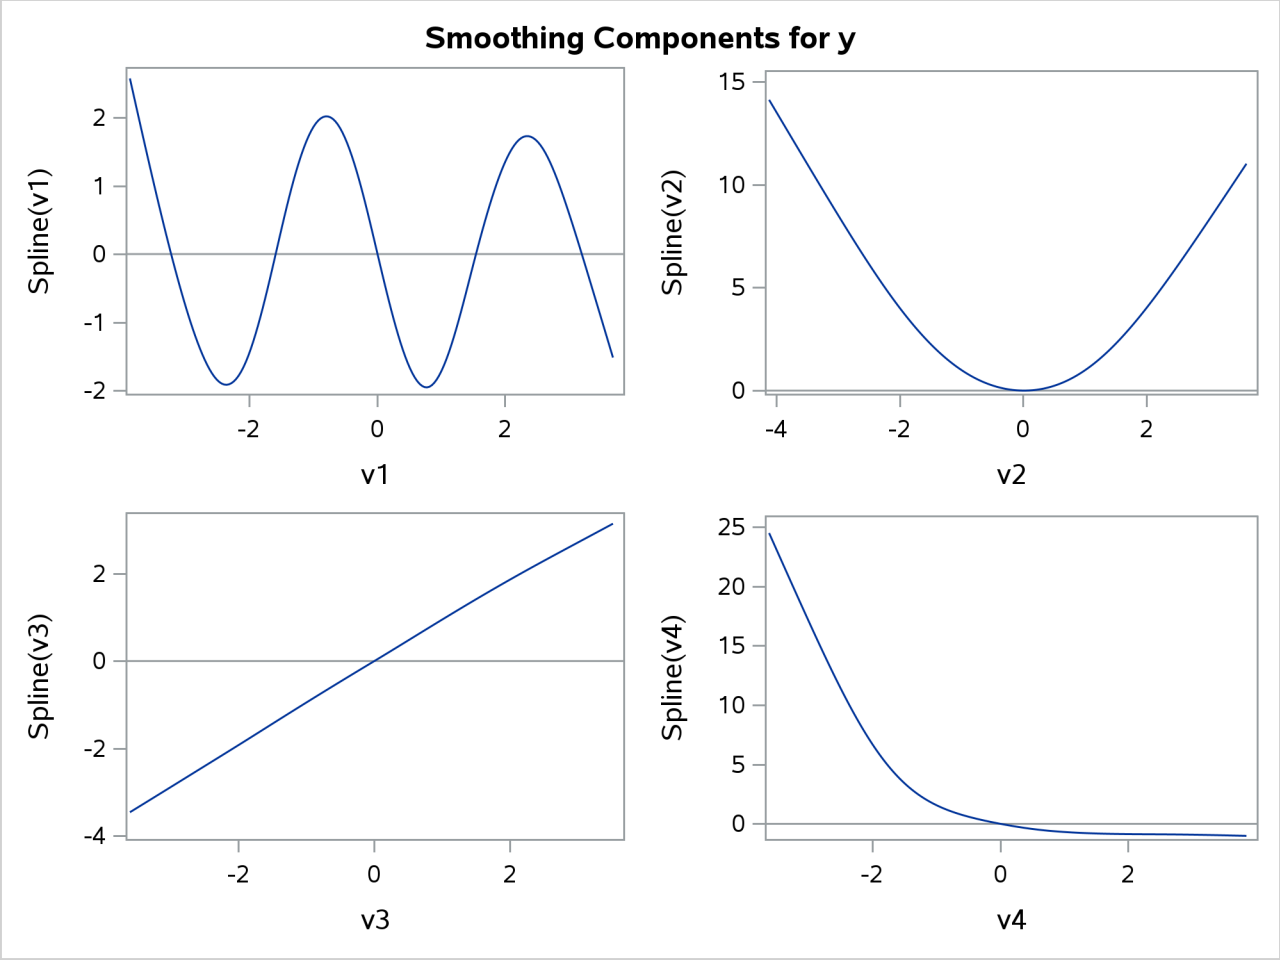
Output 13.2.10 Smoothing Component Panel Using Cross Validation

The following PROC GAMSELECT statements fit a reduced model by using spline terms for the variables v1–v4 with 10 degrees of freedom for the Spline(v1) estimate fit at each boosting iteration:

```
proc gamselect data=mylib.one plots=all;
   model y = spline(v1 / df = 10) spline(v2) spline(v3) spline(v4);
   selection method=boosting(choose=CV index=cvFold
             stopHorizon=10 stopTol = 0.0005);
run;
```

Output 13.2.11 displays the "Fit Statistics" table and "Iteration Summary" table for the reduced model. The selection process terminates early, at the 219th iteration, and has an ASE closer to the ASE of the default model (Output 13.2.6).

Output 13.2.11 Iteration Summary and Fit Statistics for Reduced Model



The GAMSELECT Procedure

Iteration Summary	
Iterations Executed	219
Selected Iteration	219
Number of Selected Effects	4

Fit Statistics	
Average Square Error	1.04808
Cross Validation ASE	1.06386

The increased degrees of freedom for Spline(v1) results in a better reconstruction than the model fit that uses the default 4 degrees of freedom with cross validation and early stopping (Output 13.2.10).

Output 13.2.12 Smoothing Component Panel for Reduced Model

Example 13.3: Options to Control Shrinkage Selection

(View the complete code for this example (gamselex3.sas) in the example repository.)

This example continues the analysis of building an additive model for the data table that is formed in Example 13.2.

The following program uses the shrinkage method to perform the selection:

```
proc gamselect data=mylib.one seed=123 plots=all;
   model y = &splineTerms;
   selection method=shrinkage;
run;
```

Output 13.3.1 shows that the selected model converged and the fittings for all the regularization parameter candidates succeeded.

Output 13.3.1 Convergence Status for Default Model

The GAMSELECT Procedure

Selected model converged. All regularization parameters succeeded.

Output 13.3.2 shows the number of tries and successes of regularization parameter fittings. It also shows how many iterations the selected model required and how many effects were selected.

Output 13.3.2 Iteration Summary for Default Model

Iteration Summary	
Number of Penalty Parameter Set Tries	200
Number of Penalty Parameter Set Successes	200
Number of Reweighted Iterations for Selected Model	12
Number of Selected Effects	6

Output 13.3.3 displays the upper bounds for the regularization parameters that PROC GAMSELECT computed from the input data table and the selected values after the grid search.

Output 13.3.3 Regularization Parameter Summary for Default Model

Shrinkage Regularization Parameter Summary		
Penalty	**Maximum**	**Chosen**
Sparsity	2.097253	0.030225
Smoothness	0.5503	0.001075
Generalized Ridge	0	0

Output 13.3.4 shows that six effects are selected: the intercept, the splines of four variables (v1–v4) that construct the true model, and one additional spline of variable v15.

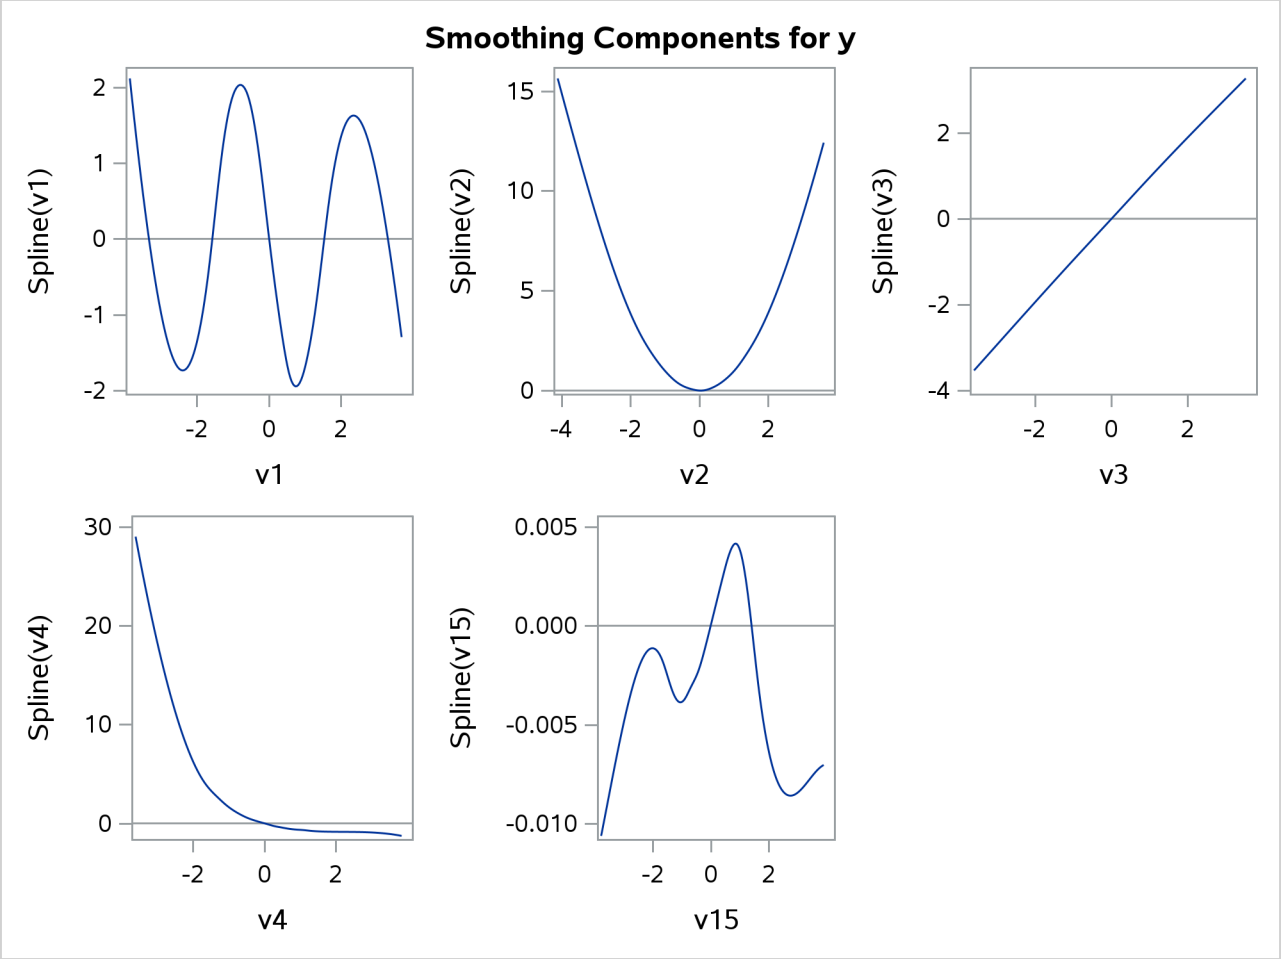
Output 13.3.4 Selected Effects for Default Model

Selected Effects	Intercept Spline(v1) Spline(v2) Spline(v3) Spline(v4) Spline(v15)

Output 13.3.5 displays the fit statistics for the model; in this case, there is only one—the ASE.

Output 13.3.5 Fit Statistics for Default Model

Fit Statistics	
Average Square Error	1.01459



Output 13.3.6 displays the values of sparsity penalty, smoothness penalty, and generalized ridge penalty for the selected spline terms. Compared to the first four splines, the last spline of variable v15 has somewhat smaller penalty values.

Output 13.3.6 Spline Regularization for Default Model

Spline Regularization			
Component	**Sparsity Penalty**	**Smoothness Penalty**	**Generalized Ridge Penalty**
Spline(v1)	0.0422	0.0143	0
Spline(v2)	0.0436	0.00521	0
Spline(v3)	0.0289	0.000061	0
Spline(v4)	0.0620	0.0120	0
Spline(v15)	0.000088	0.000031	0

The "Smoothing Component Panel" displays the fitted curves of the five selected spline terms. The vertical scale of Spline(v15) indicates that the contribution from this effect is small compared to the contribution from the other spline effects.

Output 13.3.7 Smoothing Component Panel for Default Model

Meier, Van de Geer, and Bühlmann (2009) propose an adaptive operation that forms sparsity penalties and smoothness penalties in a data-adaptive way, which is similar to the idea of the adaptive LASSO (Zou 2006). In the context of shrinkage selection, this adaptive option corresponds to setting the WEIGHT1 and WEIGHT2 options in individual spline terms, on the basis of previously computed sparsity penalty and smoothness penalty values. Using the notation in the section "Shrinkage" on page 676, you compute the adaptive weights as

$$\phi_j = 1/\sqrt{\hat{\boldsymbol{\beta}}_j' \mathbf{K}_j \hat{\boldsymbol{\beta}}_j}$$
$$\psi_j = 1/\sqrt{\hat{\boldsymbol{\beta}}_j' \boldsymbol{\Omega}_j \hat{\boldsymbol{\beta}}_j}$$

where $\sqrt{\hat{\boldsymbol{\beta}}_j' \mathbf{K}_j \hat{\boldsymbol{\beta}}_j}$ and $\sqrt{\hat{\boldsymbol{\beta}}_j' \boldsymbol{\Omega}_j \hat{\boldsymbol{\beta}}_j}$ are computed by using the selected regularization parameters (Output 13.3.3) divided by the reported sparsity penalty and smoothness penalty values, respectively, shown in Output 13.3.6.

The following program uses the computed values of ϕ_j and ψ_j from the previous analysis and performs one additional step of additive model selection in an adaptive fashion:

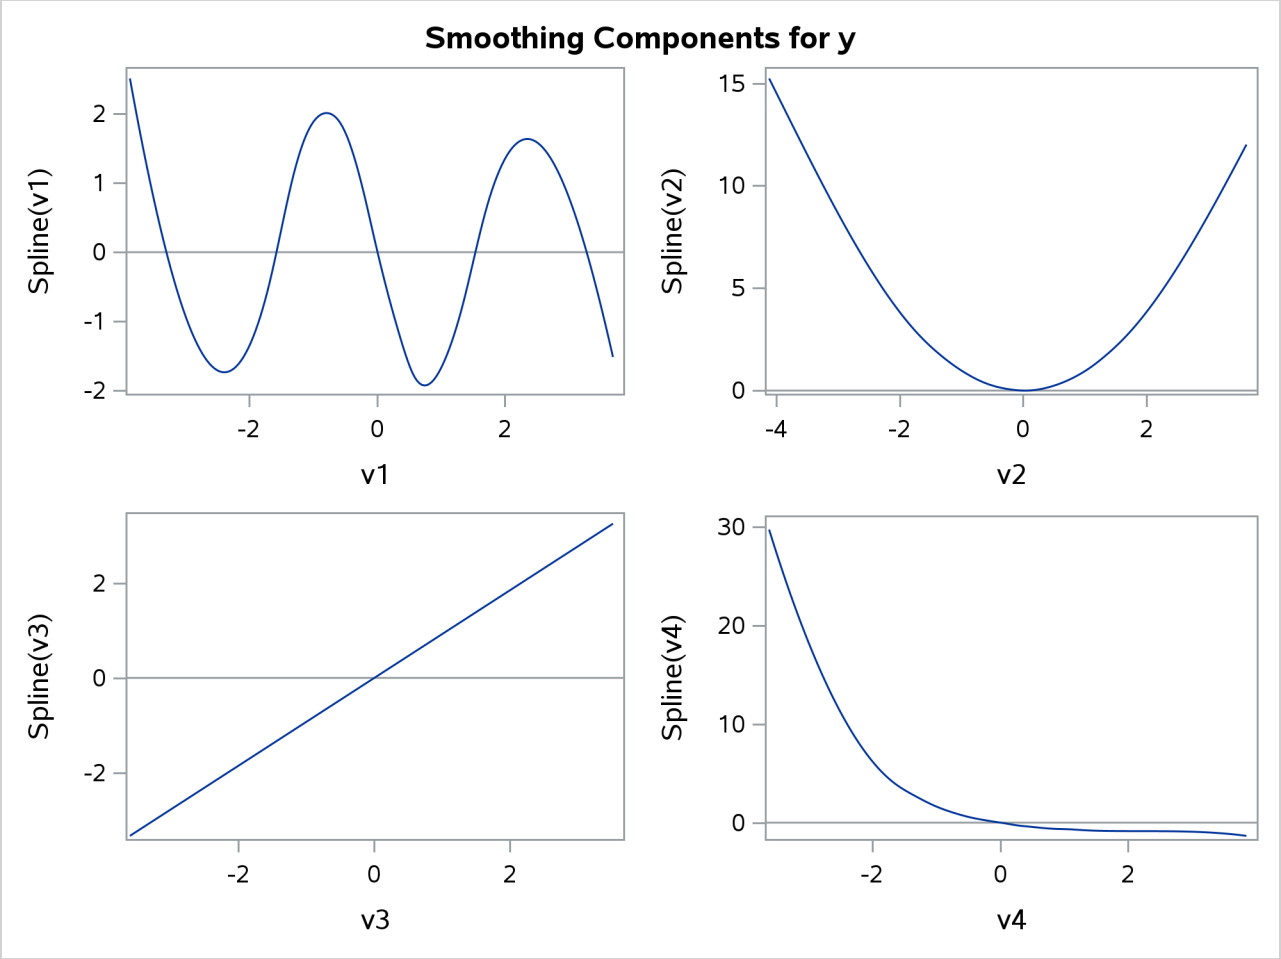
```
proc gamselect data=mylib.one seed=123 plots=all;
   model y=spline(v1 / weight1=0.716  weight2=0.075)
           spline(v2 / weight1=0.693  weight2=0.206)
           spline(v3 / weight1=1.046  weight2=17.62)
           spline(v4 / weight1=0.488  weight2=0.090)
           spline(v15/ weight1=343.5  weight2=34.68);
   selection method=shrinkage;
run;
```

Output 13.3.8 shows that the intercept and splines of the four variables that construct the true response were selected in the adaptive model.

Output 13.3.8 Selected Effects for Adaptive Model

The GAMSELECT Procedure

Selected Effects	Intercept Spline(v1) Spline(v2) Spline(v3) Spline(v4)



Output 13.3.9 displays the fit statistics for the adaptive model; in this case, there is only one—the ASE.

Output 13.3.9 Fit Statistics for Adaptive Model

Fit Statistics	
Average Square Error	1.01867

Output 13.3.10 shows the fitted curves from the adaptive model.

Output 13.3.10 Smoothing Component Panel for Adaptive Model

Overview: GENSELECT Procedure

The GENSELECT procedure fits and performs model selection for generalized linear models in SAS Viya.

The models that PROC GENSELECT supports can contain main effects that consist of both continuous and classification variables and interaction effects of these variables. The models can also include constructed effects such as splines. The procedure offers a number of effect-selection methods, including stepwise methods, modern LASSO methods, and elastic net selection. It also offers extensive capabilities for customizing the model selection by using a wide variety of selection and stopping criteria, from computationally efficient significance-level-based criteria to modern, computationally intensive validation-based criteria. PROC GENSELECT also provides a variety of diagnostics that are conditional on the selected model.

PROC GENSELECT fits models for standard distributions in the exponential family, such as the normal, Poisson, binomial, gamma, lognormal, and Tweedie distributions. In addition, the procedure fits multinomial models for ordinal and nominal response data, and it fits models for the beta, generalized Poisson, and negative binomial distributions.

The GENSELECT procedure can also fit models to correlated responses by using the generalized estimating equations (GEE) method. PROC GENSELECT supports many of the correlation structures from Liang and Zeger (1986).

PROC GENSELECT Features

The GENSELECT procedure does the following:

- estimates the parameters of a generalized linear regression model by using maximum likelihood techniques
- provides model-building syntax in the CLASS statement and the effect-based MODEL statement, which are familiar from SAS/STAT procedures (in particular, the GLM, GENMOD, LOGISTIC, GLIMMIX, and MIXED procedures)

- enables you to split classification effects into individual components by using the SPLIT option in the CLASS statement
- permits any degree of interaction effects that involve classification and continuous variables
- provides multiple link functions
- provides cumulative link models for ordinal response data and generalized logit modeling for unordered multinomial data
- provides response-variable options for binary and multinomial data as in the LOGISTIC procedure
- supports repeated measures analysis by using generalized estimating equations (GEEs) for models that use the normal, gamma, inverse Gaussian, lognormal, negative binomial, binomial, binary, and Poisson distributions
- enables model building (variable selection) through the SELECTION statement
- provides a WEIGHT statement for weighted analysis
- provides a FREQ statement for grouped analysis
- provides a CODE statement to produce SAS code that can score a new data set
- provides an OUTPUT statement to produce a data table that contains predicted probabilities and other observationwise statistics
- uses ODS Graphics to create model selection plots as part of its output. For more information about ODS Graphics, see the section "ODS Graphics" on page 782.

Because the GENSELECT procedure runs on CAS, it also does the following:

- enables you to run on a cluster of machines that distribute the data and the computations
- enables you to run in single-machine mode on CAS
- exploits all the available cores and concurrent threads. For information about how PROC GENSELECT uses threads, see the section "Multithreading" on page 102 in Chapter 2, "Shared Concepts."

PROC GENSELECT Compared with Other SAS Procedures

The GENSELECT procedure provides generalized linear modeling functionality that is comparable to that of the HPGENSELECT and GENMOD procedures in SAS/STAT software.

PROC GENSELECT Compared with the HPGENSELECT Procedure

The functionality of the GENSELECT procedure closely resembles that of the HPGENSELECT procedure, which is a high-performance procedure. The GENSELECT procedure is the next generation of the HPGENSELECT procedure, and it was developed specifically for SAS Viya. Both procedures are designed to run on a cluster of machines that distribute the data and the computations.

Both the GENSELECT and HPGENSELECT procedures fit and perform model selection for generalized linear models. The models can contain main effects that consist of both continuous and classification variables and interaction effects of these variables. The GENSELECT procedure is additionally capable of constructing complex effects, including univariate spline and polynomial expansions. The default parameterization of CLASS variables in both procedures is the GLM parameterization.

If you do not specify a link function with the LINK= option, the GENSELECT procedure uses the logarithm link function as the default for both the gamma and the inverse Gaussian distributions. The HPGENSELECT procedure uses the reciprocal link function as the default for the gamma distribution, and the reciprocal squared as the default for the inverse Gaussian distribution.

With the GENSELECT and HPGENSELECT procedures, you request model selection by using the SELECTION statement. Both procedures offer the same methods of effect selection, but the GENSELECT procedure also produces selection plots by using ODS Graphics.

Both procedures use a modification of the Newton-Raphson algorithm with a ridged Hessian by default. You can choose different optimization techniques, including first-order methods that do not require a crossproducts matrix or Hessian, by using the TECHNIQUE= option. The default method for the Tweedie distribution is a quasi-Newton method.

PROC GENSELECT Compared with the GENMOD Procedure

The GENMOD procedure fits generalized linear models. The GENSELECT procedure fits and performs model selection for generalized linear models. The models can contain main effects that consist of both continuous and classification variables and interaction effects of these variables. The default parameterization of CLASS variables in both procedures is the GLM parameterization.

If you do not specify a link function with the LINK= option, the GENSELECT procedure uses the logarithm link function as the default for both the gamma and the inverse Gaussian distributions. The GENMOD procedure uses the reciprocal link function as the default for the gamma distribution, and the reciprocal squared as the default for the inverse Gaussian distribution.

Both procedures use a modification of the Newton-Raphson algorithm with a ridged Hessian by default. You can instead choose Fisher scoring in PROC GENMOD.

The GENMOD procedure offers a wide variety of postfitting analyses, such as contrasts, estimates, tests of model effects, and least squares means. The GENSELECT procedure is limited in postfitting functionality because it is primarily designed for large-data tasks, such as predictive model building, model fitting, and scoring.

The GENSELECT procedure is specifically designed to operate in SAS Viya, and it performs computations in multiple threads. The GENMOD procedure executes in a single thread on a single machine.

Using CAS Sessions and CAS Engine Librefs

SAS Cloud Analytic Services (CAS) is the analytic server and associated cloud services in SAS Viya. This section describes how to create a CAS session and set up a CAS engine libref that you can use to connect to the CAS session. It assumes that you have a CAS server already available; contact your system administrator if you need help starting and terminating a server. This CAS server is identified by specifying the host on which it runs and the port on which it listens for communications. To simplify your interactions with this CAS server, the host information and port information for the server are stored as SAS option values that are retrieved automatically whenever this CAS server needs to be accessed. You can examine the host and port values for the server at your site by using the following statements:

```
proc options option=(CASHOST CASPORT);
run;
```

In addition to starting a CAS server, your system administrator might also have created a CAS session and a CAS engine libref for your use. You can define your own sessions and CAS engine librefs that connect to the CAS server as shown in the following statements:

```
cas mysess;
libname mylib cas sessref=mysess;
```

The CAS statement creates the CAS session named mysess, and the LIBNAME statement creates the mylib CAS engine libref that you use to connect to this session. It is not necessary to explicitly name the CASHOST and CASPORT of the CAS server in the CAS statement, because these values are retrieved from the corresponding SAS option values.

If you have created the mysess session, you can terminate it by using the TERMINATE option in the CAS statement as follows:

```
cas mysess terminate;
```

For more information about the CAS and LIBNAME statements, see the section "Introduction to Shared Concepts" on page 6 in Chapter 2, "Shared Concepts."

Getting Started: GENSELECT Procedure

Poisson Regression for Count Data

(View the complete code for this example at https://github.com/sascommunities/doc-supplement-casstat/tree/main/Examples/gengs1.sas.)

NOTE: Input data must be in a CAS table that is accessible in your CAS session. You must refer to this table by using a two-level name. The first level must be a CAS engine libref, and the second level must be the table name. For more information, see the sections "Using CAS Sessions and CAS Engine Librefs" on page 7 and "Loading a SAS Data Set onto a CAS Server" on page 7 in Chapter 2, "Shared Concepts."

This example illustrates how you can use PROC GENSELECT to perform Poisson regression for count data. The following DATA step creates the data table getStarted, which consists of 100 observations on a count response variable (Y); a continuous variable (Total) to be used in a later analysis; and five categorical variables (C1–C5), each of which has four numerical levels:

```
data mylib.getStarted;
  input C1-C5 Y Total;
  datalines;
0 3 1 1 3 2 28.361
2 3 0 3 1 2 39.831
1 3 2 2 2 1 17.133
1 2 0 0 3 2 12.769

;
```

These statements assume that your libref is named mylib, but you can substitute any appropriately defined libref.

The following statements fit a log-linked Poisson model to these data by using classification effects for the variables C1–C5:

```
proc genselect data=mylib.getStarted;
   class C1-C5;
   model Y = C1-C5 /  Distribution=Poisson Link=Log;
run;
```

The output from this analysis is presented in Figure 14.1 through Figure 14.7.

Figure 14.1 displays the "Model Information" table. The variable Y is an integer-valued variable that is modeled by using a Poisson probability distribution, and the mean of Y is modeled by using a log link function. The GENSELECT procedure uses a Newton-Raphson algorithm to fit the model. The CLASS variables C1–C5 are parameterized by using GLM parameterization, which is the default.

Figure 14.1 Model Information

The GENSELECT Procedure

Model Information	
Data Source	GETSTARTED
Response Variable	Y
Distribution	Poisson
Link Function	Log
Optimization Technique	Newton-Raphson with Ridging

Each of the CLASS variables C1–C5 has four unique formatted levels, which are displayed in the "Class Level Information" table in Figure 14.2.

Figure 14.2 Class Level Information

Class Level Information		
Class	**Levels**	**Values**
C1	4	0 1 2 3
C2	4	0 1 2 3
C3	4	0 1 2 3
C4	4	0 1 2 3
C5	4	0 1 2 3

Figure 14.3 displays the "Number of Observations" table. All 100 observations in the data set are used in the analysis.

Figure 14.3 Number of Observations

Number of Observations Read	100
Number of Observations Used	100

Figure 14.4 displays the "Dimensions" table for this model. This table summarizes some important sizes of various model components. For example, it shows that there are 21 columns in the design matrix $\mathbf{X}$: 1 column for the intercept and 20 columns for the effects that are associated with the classification variables C1–C5. However, the rank of the crossproducts matrix is only 16. Because the classification variables C1–C5 use GLM parameterization and because the model contains an intercept, there is one singularity in the crossproducts matrix of the model for each classification variable. Consequently, only 16 parameters enter the optimization.

Figure 14.4 Dimensions in Poisson Regression

Dimensions	
Columns in Design	21
Number of Effects	6
Max Effect Columns	4
Rank of Design	16
Parameters in Optimization	16

Figure 14.5 displays the final convergence status of the Newton-Raphson algorithm. The FCONV= convergence criterion is satisfied.

Figure 14.5 Convergence Status

Convergence criterion (FCONV=1E-7) satisfied.

The "Fit Statistics" table is shown in Figure 14.6. The –2 log likelihood at the converged estimates is 290.16169. You can use this value to compare the model to nested model alternatives by means of a likelihood ratio test. To compare models that are not nested, information criteria such as AIC (Akaike's information criterion), AICC (Akaike's bias-corrected information criterion), and BIC (Schwarz Bayesian information criterion) are used. These criteria penalize the –2 log likelihood for the number of parameters.

Figure 14.6 Fit Statistics

Fit Statistics	
-2 Log Likelihood	290.16169
AIC (smaller is better)	322.16169
AICC (smaller is better)	328.71590
SBC (smaller is better)	363.84441

The "Parameter Estimates" table in Figure 14.7 shows that many parameters have fairly large *p*-values, indicating that one or more of the model effects might not be necessary.

Figure 14.7 Parameter Estimates

Parameter Estimates

Parameter	DF	Estimate	Standard Error	Chi-Square	Pr > ChiSq
Intercept	1	0.881904	0.382730	5.3095	0.0212

Syntax: GENSELECT Procedure

The following statements are available in the GENSELECT procedure:

PROC GENSELECT < *options* > ;
BY *variables* ;
CLASS *variable* < **(***options***)** >. . . < *variable* < **(***options***)** > > < / *global-options* > ;
CODE < *options* > ;
DISPLAY < *table-list* > < / *options* > ;
DISPLAYOUT *table-spec-list* < / *options* > ;
EFFECT *name***=***effect-type***(***variables* < / *options* >**)** ;
FREQ *variable* ;
MODEL *response*< **(***response-options***)** > **=** < *effects* > < / *model-options* > ;
MODEL *events/trials*< **(***response-options***)** > **=** < *effects* > < / *model-options* > ;
LSMEANS < *model-effects* > < / *options* > ;
OUTPUT OUT=*libref.data-table* < *keyword* < **=***name* > >. . . < *keyword* < **=***name* > > < *options* > ;
PARTITION < *partition-options* > ;
REPEATED SUBJECT=*subject-effect* < / *repeated-options* > ;
RESTRICT *constraint-specification* < / *restriction-options* > ;
SELECTION < **METHOD=***method* < *(method-options)* > >< *options* > ;
STORE < **OUT=** >*libref.data-table* ;
WEIGHT *variable* < / **NORMALIZE** > ;

The PROC GENSELECT statement and a MODEL statement are required. The CLASS statement can appear multiple times. If a CLASS statement is specified, it must precede the MODEL statement.

PROC GENSELECT Statement

PROC GENSELECT < *options* > ;

The PROC GENSELECT statement invokes the procedure. Table 14.1 summarizes the available *options* in the PROC GENSELECT statement by function. They are then described fully in alphabetical order.

Table 14.1 PROC GENSELECT Statement Options

Option	Description
Basic Options	
ALPHA=	Specifies a global significance level
APPLYROWORDER	Uses group and order information from the input data table
DATA=	Specifies the input data table
FITDATA	Declares the DATA= table to be the same input data table used to build the model
INPARMEST=	Specifies starting values for the optimization
MAXRESPONSELEVELS=	Specifies the maximum number of response levels allowed when you have a polytomous response variable
PAGEOBS=	Specifies the maximum number of observations to be computed in each batch

Table 14.1 *continued*

Option	Description
RESTORE=	Specifies the input analytic store
SEED=	Specifies the random number seed for LS-means and partition fractions
Options Related to Output	
CLB	Constructs confidence limits for the parameter estimates
CORRB	Displays the "Parameter Estimates Correlation Matrix" table
COVB	Displays the "Parameter Estimates Covariance Matrix" table
ITHIST	Displays the "Iteration History" table
NOCHECK	Disables checking for infinite parameters
NOCLPRINT	Limits or suppresses the display of classification variable levels
NOSTDERR	Suppresses computation of the covariance matrix and standard errors
NOXPX	Suppresses computation of the Hessian matrices
PARTFIT	Displays the fit statistics that are produced when your data are partitioned
STB	Displays standardized estimates
TYPE3	Produces the Type 3 or joint tests of effects
USELASTITER	Continues computations when the optimization fails
Options Related to Optimization	
ABSCONV=	Tunes the absolute function convergence criterion
ABSFCONV=	Tunes the absolute function difference convergence criterion
ABSGCONV=	Tunes the absolute gradient convergence criterion
ABSXCONV=	Tunes the absolute parameter convergence criterion
FCONV=	Tunes the relative function difference convergence criterion
FCONV2=	Tunes the second relative function difference convergence criterion
GCONV=	Tunes the relative gradient convergence criterion
GCONV2=	Tunes the second relative gradient convergence criterion
XCONV=	Tunes the relative gradient convergence criterion
MAXFUNC=	Specifies the maximum number of function evaluations in any optimization
MAXITER=	Chooses the maximum number of iterations in any optimization
MAXTIME=	Specifies the upper limit of CPU time (in seconds) for any optimization
MINITER=	Specifies the minimum number of iterations in any optimization
NORMALIZE=	Specifies whether the objective function is normalized during optimization
TECHNIQUE=	Selects the optimization technique
LASSO Options	
LASSORHO=	Specifies the base regularization parameter for the LASSO method
LASSOSTEPS=	Specifies the maximum number of steps for the LASSO method
LASSOTOL=	Specifies the convergence criterion for the LASSO method

The optimization options are fully described in the section "Optimization Options" on page 57 in Chapter 2, "Shared Concepts." The following list describes the other options available in the PROC GENSELECT statement:

ALPHA=*number*
specifies a global significance level for the construction of confidence intervals. The confidence level is 1 – *number*. The value of *number* must be between 0 and 1. You can override this global significance level by specifying this option in the OUTPUT statement. By default, ALPHA=0.05.

APPLYROWORDER
uses group and order information from the input data table. You can add this information to the input table by using the **`partition`** action in the **`table`** action set. For more information, see the section "The APPLYROWORDER Option" on page 107 in Chapter 2, "Shared Concepts." By default, the APPLYROWORDER option is not enabled. If you specify this option but the table does not contain group and order information, the procedure terminates with an error.

NOTE: You can use group and order information for a repeated measures analysis if the group information meets certain criteria. For more information, see the section "Using a Preexisting Table Order" on page 767.

CLB
constructs confidence limits for each of the parameter estimates. The confidence level is 0.95 by default; you can change it by specifying the ALPHA= option. This option is not available when you use either LASSO selection or elastic net selection.

CORRB
creates the "Parameter Estimates Correlation Matrix" table. The correlation matrix is computed by normalizing the covariance matrix $\mathbf{\Sigma}$. That is, if σ_{ij} is an element of $\mathbf{\Sigma}$, then the corresponding element of the correlation matrix is $\sigma_{ij}/\sigma_i\sigma_j$, where $\sigma_i = \sqrt{\sigma_{ii}}$. This option is not available when you use either LASSO selection or elastic net selection.

COVB
creates the "Parameter Estimates Covariance Matrix" table. The covariance matrix is computed as the inverse of the negative of the matrix of second derivatives of the log-likelihood function with respect to the model parameters (the Hessian matrix). This option is not available when you use either LASSO selection or elastic net selection.

DATA=*libref.data-table*
names the input data table for PROC GENSELECT to use. The default is the most recently created data table. *libref.data-table* is a two-level name, where

libref refers to a collection of information that is defined in the LIBNAME statement and includes the library, which includes a path to the data, and a session identifier, which defaults to the active session but which can be explicitly defined in the LIBNAME statement. For more information about *libref*, see the section "Using CAS Sessions and CAS Engine Librefs" on page 707.

data-table specifies the name of the input data table.

FITDATA
declares the DATA= table to be the same input data table that is used for building the model, when you also specify the RESTORE= option. The FITDATA option enables you to specify the PARTFIT option to produce more fit statistics, to compute all the statistics from the OUTPUT statement that are available for your model, and to group computations according to the partition roles.

INPARMEST=*libref.data-table*
names an input data table that contains starting values. *libref.data-table* is a two-level name, where *libref* refers to the library, and *data-table* specifies the name of the output data table. For more information about this two-level name, see the DATA= option and the section "Using CAS Sessions and CAS Engine Librefs" on page 707.

The input data table must contain an Estimate column and a ParmName column, and it can optionally contain your BY variables. You can create a version of this table by using a DISPLAYOUT statement to produce the "Parameter Estimates" table from a PROC GENSELECT program. For example:

```
displayout parameterestimates=pe;
```

You can then modify the parameter estimates in this table and read them back in by using the following statement:

```
proc genselect inparmest=mylib.pe;
```

ITHIST
generates the "Iteration History" table.

LASSORHO=*r*
specifies the base regularization parameter for the LASSO model selection method. The regularization parameter for step i is r^i. By default, LASSORHO=0.8.

LASSOSTEPS=*n*
specifies the maximum number of steps for LASSO model selection. By default, LASSOSTEPS=20.

LASSOTOL=*r*
specifies the convergence tolerance for the optimization algorithm that solves for the LASSO parameter estimates at each step of LASSO model selection. By default, LASSOTOL=1E–6.

MAXRESPONSELEVELS=*value*
specifies the maximum number of response levels that are allowed when you have a polytomous response variable. By default, MAXRESPONSELEVELS=100.

NOCHECK
disables the checking process that determines whether maximum likelihood estimates of the regression parameters exist. For more information, see the section "Existence of Maximum Likelihood Estimates" on page 759.

NOCLPRINT<=*number*>
suppresses the display of the "Class Level Information" table if you do not specify *number*. If you specify *number*, the values of the classification variables are displayed for only those variables whose number of levels is less than *number*. Specifying *number* helps to reduce the size of the "Class Level Information" table if some classification variables have a large number of levels.

NOSTDERR
suppresses computation of the covariance matrix and the standard errors of the regression coefficients. When the model contains many variables (thousands), the inversion of the Hessian matrix to derive the covariance matrix and the standard errors of the regression coefficients can be time-consuming. The CORRB, COVB, and TYPE3 options are not available when the NOSTDERR option is specified. This option also disables the quasi-complete separation check; for more information, see the section "Existence of Maximum Likelihood Estimates" on page 759.

NOXPX
suppresses Hessian and $\mathbf{X}'\mathbf{X}$ computations and invokes the NOSTDERR option. When the model contains many variables (thousands), computing the Hessian matrix during model fitting can be time-consuming. The CLB, CORRB, COVB, and TYPE3 options, the REPEATED statement, the OUTPUT statement options that rely on the covariance, and confidence limits for the parameters and for the OUTPUT and LSMEANS statements are not available when you specify the NOXPX option. The forward, backward, and stepwise selection methods are not available; however, you can specify the LASSO and elastic net methods. This option invokes the TECHNIQUE=LBFGS option by default, and the NEWRAP, NRRIDG, and TRUREG optimization techniques are not available. Because the method of identifying linearly dependent variables relies on the $\mathbf{X}'\mathbf{X}$ matrix, some parameters that should be assigned 0 degrees of freedom can be missed.

PAGEOBS=*number* | **AUTO**

MAXOPTBATCH=*number* | **AUTO**
specifies the maximum number of observations to be included in a batch. During the optimization, the GENSELECT procedure reads at most *number* observations from the data table into memory; performs the appropriate log-likelihood, gradient, and Hessian computations on that batch of observations; then discards those observations and reads in the next batch of data for processing. Generally, a smaller *number* decreases memory usage but might lead to longer computation times, whereas a larger *number* might lead to shorter computation times but increases memory usage. The default PAGEOBS=AUTO option determines whether the entire data table can be held in a subset of your available memory; if it cannot, then *number* is set to 256.

PARTFIT
displays fit statistics in the "Fit Statistics" table that are usually produced when your data are partitioned. This option is not required when you specify a PARTITION statement. The statistic that is added to the table is the average square error (or Brier score).

RESTORE=*libref.data-table*
specifies the name of the analytic store that contains the context and results of a model that is selected and stored from a previous statistical analysis. The analytic store is created by a STORE statement from a previous PROC GENSELECT call or by a **`store`** parameter that is specified in a previous **`genmod`** action call.

The displayed output can include the following content:

- information about the analytic store
- notes that are stored by the TEXT= option of the STORE statement
- a Replay section, consisting of tables that are produced when the stored model is fit
- a Restore section, consisting of tables that are produced by applying the stored model to a specified input data table

You can specify the STB and CLB options in the PROC GENSELECT statement to modify the "Parameter Estimates" table; you can specify the CORRB, COVB, and TYPE3 options to display those tables; you can specify the CODE statement to produce SAS code for scoring; and you can specify LSMEANS statements to compute least squares means. If you specify a DATA= data table, then you can also specify the PARTFIT option, and you can score that data table by specifying the OUTPUT statement.

If the analytic store is created using BY-group processing, then the results are displayed according to each BY group. If you specify a DATA= input data table, then you must also specify the same BY statement that was used to create the store.

If a PARTITION statement is used to create the stored model, then the Replay section displays only information that is computed from the original training data. For the Restore section, if you create the partition for the stored model by using a ROLE variable and also specify the FITDATA option, then the ROLE variable must exist in the DATA= table and the Restore section displays results according to the roles. However, if the partitions for the stored model are created using a FRACTION option, then the roles are ignored because the roles cannot be reliably re-created; this means that output statistics that rely on the input data are not computed.

Because the selected model from a previous analysis is stored, statements and options specific to model specification, selection, and optimization are not available. In particular, the CLASS, EFFECT, FREQ, MODEL, PARTITION, REPEATED, SELECTION, STORE, and WEIGHT statements are not available to be used with the RESTORE= option.

libref.data-table is a two-level name, where *libref* refers to the library, and *data-table* specifies the name of the input data table. For more information about this two-level name, see the DATA= option and the section "Using CAS Sessions and CAS Engine Librefs" on page 707.

SEED=*number*

specifies an integer to be used to start the pseudorandom number generator for the LSMEANS statement's ADJUST=SIMULATE option and for the PARTITION statement's FRACTION option. If you do not specify a seed, or if you specify a *number* less than or equal to 0, the seed is generated by reading the time of day from the computer's clock.

STB

displays the standardized estimates of the parameters in the "Parameter Estimates" table. The standardized estimate of β_i is given by $\widehat{\beta}_i/(s/s_i)$, where s_i is the total sample standard deviation for the ith explanatory variable and

$$s = \begin{cases} \pi/\sqrt{3} & \text{LOGIT and GLOGIT links} \\ \pi/\sqrt{6} & \text{CLOGLOG and LOGLOG links} \\ 1 & \text{all other links} \end{cases}$$

The sample standard deviations for parameters that are associated with CLASS variables are computed using their codings. The standardized estimates are not computed for the intercept parameters.

TYPE3
computes Wald statistics for Type 3 contrasts for each effect that you specify in the MODEL statement. This option is not available for models that you fit by using the GEE method. This option is also not available when you use either LASSO selection or elastic net selection. For more information, see the section "Joint Tests and Type 3 Tests" on page 772.

USELASTITER
continues to perform computations by using the last iteration of the optimization when the optimization fails. By default, computations cease when a failure occurs.

BY Statement

BY *variables* **;**

You can specify a BY statement in PROC GENSELECT to obtain separate analyses of observations in groups that are defined by the values of the BY variables. If you specify more than one BY statement, only the last one specified is used. For more information, see the discussion of BY-group processing in the "Grouping Data" section of *SAS Programmers Guide: Essentials*.

CLASS Statement

CLASS *variable* <**(***options***)**>. . . <*variable* <**(***options***)**>> </ *global-options*> **;**

The CLASS statement names the classification variables to be used as explanatory variables in the analysis. You can list the response variable for binary models in the CLASS statement, but this is not required. Table 14.2 summarizes the values that you can use for either an *option* or a *global-option*. The options are fully documented in the section "CLASS Statement" on page 9 in Chapter 2, "Shared Concepts."

Table 14.2 CLASS Statement Options

Option	Description
DESCENDING	Reverses the sort order
MISSING	Treats missing values as valid levels
ORDER=	Specifies the sort order for the levels
PARAM=	Specifies the parameterization of the variable
REF=	Specifies the reference level of the variable
SPLIT	Splits levels of CLASS variables into independent effects

CODE Statement

CODE < *options* > **;**

The CODE statement writes SAS DATA step code for computing predicted values of the fitted model to a file or to a table. To score new data, you can then include the file in a DATA step, or you can specify the table in the **`runCodeTable`** action in the **`dataStep`** action set (for more information, see *SAS Viya: System Programming Guide*).

Table 14.3 summarizes the *options* available in the CODE statement.

Table 14.3 CODE Statement Options

Option	Description
COMMENT	Adds comments to the generated code
FILE=	Names the file in which to save the generated code
FORMATWIDTH=	Specifies the numeric format width for the regression coefficients
INDENTSIZE=	Specifies the number of spaces to indent the generated code
LABELID=	Specifies a number used to construct names and labels
LINESIZE=	Specifies the line size for the generated code
NOTRIM	Compares formatted values, including blank padding
OUT=	Names an output table in which to save the generated code

For more information about the syntax of the CODE statement, see the section "CODE Statement" on page 13 in Chapter 2, "Shared Concepts."

DISPLAY Statement

DISPLAY < *table-list* > < / *options* > **;**

The DISPLAY statement enables you to specify a list of display tables to display or exclude. This statement is similar to the ODS SELECT, ODS EXCLUDE, and ODS TRACE statements. However, the DISPLAY statement can improve performance when a large number of tables could be generated (such as in BY-group processing). The procedure processes the DISPLAY statement on a CAS server and thus sends only a subset of ODS tables to the SAS client. Because ODS statements are processed on a SAS client, first all the generated display tables are sent to the client, and then the client creates a subset.

If you use both DISPLAY and ODS statements together, the DISPLAY statement takes precedence over the ODS statements. Note that the ODS EXCLUDE statement processes tables that are sent to the client after they have been filtered by the DISPLAY statement. In some cases, it might appear that the ODS EXCLUDE statement is taking precedence because it can further filter the tables. For more information about ODS, see *SAS Output Delivery System: Procedures Guide*.

You can specify the *table-list* as a list of table names, paths, partial pathnames, and regular expressions.

The table names that you can specify are listed in the section "ODS Table Names" on page 780. A path is a table name that is prefixed with dot-separated grouping information. For example, a

SelectionSummary table that a procedure produces during a selection routine might have the path *Bygroup1.Summary.SelectionSummary*. A partial pathname does not include all groups; for example, *SelectionSummary* and *Summary.SelectionSummary* are partial pathnames for *Bygroup1.Summary.SelectionSummary*.

When you specify a table name or partial pathname, all display tables whose paths end in the specified name are selected for display or exclusion. For example, both *SelectionSummary* and *Summary.SelectionSummary* select *Bygroup1.Summary.SelectionSummary*.

A regular expression is enclosed in forward slashes (/). For example, specifying "/tions/" selects all pathnames that contain the substring "tions"; in particular, the *Bygroup1.Summary.SelectionSummary* table is selected. Specifying "!/tions/" selects all pathnames that do not contain the substring "tions"; in particular, the *Bygroup1.Summary.SelectionSummary* table is not selected.

You can specify the following *options* after a slash (/):

CASESENSITIVE
performs a case-sensitive comparison of table names in the *table-list* to display table names when tables are subsetted for display. To preserve case, you must enclose table names in the *table-list* in quotation marks.

EXCLUDE
displays all display tables except those that you specify in the *table-list*.

EXCLUDEALL
suppresses display of all tables. This option takes precedence over the other options.

TRACE
displays the display table names, labels, and paths.

DISPLAYOUT Statement

DISPLAYOUT *table-spec-list* < / *options* > **;**

The DISPLAYOUT statement enables you to create output tables from your displayed output. This statement is similar to the ODS OUTPUT statement. For more information about ODS, see *SAS Output Delivery System: Procedures Guide*.

The *table-spec-list* specifies a list of output tables to create. Each entry in the list has either a *key=value* format or a *key* format:

key=value specifies *key* as the ODS table name, path, or partial pathname, and specifies *value* as the output table name.

key specifies *key* as the ODS table name and also as the output table name.

The ODS table names that you can specify are listed in the section "ODS Table Names" on page 780. You cannot specify the ODS table named OutputCasTables in the *table-spec-list*.

Table names and partial pathnames are discussed under the DISPLAY statement. The DISPLAYOUT statement does not support regular expressions.

You can specify the following *options* after a slash (/):

INCLUDEALL
creates output tables for all display tables. The name of the created output table is the same as the name of the corresponding display table. If you specify this option, the *table-spec-list* specification is ignored.

NOREPLACE
does not replace any existing output table of the same name.

REPEATED
replicates all output tables on all nodes.

EFFECT Statement

EFFECT *name*=*effect-type* **(***variables* < / *options* >**) ;**

The EFFECT statement enables you to construct special collections of columns for design matrices. These collections are referred to as *constructed effects* to distinguish them from the usual model effects that are formed from continuous or classification variables, as discussed in the section "GLM Parameterization of Classification Variables and Effects" on page 67 in Chapter 2, "Shared Concepts."

You can specify the following *effect-types*:

COLLECTION specifies a collection effect that defines one or more variables as a single effect that has multiple degrees of freedom. The variables in a collection are considered as a unit for purposes of estimation and inference.

MULTIMEMBER | MM specifies a multimember classification effect whose levels are determined by one or more variables that appear in a CLASS statement.

POLYNOMIAL | POLY specifies a multivariate polynomial effect in the specified numeric variables.

SPLINE specifies a regression spline effect whose columns are univariate spline expansions of one or more variables. A spline expansion replaces the original variable with an expanded or larger set of new variables.

Table 14.4 summarizes the *options* available in the EFFECT statement.

Table 14.4 EFFECT Statement Options

Option	Description
Collection Effects Options	
DETAILS	Displays the constituents of the collection effect

Table 14.4 *continued*

Option	Description
Multimember Effects Options	
DETAILS	Displays the levels of the multimember effect
NOEFFECT	Specifies that observations whose levels are all missing for the multimember variables should have 0 values in the corresponding design matrix columns
STDIZE	Standardizes the design matrix entries so that each observation has a sum of 1
WEIGHT=	Specifies the weight variable for the contributions of each classification effect
Polynomial Effects Options	
DEGREE=	Specifies the degree of the polynomial
DETAILS	Displays details of the specified polynomial
MDEGREE=	Specifies the maximum degree of any variable in a term of the polynomial
NOSEPARATE	Treats the polynomial as a single effect with multiple degrees of freedom
STANDARDIZE=	Specifies centering and scaling suboptions for the variables that define the polynomial
Spline Effects Options	
BASIS=	Specifies the type of basis (B-spline basis or truncated power function basis) for the spline effect
DATABOUNDARY	Uses the extremes of the data as boundary knots for a B-spline basis
DEGREE=	Specifies the degree of the spline effect
DETAILS	Displays the knots and locations for each spline basis function
KNOTMAX=	Requests equally spaced right-side boundary knots starting at the variables' maximum and ending at the KNOTMAX= value
KNOTMETHOD=	Specifies how to construct the knots for the spline effect
KNOTMIN=	Requests equally spaced left-side boundary knots starting at the KNOTMIN= value and ending at the variables' minimum value
NATURALCUBIC	Specifies a natural cubic spline basis for the spline effect
SEPARATE	Treats the spline basis for each variable as a separate effect when multiple variables are specified
SPLIT	Treats each design matrix column as a separate effect for selection methods

For more information about the syntax of these *effect-types* and how columns of constructed effects are computed, see the section "EFFECT Statement" on page 18 in Chapter 2, "Shared Concepts."

FREQ Statement

FREQ *variable* **;**

The *variable* in the FREQ statement identifies a numeric variable in the input data table that contains the frequency of occurrence of each observation. PROC GENSELECT treats each observation as if it appears f times, where f is the value of the FREQ *variable* for the observation. If f is not an integer, it is truncated to an integer. If f is less than 1 or missing, the observation is not used in the analysis. When you omit the FREQ statement, each observation is assigned a frequency of 1.

In the case of models that are fit using generalized estimating equations (GEEs), the frequencies apply to the subject, so the frequency must be the same for all observations within each subject.

LSMEANS Statement

LSMEANS *model-effects* < / *options* > **;**

LSMEANS EFFECT=*model-effects* < / *options* > **;**

The LSMEANS statement computes and compares least squares means (LS-means) of fixed effects. LS-means are *predicted population margins*—that is, they estimate the marginal means over a balanced population. In a sense, LS-means are to unbalanced designs as class and subclass arithmetic means are to balanced designs.

LS-means can be computed for any effect in the procedure's MODEL statement that involves only classification variables. You can specify multiple *model-effects* in one or more LSMEANS statements that appear after the MODEL statement. When you restore a model from an item store, you must specify the desired *model-effects* in the EFFECT= option before the slash (/).

Table 14.5 summarizes the *options* available in the LSMEANS statement.

Table 14.5 LSMEANS Statement Options

Option	Description
Construction and Computation of LS-Means	
AT	Modifies covariate values used to compute LS-means
ATVAR	Modifies covariate values for restored models
DIFF	Computes differences of LS-means
SINGULAR=	Tunes estimability checking
***p*-Values**	
ADJUST=	Specifies the multiple comparison adjustment method for LS-means differences
ALPHA=α	Specifies the confidence level ($1-\alpha$)
Statistical Output	
CL	Constructs confidence limits for means and mean differences
CORR	Displays the correlation matrix of LS-means
COV	Displays the covariance matrix of LS-means
E	Displays the $\mathbf{L}$ matrix

For more information about the syntax of the LSMEANS statement, see the section "LSMEANS Statement" on page 34 in Chapter 2, "Shared Concepts."

LS-means analysis is not available if you use LASSO or elastic net selection.

MODEL Statement

MODEL *response* < **(***response-options***)** > **=** < *effects* > < / *model-options* > **;**

MODEL *events* / *trials* < **(***response-options***)** > **=** < *effects* > < / *model-options* > **;**

The MODEL statement defines the statistical model in terms of a *response* variable (the target) or an *events/trials* specification, model *effects* that are constructed from variables in the input data table, and *model-options*. An intercept is included in the model by default. You can remove the intercept by specifying the NOINT option.

You can specify a single *response* variable that contains your response values. When you have binomial data, you can specify the *events/trials* form of the response, where one variable contains the number of positive responses (or events) and another variable contains the number of trials. Note that the values of both *events* and (*trials* – *events*) must be nonnegative and the value of *trials* must be positive.

For information about constructing the model effects, see the section "Specification and Parameterization of Model Effects" on page 64 in Chapter 2, "Shared Concepts."

There are two sets of options in the MODEL statement. The *response-options* determine how the GENSELECT procedure models probabilities for binary and multinomial data. The *model-options* control other aspects of model formation and inference. Table 14.6 summarizes these options.

Table 14.6 MODEL Statement Options

Option	Description
Response Variable Options	
DESCENDING	Reverses the response categories
EVENT=	Specifies the event category
ORDER=	Specifies the sort order
REF=	Specifies the reference category
Model Options	
CENTER	Centers and scales continuous main effects
CENTERLASSO	Centers and scales all effects for model selection by the LASSO method and the elastic net method
CLB	Requests confidence limits
DISTRIBUTION=	Specifies the response distribution
INCLUDE=	Includes effects in all models for model selection
INFORMATIVE	Models missing values by using extra indicator variables
LINK=	Specifies the link function
NOINT	Suppresses the intercept
OFFSET=	Specifies the offset variable
PHI=	Specifies a fixed dispersion parameter

Table 14.6 *continued*

Option	Description
START=	Includes effects in the initial model for model selection
TYPE3	Displays the Type 3 or joint tests of effects

Response Variable Options

Response variable options determine how the GENSELECT procedure models probabilities for binary and multinomial data.

You can specify the following *response-options* by enclosing them in parentheses after the *response* or *trials* variable.

DESCENDING

DESC

reverses the order of the response categories. If you specify both the DESCENDING and ORDER= options, PROC GENSELECT orders the response categories according to the ORDER= option and then reverses that order.

EVENT='*category***' | FIRST | LAST**

specifies the event category for the binary and multinomial response model. PROC GENSELECT models the probability of the event category. The EVENT= option has no effect when there are more than two response categories.

You can specify one of the following:

'*category*'

specifies the value (formatted, if a format is applied) of the event category in quotation marks.

FIRST

designates the first ordered category as the event.

LAST

designates the last ordered category as the event.

By default, EVENT=FIRST.

For example, the following statements specify that observations whose formatted value is 1 represent events in the data. The probability that PROC GENSELECT models is thus the probability that the variable def takes the (formatted) value 1.

```
proc genselect data=mylib.MyData;
   class A B C;
   model def(event ='1') = A B C x1 x2 x3;
run;
```

ORDER=FORMATTED | FREQ | INTERNAL
specifies the sort order for the levels of the *response* variable. You can specify the following values:

FORMATTED sorts the levels by external formatted value, except for numeric variables that have no explicit format, which are sorted by their unformatted (internal) value. For numeric variables for which you have supplied no explicit format (that is, for which there is no corresponding FORMAT statement in the current PROC GENSELECT run or in the DATA step that created the data table), the levels are ordered by their internal (numeric) value. The sort order is machine-dependent.

FREQ sorts the levels by descending frequency count (levels that have the most observations come first in the order).

INTERNAL sorts the levels by unformatted value. The sort order is machine-dependent.

By default, ORDER=FORMATTED.

For more information about sort order, see the chapter on the SORT procedure in the *Base SAS Procedures Guide* and the discussion of BY-group processing in *SAS Programmers Guide: Essentials*.

REF='*category***' | FIRST | LAST**
specifies the reference category for the generalized logit model and the binary response model. For the generalized logit model, each logit contrasts a nonreference category with the reference category. For the binary response model, specifying one response category as the reference is the same as specifying the other response category as the event. You can specify one of the following:

'*category*'
specifies the value (formatted, if a format is applied) of the reference category in quotation marks.

FIRST
designates the first ordered category as the reference.

LAST
designates the last ordered category as the reference.

By default, REF=LAST.

Model Options

You can specify the following *model-options* after a slash (/):

CENTER
centers and scales continuous main effects for internal computation. (Continuous main effects are centered and scaled to aid in computing maximum likelihood estimates.) Parameter estimates and related statistics are always reported on the original scale. This option has no effect if you specify the LASSO model selection method or the elastic net selection method; instead, you should specify the CENTERLASSO option.

CENTERLASSO< =TRUE | FALSE >
specifies whether all effects, including categorical effects, are centered and scaled internally for the LASSO model selection method or the elastic net selection method. (Effects are centered and scaled to aid in model selection.) Parameter estimates and related statistics are always reported on the original scale. By default, CENTERLASSO=TRUE.

CLB
constructs confidence limits for each parameter estimate. The confidence level is 0.95 by default; you can change it by specifying the ALPHA= option. The CLB option is not available when you use either LASSO selection or elastic net selection.

DISTRIBUTION=*keyword*
specifies the response distribution for the model. The *keywords* and the associated distributions are shown in Table 14.7. For information about default and commonly used link functions for each distribution function, see Table 14.9.

Table 14.7 Built-In Distribution Functions

Keyword	Distribution Function
BETA	Beta
BINARY	Binary
BINOMIAL	Binary or binomial
EXPONENTIAL	Exponential
GAMMA	Gamma
GENPOISSON | GPOISSON	Generalized Poisson
GEOMETRIC	Geometric
IGAUSSIAN | IG	Inverse Gaussian
LOGNORMAL | LOGN	Lognormal
MULTINOMIAL	Multinomial. For ordinal responses, it fits a model that has a cumulative link function. For nominal responses, it fits a model that has a generalized logit link function.
NEGATIVEBINOMIAL | NB	Negative binomial
NORMAL | GAUSSIAN	Normal
POISSON	Poisson
T<ν>	t with ν degrees of freedom. If you do not specify ν, a value of $\nu = 3$ is used.
TWEEDIE< (*Tweedie-options*) >	Tweedie
WEIBULL	Two-parameter Weibull

When DISTRIBUTION=TWEEDIE, you can specify the following *Tweedie-options*:

EQL
uses extended quasi-likelihood instead of Tweedie log likelihood in parameter estimation.

INITIALP=*value*
specifies a starting *value* for iterative estimation of the Tweedie power parameter.

OPTMETHOD=*Tweedie-optimization-option*
specifies the optimization method for iterative estimation of the Tweedie model parameters. You can specify the following *Tweedie-optimization-options*:

EQL
uses extended quasi-likelihood for a sample of the data, followed by extended quasi-likelihood for the full data. This is equivalent to the EQL *Tweedie-option*.

EQLLHOOD
uses extended quasi-likelihood for a sample of the data, followed by Tweedie log likelihood for the full data. This is the default method.

FINALLHOOD
uses a four-stage approach to estimating the Tweedie model parameters. The four stages are as follows:

1. extended quasi-likelihood for a sample of the data
2. Tweedie log likelihood for a sample of the data
3. extended quasi-likelihood for the full data
4. Tweedie log likelihood for the full data

LHOOD
uses Tweedie log likelihood be for a sample of the data, followed by Tweedie log likelihood for the full data.

P=*value*
specifies a *value* to use as a fixed Tweedie power parameter.

SAMPLEFRAC=*value*
specifies a *value* to use as the fraction of the data that are used to compute starting values for the Tweedie distribution. The *value* must be between 0 and 1.

INCLUDE=*n*

INCLUDE=*single-effect*

INCLUDE=(*effect-list***)**
forces effects to be included in all models. If you specify INCLUDE=*n*, then the first *n* effects that are listed in the MODEL statement are included in all models. If you specify INCLUDE=*single-effect* or if you specify a list of effects within parentheses, then the specified effects are forced into all models. The effects that you specify in the INCLUDE= option must be explanatory effects that are specified in the MODEL statement before the slash (/). This option is not available if you use elastic net selection.

INFORMATIVE

models missing values by using extra model effects. These effects consist of dummy variables that take the value 1 when the value of a continuous model variable involved in the effect is missing, and take the value 0 otherwise. The missing value in the original model effect is replaced by the average value of the effect for the nonmissing values. For continuous-by-class effects, such as A*x, where A is a classification variable and x is a continuous variable, informative missingness creates multiple dummy columns and substitutes the effect mean of x that corresponds to the respective level of A. Missing values for classification variables are treated as valid levels. For more information about informative missingness, see the section "Informative Missingness" on page 99 in Chapter 2, "Shared Concepts."

LINK=*keyword*

specifies the link function for the model. The *keywords* and their associated link functions are shown in Table 14.8. Default and commonly used link functions for the available distributions are shown in Table 14.9.

Table 14.8 Built-In Link Functions

Keyword	Link Function	$g(\mu) = \eta =$
CLOGLOG | CLL	Complementary log-log or cumulative complementary log-log	$\log(-\log(1-\mu))$
GLOGIT	Generalized logit	$\log(\mu_j/\mu_J)$
IDENTITY | ID	Identity	μ
INVERSE | RECIPROCAL | RECIP	Reciprocal	$\frac{1}{\mu}$
POWERMINUS2 | INV2 | POWMINUS2	Reciprocal square	$\frac{1}{\mu^2}$
POWER(p)	Power	μ^p
LOG	Logarithm	$\log(\mu)$
LOGIT	Logit or cumulative logit	$\log(\mu/(1-\mu))$
LOGLOG	Log-log or cumulative log-log	$-\log(-\log(\mu))$
PROBIT | NORMIT	Probit or cumulative probit	$\Phi^{-1}(\mu)$

For the probit and cumulative probit links, $\Phi^{-1}(\cdot)$ denotes the quantile function of the standard normal distribution.

If you do not specify the LINK= option, a default link function is used, as shown in Table 14.9. For binary or multinomial distributions, only the link functions shown in Table 14.9 are available. For the other distributions, you can use any link function shown in Table 14.8 by specifying the LINK= option. Other commonly used link functions for each distribution are shown in Table 14.9.

Table 14.9 Default and Commonly Used Link Functions

Value of the DISTRIBUTION= Option	Default Link Function	Other Commonly Used Link Functions
BETA	Logit	Probit, complementary log-log, log-log
BINARY	Logit	Probit, complementary log-log, log-log
BINOMIAL	Logit	Probit, complementary log-log, log-log
EXPONENTIAL	Log	
GAMMA	Log	
GENPOISSON | GPOISSON	Log	
GEOMETRIC	Log	
INVERSEGAUSSIAN | IG	Log	
LOGNORMAL | LOGN	Identity	
MULTINOMIAL	Cumulative logit	Cumulative probit, cumulative complementary log-log, cumulative log-log, generalized logit
NEGATIVEBINOMIAL | NB	Log	
NORMAL | GAUSSIAN	Identity	Log
POISSON	Log	
T	Identity	
TWEEDIE	Log	
WEIBULL	Log	

NOINT
includes no intercept in the model. An intercept is included by default. The NOINT option is not available for multinomial models.

OFFSET=*variable*
specifies a *variable* to be used as an offset to the linear predictor. An offset plays the role of an effect whose coefficient is known to be 1. The offset variable cannot appear in the CLASS statement or elsewhere in the MODEL statement. Observations that have missing values for the offset variable are excluded from the analysis.

PHI=*number*
specifies a fixed dispersion parameter for those distributions that have a dispersion parameter. The dispersion parameter that is used in all computations is fixed at *number* and not estimated.

START=*n*

START=*single-effect*

START=(*effects***)**
begins the selection process from the designated initial model for the forward selection method. If you specify START=*n*, then the starting model includes the first *n* effects that are listed in the MODEL statement. If you specify START=*single-effect* or START=(*effects*), then the starting model includes those specified effects. The effects that you specify in the START= option must be explanatory effects that are specified in the MODEL statement before the slash (/). This option is not available when you specify METHOD=BACKWARD or ELASTICNET in the SELECTION statement.

TYPE3
computes Wald statistics for Type 3 contrasts for each effect that you specify in the MODEL statement. This option is not available for models that you fit by using the GEE method. For more information, see the section "Joint Tests and Type 3 Tests" on page 772.

OUTPUT Statement

OUTPUT OUT=*libref.data-table*
< **ALL** > < **ALPHA=***number* > < **COPYVARS=***(variables)* >
< *keyword* < **=***name* > >. . . < *keyword* < **=***name* > > **;**

The OUTPUT statement creates a data table that contains observationwise statistics that PROC GENSELECT computes after fitting the model. In order to avoid data duplication for large data tables, the variables in the input data table are *not* included in the output data table unless you specify them in the COPYVAR= option.

If the response variable has more than two categories, you can request the "Basic Options" listed in Table 14.10; the other diagnostic statistics are not available. These statistics are computed for every response category, and the automatic variable _LEVEL_ identifies the response category on which the computed values are based. That is, every observation generates several rows in the output data set. If you also specify the OBSCAT option, then the observationwise statistics are computed only for the observed response category, which is indicated by the value of the _LEVEL_ variable.

The output statistics are computed based on the final parameter estimates. If the optimization does not converge, then the output data table is not created. If you perform elastic net or LASSO selection, or if you specify the NOXPX or NOSTDERR option, then your analysis does not generate a covariance matrix, and you cannot produce the basic and diagnostic statistics in Table 14.10 that require a covariance matrix.

For observations in which only the response variable is missing, values of the linear predictor and the predicted values are computed even though these observations do not affect the model fit. This enables, for example, predicted values to be computed for new observations.

You must specify the following option:

OUT=*libref.data-table*
names the output data table for PROC GENSELECT to use. You must specify this option before any other options. *libref.data-table* is a two-level name, where

libref refers to a collection of information that is defined in the LIBNAME statement and includes the library, which includes a path to where the data table is to be stored, and a session identifier, which defaults to the active session but which can be explicitly defined in the LIBNAME statement. For more information about *libref*, see the section "Using CAS Sessions and CAS Engine Librefs" on page 707.

data-table specifies the name of the output data table.

You can also specify the following syntax elements:

ALL

ALLSTAT
adds all available statistics to the output data table.

ALPHA=*number*
specifies the significance level for the construction of confidence intervals in the output data table. The confidence level is $1 - number$. The value of *number* must be between 0 and 1. By default, *number* is equal to the value of the ALPHA= option in the PROC GENSELECT statement, or 0.05 if that option is not specified.

COPYVAR=*variable*

COPYVARS=(*variables***)**
transfers one or more *variables* from the input data table to the output data table.

OBSCAT
requests (for multinomial models) that observationwise statistics be produced only for the observed response level. If you do not specify this option and the response variable has J levels, then the following outputs are created: for cumulative link models, $J - 1$ records are output for every observation in the input data that corresponds to the $J - 1$ lower-ordered response categories; for generalized logit models, J records are output that correspond to all J response categories.

keyword **<** **=***name* **>**
specifies a statistic to include in the output data table and optionally names the variable *name*. If you do not provide a *name*, the GENSELECT procedure assigns a default name based on the type of statistic requested. If a statistic is not available for your model then that request is ignored.

Table 14.10 summarizes the *keywords* available in the OUTPUT statement.

Table 14.10 OUTPUT Statement Keywords

Keyword	Description	Default Name
Basic Options		
INDIVIDUAL	Specifies the individual predicted probabilities	_IPRED_
PREDICTED	Specifies the predicted probabilities	_PRED_
XBETA	Specifies the linear predictor	_XBETA_
Basic Options Requiring the Covariance		
LCL	Specifies the lower confidence limit for the linear predictor	_LCL_
LCLM	Specifies the lower confidence limit for the event probability	_LCLM_
STDXBETA	Specifies the standard error estimate of the linear predictor	_STDXBETA_
UCL	Specifies the upper confidence limit for the linear predictor	_UCL_
UCLM	Specifies the upper confidence limit for the event probability	_UCLM_
Diagnostic Options		
RESCHI	Specifies the Pearson chi-square residual	_RESCHI_
RESDEV	Specifies the deviance residual	_RESDEV_
RESRAW	Specifies the raw residual	_RESRAW_
RESWORK	Specifies the working residual	_RESWORK_
Diagnostic Options Requiring the Covariance		
CBAR	Specifies the confidence interval displacement	_CBAR_

Table 14.10 *continued*

Keyword	Description	Default Names
DIFCHISQ	Specifies the deletion chi-square goodness-of-fit change	_DIFCHISQUARE_
DIFDEV	Specifies the deletion deviance change	_DIFDEVIANCE_
H	Specifies the leverage	_HATDIAG_
RESLIK	Specifies the likelihood residual	_RESLIK_
STDRESCHI	Specifies the standardized Pearson chi-square residual	_STDRESCHI_
STDRESDEV	Specifies the standardized deviance residual	_STDRESDEV_
Miscellaneous Options for Binary and Multinomial Response Data		
INTO	Names the level into which the observation is classified	_INTO_
LEVEL	Names the response level for a row of the output	_LEVEL_
Option for Generalized Estimating Equations		
CLEVERAGE	Names the cluster leverage	_CLEVERAGE_

The following lists describe these *keywords*. For more information, see the section "Predicted Values and Regression Diagnostics" on page 768.

CBAR

specifies the confidence interval displacement diagnostic that measures the overall change in the global regression estimates that results from deleting an individual observation. The default name is _CBAR_.

DIFCHISQ

specifies the change in the chi-square goodness-of-fit statistic that results from deleting the individual observation. The default name is _DIFCHISQUARE_.

DIFDEV

specifies the change in the deviance that results from deleting the individual observation. The default name is _DIFDEVIANCE_. This statistic is not supported for GEEs.

H

specifies the diagonal element of the hat matrix (leverage) for detecting extreme points in the design space. The default name is _HATDIAG_. For GEEs, the leverage value is the corresponding diagonal element of the cluster leverage matrix.

INDIVIDUAL

IPRED

IPROB

IP

specifies the individual predicted values for multinomial response variables. For a response variable Y with three levels, 1, 2, and 3, the individual probabilities are $\Pr(Y = 1)$, $\Pr(Y = 2)$, and $\Pr(Y = 3)$. The default name is _IPRED_.

INTO< (*cutpoint*) >
names the variable that contains the level of the response into which an observation is classified. The default name is _INTO_. Multinomial models classify observations into the level that has the largest model-predicted probability. For binary or binomial response variables, if the predicted probability of an observation equals or exceeds the cutpoint, the observation is classified as an event; otherwise it is classified as a nonevent. You can specify the *cutpoint* value as a number between 0 and 1. The default value is 0.5.

LCL

LOWERXBETA
names the variable that contains the lower confidence limits for the linear predictor. The default name is _LCL_. You can set the confidence level by specifying the ALPHA= option.

LCLM

LOWERMEAN

LOWER
specifies the lower confidence limits for the mean. The default name is _LCLM_. You can set the confidence level by specifying the ALPHA= option.

LEVEL
names the variable that contains the level of the response for a given row of the output. The default name is _LEVEL_.

PREDICTED

PRED

PROB

P
specifies the predicted values for the response variable. It specifies the predicted probabilities of events for binary and nominal response variables and the cumulative predicted probabilities for ordinal response variables. For a response variable Y with three levels, 1, 2, and 3, the cumulative probabilities are $\Pr(\mathrm{Y} \leq 1)$ and $\Pr(\mathrm{Y} \leq 2)$, but by default the last level, $\Pr(\mathrm{Y} \leq 3) = 1$, is not output. The default name is _PRED_.

RESCHI

PEARSON
specifies the Pearson residual for identifying poorly fitted observations. The default name is _RESCHI_.

RESDEV
specifies the deviance residual for identifying poorly fitted observations. The default name is _RESDEV_. This statistic is not supported for GEEs.

RESLIK
specifies the likelihood residual for identifying poorly fitted observations. The default name is _RESLIK_. This statistic is not supported for GEEs.

RESRAW

RESIDUAL

R

specifies the raw residual for identifying poorly fitted observations. The default name is _RESRAW_.

RESWORK

specifies the working residual for identifying poorly fitted observations. The default name is _RESWORK_.

ROLE

specifies the numeric variable that indicates the role played by each observation in fitting the model. The default name is _ROLE_. Table 14.11 shows how this variable is interpreted for each observation.

Table 14.11 Role Interpretation

Value	Observation Role
0	Not used
1	Training
2	Validation
3	Testing

If you do not partition the input data by specifying a PARTITION statement, then the role variable value is 1 for observations that are used in fitting the model and 0 for observations that have at least one missing or invalid value for the response, regressor, frequency, or weight variables.

STDRESCHI

specifies the standardized Pearson (chi-square) residual for identifying observations that are poorly accounted for by the model. The default name is _STDRESCHI_.

STDRESDEV

specifies the standardized deviance residual for identifying poorly fitted observations. The default name is _STDRESDEV_. This statistic is not supported for GEEs.

STDXBETA

specifies the standard error estimates of XBETA. The default name is _STDXBETA_.

UCL

UPPERXBETA

specifies the variable that contains the upper confidence limits for the linear predictor. The default name is _UCL_. You can set the confidence level by specifying the ALPHA= option.

UCLM

UPPERMEAN

UPPER

specifies the variable that contains the upper confidence limits for the mean. The default name is _UCLM_. You can set the confidence level by specifying the ALPHA= option.

XBETA

LINP

specifies the linear predictor. The default name is _XBETA_.

The following additional output statistic is available for GEEs. For more information about diagnostic statistics, see the section "Diagnostics for Models Fit by Generalized Estimating Equations (GEEs)" on page 771.

CLEVERAGE

CH

CLEV

specifies the cluster leverage. The default name is _CLEVERAGE_.

PARTITION Statement

PARTITION *partition-option* **;**

The PARTITION statement specifies how observations in the input data set are logically partitioned into disjoint subsets for model training, validation, and testing. For more information, see the section "Using Validation and Test Data" on page 101 in Chapter 2, "Shared Concepts." Either you can designate a variable in the input data table and a set of formatted values of that variable to determine the role of each observation, or you can specify proportions to use for randomly assigning observations to each role.

You must specify exactly one of the following *partition-options*:

FRACTION(< TEST=*fraction* **> < VALIDATE=***fraction* **> < SEED=***number* **>)**

randomly assigns specified proportions of the observations in the input data table to the roles. You specify the proportions for testing and validation by using the TEST= and VALIDATE= suboptions. If you specify both the TEST= and VALIDATE= suboptions, then the sum of the specified fractions must be less than 1 and the remaining fraction is the proportion of the observations assigned to the training role. The SEED= option specifies an integer that is used to start the pseudorandom number generator for random partitioning of data for training, testing, and validation. If you do not specify SEED=*number* or if *number* is less than or equal to 0, the seed is generated by reading the time of day from the computer's clock.

ROLE=*variable* **(< TEST='***value***' > < TRAIN='***value***' > < VALIDATE='***value***' >)**

ROLEVAR=*variable* **(< TEST='***value***' > < TRAIN='***value***' > < VALIDATE='***value***' >)**

names the *variable* in the input data table whose values are used to assign roles to each observation. This *variable* cannot also appear as an analysis variable in other statements or options. The TEST=, TRAIN=, and VALIDATE= suboptions specify the formatted values of this variable that are used to assign observation roles. If you do not specify the TRAIN= suboption, then all observations whose role is not determined by the TEST= or VALIDATE= suboption are assigned to the training role.

For more information, see the section "Partition Fit Statistics" on page 767.

REPEATED Statement

REPEATED SUBJECT=<*subject-effect*> / < *repeated-options* > **;**

The REPEATED statement performs a repeated measures analysis by using generalized estimating equations (GEEs). GEE analysis is available for models that use the normal, gamma, inverse Gaussian, negative binomial, binomial, binary, and Poisson distributions. GEE analysis is not supported when you perform model selection, when you perform a partitioned analysis, or when you specify parameter restrictions.

The *repeated-options* specify the working correlation structure, output options, and controls for the iterative fitting algorithm.

Table 14.12 summarizes the *repeated-options* in the REPEATED statement by function.

Table 14.12 REPEATED Statement Options

Option	Description
Basic Options	
SUBJECT=	Identifies subjects in the input data
TYPE=	Specifies the working correlation type
WITHIN=	Specifies a within-subject effect
Options Related to Output	
CORRB	Produces both the model-based and empirical estimated regression parameter correlation matrices
CORRW	Produces the working correlation matrix
COVB	Produces both the model-based and empirical estimated regression parameter covariance matrices
ECORRB	Produces the estimated regression parameter empirical correlation matrix
ECOVB	Produces the estimated regression parameter empirical covariance matrix
MCORRB	Produces the estimated regression parameter model-based correlation matrix
MCOVB	Produces the estimated regression parameter model-based covariance matrix
MODELSE	Produces a parameter estimates table that displays and uses the model-based standard errors
PRINTMLE	Produces a parameter estimates table that displays the maximum likelihood estimates

Basic Options

SUBJECT=*subject-effect*

identifies subjects in the input data set. A *subject-effect* is required; it can contain a single variable, an interaction effect, a nested effect, or a combination of these. Each variable that the *subject-effect* contains must be listed in the CLASS statement. Each distinct level of the effect identifies a different subject. Responses from different subjects are assumed to be independent, but responses within subjects are assumed to be correlated.

You can specify the following *options* after a slash (/):

TYPE=*<type>*

specifies the working correlation type that is used in the repeated measures analysis. The working correlation structure describes the way that a subject's repeated measures are assumed to correlate with each other.

You can specify one of the following working correlation types:

AR | AR(1)

specifies the autoregressive-1 working correlation.

CS | EXCH

specifies the exchangeable working correlation.

IND

specifies the independence working correlation.

MDEP*(m)* **| TOEP***(m)*

specifies the m-dependent working correlation. By default, $m = 1$.

UN | UNSTR | UNSTRUCTURED

specifies the unstructured working correlation.

By default, TYPE=IND.

WITHIN=*within-effect*

WITHINSUBJECT=*within-effect*

specifies a within-subject effect for the repeated measures model. This effect must be composed of CLASS variables. The purpose of the within-subject effect is to define an order for the repeated measures that correspond to each subject. This definition can be critical for reproducibility when you use an order-sensitive correlation structure.

If you do not specify a within-subject effect, the order of the repeated measures is determined by the order in which they are read. This order can vary, depending on your computing resources. Therefore, a within-subject effect is required when you specify the autoregressive, m-dependent, or unstructured working correlation type. When you use one of these working correlation types, the levels of the within-subject effect must be unique within each subject.

If you use multiple variables to define the within-subject effect, the specification of the variables within this effect will have an impact on the analysis if the working correlation type depends on the ordering of the repeated measures. The autoregressive, m-dependent, and unstructured working correlation types use the levelization of the within-subject effect to locate observations within the correlation matrix, and depend on the order that is produced by the levelization.

In particular, if you define the within-subject effect by using the interaction of two or more variables, then the hierarchy of levelization and the resulting ordering of the repeated measures will depend on the order in which you list the variables in the CLASS statement.

For example, assume that you are using the interaction of the variables w1 and w2 as the within-subject effect in a repeated measures analysis. Furthermore, assume that w1 takes the values 'A' and 'B' and w2 takes the values 'L' and 'H'. The following statements list these variables in the order w2, w1 in the CLASS statement:

```
proc genselect data=mylib.health;
   class subject w2 w1;
   model outcome(event='1') = x1 x2 / dist=binary;
   repeated subject=subject / type=mdep(2) within=w1*w2;
run;
```

In this case, the order of the variables in the CLASS statement results in a levelization in which the value of w1 changes faster than the value of w2. Table 14.13 shows this levelization.

Table 14.13 Levelization Order When Variable Order Is w2, w1

Value of w1	Value of w2	Levelization Order
A	L	0
B	L	1
A	H	2
B	H	3

If you reverse the order of the variables in the CLASS statement, the levelization has a different hierarchy. In this hierarchy, the value of w2 changes faster than the value of w1. Table 14.14 shows that the levelization order that is assigned to each unique combination of the variables does not match the levelization order shown in Table 14.13.

Table 14.14 Levelization Order When Variable Order Is w1, w2

Value of w1	Value of w2	Levelization Order
A	L	0
B	L	2
A	H	1
B	H	3

Because the specified working correlation structure (*m*-dependent) relies on this ordering, the parameter estimates differ from those that are produced by the ordering shown in Table 14.13. The autoregressive and unstructured working correlation structures also result in different parameter estimates for the different orderings.

If you use two variables to define the within-subject effect, you can use a nested effect to enforce a specific levelization hierarchy. However, the best practice is to use a single variable in the within-subject effect.

Options Related to Output

CORRB
produces both the model-based and empirical estimated regression parameter correlation matrices.

CORRW
produces the estimated working correlation matrix. This matrix shows the estimated correlation between pairs of repeated measurements.

COVB
produces both the model-based and empirical estimated regression parameter covariance matrices.

ECORRB
produces the empirical estimated regression parameter correlation matrix.

ECOVB
produces the empirical estimated regression parameter covariance matrix.

MCORRB
produces the model-based estimated regression parameter correlation matrix.

MCOVB
produces the model-based estimated regression parameter covariance matrix.

MODELSE
produces a table that displays the parameter estimates from the repeated measures analysis, but using the model-based standard error estimates. By default, only a table that uses the empirical standard error estimates is shown.

PRINTMLE
produces a table that displays the parameter estimates and standard errors from maximum likelihood estimation, assuming no within-subject correlation. This table corresponds to the "Parameter Estimates" table that the procedure produces when you do not request a repeated measures analysis.

RESTRICT Statement

RESTRICT *constraint-specification* < **,** . . . **,** *constraint-specification* >
< *operator* < *value* > > < / *option* > **;**

The RESTRICT statement enables you to specify linear equality or inequality constraints among the parameters of a model. These restrictions are incorporated into the maximum likelihood analysis.

You can specify the following *option* after a slash (/):

DIVISOR=*value*
specifies a *value* by which all coefficients on the right-hand and left-hand sides of the restriction are divided.

Linear Constraints

There are several reasons why you might want to place constraints and restrictions on the model parameters:

- to fix a parameter at a particular value
- to equate parameters in a model
- to impose order conditions on the parameters in a model
- to specify contrasts among the parameters that the fitted model should honor

A restriction is composed of a left-hand side and a right-hand side, separated by an operator. If you do not specify the operator and right-hand side, the restriction is assumed to be an equality constraint against zero. If you do not specify the right-hand side, the value is assumed to be zero.

The *constraint-specification* takes the form

model-effect value-list < . . . *model-effect value-list* >

You must specify at least one *model-effect*, followed by one or more values in the *value-list*. The values in the list correspond to the multipliers of the corresponding parameter that is associated with the position in the model effect. If you specify more values in the *value-list* than the *model-effect* occupies in the model design matrix, the extra coefficients are ignored.

NOTE: You cannot use a specific *model-effect* more than once in a *constraint-specification*.

You can use the following operators to separate the left- and right-hand sides of a restriction: `=`, `>`, `<`, `>=`, `<=`. If there is no *operator*, then `=0` is the assumed *operator rhs-value* pair. If there is an *operator* but no *rhs-value*, then `0` is the assumed *rhs-value*.

Basic Syntax

The following SAS statements provide an example. Here, A is a CLASS variable that has three levels.

```
proc genselect data=mylib.binom;
   class A;
   model y/n = A x /  dist=binomial;
   restrict A 1 0 -1;
   restrict x 2 >= 0.5;
run;
```

The linear predictor for this model can be written as

$$\eta = \beta_0 + \beta_1 A_1 + \beta_2 A_2 + \beta_3 A_3 + x\beta_4$$

where A_k is the binary variable that is associated with the kth level of A.

The first RESTRICT statement specifies that the parameter estimates that are associated with the first and third levels of the A effect be identical. In terms of the linear predictor, the restriction can be written as

$$\beta_1 - \beta_3 = 0$$

In the default GLM parameterization, $\beta_3 = 0$, so this RESTRICT statement has the effect of setting $\beta_1 = 0$.

The second RESTRICT statement involves the regression parameter that is associated with the variable x and specifies that the parameter estimate satisfy $\beta_4 \geq 0.25$. In terms of the linear predictor, the restriction can be written as

$$2\beta_4 \geq \frac{1}{2}$$

PROC GENSELECT applies both of these restrictions when it computes the maximum likelihood estimates of the regression parameters of the model.

Generalized Logit Syntax

The generalized logit model for a nominal multinomial response consists of a regression model for each nonreference level of the response variable. To specify restrictions for effects in specific components of the model, you specify a restriction for each component to which you want to apply constraints. You specify each restriction in the sort order of the response variable and separate them with commas.

You must specify a restriction in which you set *value-list* to zero for each component model that has a lower response variable sort order than the component model to which you want to apply constraints.

The following SAS statements provide an example. In this example, a generalized logit regression model is fitted to the categorical response variable Y. The response variable has four different levels. The generalized logit model consists of a regression model that has a CLASS regressor variable named Visit and a continuous regressor variable named Lage for each level of the response variable Y. The RESTRICT statements constrain the model to have identical values of the estimated regression coefficient for Lage for all three nonreference categories of Y; that is, a common-slopes model is fitted. In the second RESTRICT statement, the *constraint-specification* of *Lage 0* is necessary as a placeholder and does not affect the regression coefficient of Lage for the first level of Y.

```
proc genselect data=mylib.mult;
   class Visit / Param=Ref;
   model Y=Visit Lage/dist=Multinomial link=Glogit;
   restrict Lage 1 , Lage -1;
   restrict Lage 0 , Lage  1, Lage -1;
run;
```

Some distributions involve a dispersion parameter (the parameter ϕ in the expressions for the log likelihood), and in the case of the Tweedie distribution, a power parameter. You cannot use the RESTRICT statement to constrain either of these parameters. Instead, you can use the MODEL statement option PHI= to set the dispersion to a fixed value. Likewise, you can use the MODEL statement option P= to set the Tweedie power parameter to a fixed value.

In multinomial models, you cannot constrain the intercept parameter to be equal to zero.

Linear constraints are not supported in repeated measures (GEE) analysis, in model selection, or when you have specified informative missingness. Furthermore, linear constraints are not supported for polynomial constructed effects.

SELECTION Statement

SELECTION < **METHOD=***method* < *(method-options)* > >< *options* > **;**

The SELECTION statement performs model selection by examining whether effects should be added to or removed from the model according to rules that are defined by model selection methods. The statement is fully documented in the section "SELECTION Statement" on page 42 in Chapter 2, "Shared Concepts."

The GENSELECT procedure supports the following effect-selection *methods* in the SELECTION statement:

BACKWARD performs backward elimination. This method starts with all effects in the model and deletes effects.

BACKWARD(FAST) performs fast backward elimination when SELECT=SL. This method starts with all effects in the model and deletes effects without refitting the model.

ELASTICNET performs elastic net selection. This method selects effects by fitting a sequence of candidate models with a grid of regularization parameters. For more information, see the section "Elastic Net Selection" on page 83 in Chapter 2, "Shared Concepts."

FORWARD performs forward selection. This method starts with no effects in the model and adds effects.

LASSO performs model selection by the group LASSO method. This method adds and removes effects by using a sequence of LASSO steps. For more information, see the section "Group LASSO Selection" on page 87 in Chapter 2, "Shared Concepts."

NONE results in no model selection. This method fits the full model.

STEPWISE performs stepwise selection. This method is similar to the FORWARD method except that effects already in the model do not necessarily stay there.

By default, METHOD=STEPWISE.

The SELECT=, CHOOSE=, and STOP= *method-options* default to SBC. These defaults differ from their corresponding defaults in the HPGENSELECT procedure in SAS/STAT software.

You can specify the following criteria in the SELECT=, CHOOSE=, and STOP= *method-options*:

AIC uses Akaike's information criterion (Akaike 1974).

AICC uses a small-sample bias corrected version of Akaike's information criterion, as promoted in Hurvich and Tsai (1989) and Burnham and Anderson (1998).

SBC | BIC uses the Schwarz Bayesian criterion (Schwarz 1978).

SL uses the significance level of the score test as the criterion (not available for the CHOOSE= option).

VALIDATE uses the average square error (ASE) that is computed on the validation data as the criterion (not available for the SELECT= option).

For more information, see the section "Information Criteria" on page 767. If you specify the PARTITION statement, then the AIC, AICC, SBC, and SL statistics are computed on the training data; otherwise they are computed on the full data table.

Forward selection where you also specify the NOINT option is available only for the following models: binary, binomial, exponential, geometric, and Poisson.

If you specify METHOD=LASSO, then the value of the CHOOSE= option is SBC by default, you can specify CHOOSE=NONE to select the model in the last LASSO step, and the STOPHORIZON= option has no effect.

If you specify METHOD=ELASTICNET, then the HIERARCHY= and STOPHORIZON= options have no effect. The elastic net method is not currently available with the lognormal distribution.

NOTE: If you use the fast backward elimination method, then the –2 log-likelihood, AIC, AICC, and SBC statistics are approximated at each step where the model is not refit, and hence they do not match the values that are computed when that model is fit outside the selection routine. Similarly, if you specify SELECT=AIC, AICC, or SBC, the selection criteria are estimated (Lawless and Singhal 1978), and hence they do not match the values that are computed when that model is fit outside the selection routine.

NOTE: The default model hierarchy method is HIERARCHY=NONE for the forward and fast backward selection methods. The backward elimination method always uses the HIERARCHY=SINGLE *method-option*.

The LASSO method produces a summary table that displays the effects that are added or removed at each step; the LASSO regularization parameter; and the AIC, AICC, and SBC fit statistics. The elastic net method produces a similar summary table that includes the selected effects, the regularization parameter, and the value of the CHOOSE= criterion. For the other methods, you can specify the following values for the DETAILS= option:

SUMMARY produces a summary table that shows the effect that is added or removed at each step along with the SELECT=, CHOOSE=, and STOP= criteria. The summary table is produced by default if the DETAILS= option is not specified.

STEPS produces the preceding summary table and displays the results from fitting each model at each step.

ALL produces the preceding tables and a detailed listing of all candidates at each step along with their ranking in terms of the selection criterion for addition to or removal from the model.

If you specify the PLOTS=CRITERIA or PLOTS=ALL option, then a plot of the fit criterion by the selection step is created for the AIC, AICC, and SBC statistics. If you also specify a PARTITION statement or the PARTFIT option, then the same type of plot is created for the ASE (for each role).

If you specify the PLOTS=FITBYROLE or PLOTS=ALL option and a PARTITION statement, then a plot of the ASE by the selection step for each role is created.

The PLOTS= option is not available for the LASSO method or the elastic net method.

Model selection is not available for repeated measures (GEE) models or when you specify linear restrictions.

STORE Statement

STORE < **OUT=***libref.data-table* > < / **NOTE** | **TEXT=***quoted-string* < *quoted-string . . .* > > **;**

The STORE statement saves the context and results of the statistical analysis. The resulting analytic store has a binary file format that cannot be modified. An example of analytic store technology is to perform a time-consuming analysis and to store its results by using the STORE statement. Later you can perform specific statistical analysis tasks based on the saved results of the previous analysis, without having to fit the model again. You can process the contents of the analytic store by specifying the RESTORE= option, as well as by specifying the ASTORE procedure and the **genmodCode**, **genmodScore**, and **genmodType3** actions in the **regression** action set (see Chapter 22, "Regression Action Set" (*SAS Visual Statistics: Programming Guide*)).

You specify the name of the analytic store by using the OUT= option. You can save notes to the analytic store by specifying them as quoted strings in the NOTE= or TEXT= option. Each quoted string begins a new line, preserves initial blanks, and can be at most 200 characters long. These text strings are displayed when you specify the item store in a RESTORE= option. *libref.data-table* is a two-level name, where *libref* refers to the library, and *data-table* specifies the name of the output data table. For more information about this two-level name, see the section "Using CAS Sessions and CAS Engine Librefs" on page 707.

WEIGHT Statement

WEIGHT *variable* < / **NORMALIZE** > **;**

The *variable* in the WEIGHT statement is used as a weight to perform a weighted analysis of the data. Observations that have nonpositive or missing weights are not included in the analysis. The values of the WEIGHT variable can be nonintegral and are not truncated. When you omit the WEIGHT statement, all observations that are used in the analysis are assigned a weight of 1.

You can specify the following option in the WEIGHT statement after a slash (/):

NORMALIZE

normalizes the weights that are specified by the WEIGHT *variable* so that they add up to the sample size. Weights are normalized by multiplying them by $\frac{\sum f_i t_i}{\sum w_i f_i t_i}$, where training observation i has a frequency equal to f_i and a weight equal to w_i, and t_i is the number of trials when you are using events/trials or multinomial-trial syntax; otherwise t_i is equal to 1. When you specify this option, the estimated covariance matrix of the parameter estimators is invariant to the scale of the WEIGHT *variable*.

Details: GENSELECT Procedure

Missing Values

Any observation that has missing values for the response, frequency, weight, offset, or explanatory variables is excluded from the analysis; however, missing values are valid for response and explanatory variables that are specified along with the MISSING option in the CLASS statement. Observations that have a nonpositive weight or a frequency less than 1 are also excluded.

The estimated linear predictor and the fitted probabilities are not computed for any observation that has missing offset or explanatory variable values. However, if only the response value is missing, the linear predictor and the fitted probabilities can be computed and output to a data set by using the OUTPUT statement.

You can also model the missing values by specifying the INFORMATIVE option in the MODEL statement. For more information about informative missingness, see the section "Informative Missingness" on page 99 in Chapter 2, "Shared Concepts."

Exponential Family Distributions

Many of the probability distributions that the GENSELECT procedure fits are members of an exponential family of distributions, which have probability distributions that are expressed as follows for some functions b and c that determine the specific distribution:

$$f(y) = \exp\left\{\frac{y\theta - b(\theta)}{\phi} + c(y,\phi)\right\}$$

For fixed ϕ, this is a one-parameter exponential family of distributions. The response variable can be discrete or continuous, so $f(y)$ represents either a probability mass function or a probability density function. A more useful parameterization of generalized linear models is by the mean and variance of the distribution:

$$\begin{aligned} \mathrm{E}(Y) &= b'(\theta) \\ \mathrm{Var}(Y) &= b''(\theta)\phi \end{aligned}$$

In generalized linear models, the mean μ of the response distribution is related to linear regression parameters through a link function,

$$g(\mu_i) = \mathbf{x}_i'\boldsymbol{\beta}$$

for the ith observation, where $\mathbf{x}_i$ is a fixed known vector of explanatory variables and $\boldsymbol{\beta}$ is a vector of regression parameters. The GENSELECT procedure parameterizes models in terms of the regression parameters $\boldsymbol{\beta}$ and either the dispersion parameter ϕ or a parameter that is related to ϕ, depending on the model. For exponential family models, the distribution variance is $\mathrm{Var}(Y) = \phi \mathrm{V}(\mu)$, where $\mathrm{V}(\mu)$ is a variance function that depends only on μ.

Other distributions that are not exponential family models but are sometimes useful in statistical modeling are also included in the GENSELECT procedure.

Response Distributions

The response distribution is the probability distribution of the response (target) variable. The GENSELECT procedure can fit data for the following exponential family distributions:

- binary distribution
- binomial distribution
- gamma distribution
- geometric distribution
- exponential distribution
- inverse Gaussian distribution
- lognormal distribution
- multinomial for ordinal or nominal responses
- negative binomial distribution
- normal (Gaussian) distribution
- Poisson distribution
- Tweedie distribution

The following distributions are not exponential family members but are also included in the GENSELECT procedure:

- beta distribution
- generalized Poisson distribution
- *t* distribution
- Weibull distribution

Expressions for the probability distributions (probability density functions for continuous variables or probability mass functions for discrete variables) are shown in the section "Response Probability Distribution Functions" on page 749. The expressions for the log-likelihood functions of these distributions are presented in the section "Log-Likelihood Functions" on page 754.

The binary (or Bernoulli) distribution is the elementary distribution of a discrete random variable that can take two values, which have the probabilities p and $1 - p$. Suppose the random variable is denoted as Y and

$$\Pr(Y = 1) = p$$
$$\Pr(Y = 0) = 1 - p$$

The value that is associated with probability p is often called the *event* or "success"; the complementary event is called the *nonevent* or "failure." A Bernoulli experiment is a random draw from a binary distribution and generates events with probability p.

If $Y_1, \ldots, Y_n$ are n independent Bernoulli random variables, then their sum follows a binomial distribution. In other words, if $Y_i = 1$ denotes an event (success) in the ith Bernoulli trial, a binomial random variable is the number of events (successes) in n independent Bernoulli trials. If you use the events/trials syntax in the MODEL statement and you specify the DISTRIBUTION=BINOMIAL option, the GENSELECT procedure fits the model as if the data had arisen from a binomial distribution. For example, the following statements fit a binomial regression model that has the regressors x1 and x2. The variables e and t represent the events and trials, respectively, for the binomial distribution:

```
proc genselect;
   model e/t = x1 x2 / distribution=Binomial;
run;
```

If the events/trials syntax is used, then both variables must be numeric and the value of the events variable cannot be less than 0 or exceed the value of the trials variable. A "Response Profile" table is not produced for binomial data, because the response variable is not subject to levelization.

If the response variable is listed in a CLASS statement and a response distribution is not specified in a DISTRIBUTION= option, then a binary distribution or a multinomial distribution that uses the default or specified link function is assumed. If the response variable is not listed in a CLASS statement and a response distribution is not specified in a DISTRIBUTION= option, then a normal distribution that uses the default or specified link function is assumed.

The multinomial distribution is a generalization of the binary distribution and allows for more than two outcome categories. Because there are more than two possible outcomes for the multinomial distribution, the terminology of "successes," "failures," "events," and "nonevents" no longer applies. With multinomial data, these outcomes are generically referred to as "categories" or levels.

Whenever the GENSELECT procedure determines that the response variable is listed in a CLASS statement and has more than two levels (unless the events/trials syntax is used), it fits the model as if the data had arisen from a multinomial distribution. By default, the procedure then assumes that the response categories are ordered, and it fits a cumulative link model by applying the default or specified link function.

If the response categories are unordered, then you should fit a generalized logit model by choosing LINK=GLOGIT in the MODEL statement.

Response Probability Distribution Functions

Beta Distribution

$$
\begin{aligned}
f(y) &= \frac{\Gamma(\phi)}{\Gamma(\mu\phi)\Gamma((1-\mu)\phi)} y^{\mu\phi-1}(1-y)^{(1-\mu)\phi-1} \quad \text{for } 0 < y < 1 \\
\mathrm{E}(Y) &= \mu \\
\mathrm{Var}(Y) &= \mu(1-\mu)/(1+\phi), \quad \phi > 0
\end{aligned}
$$

This parameterization of the beta distribution comes from Ferrari and Cribari-Neto (2004).

Binary Distribution

$$
\begin{aligned}
f(y) &= \begin{cases} p & \text{for } y = 1 \\ 1-p & \text{for } y = 0 \end{cases} \\
\mathrm{E}(Y) &= p \\
\mathrm{Var}(Y) &= p(1-p)
\end{aligned}
$$

Binomial Distribution

$$
\begin{aligned}
f(y) &= \binom{n}{r} \mu^r (1-\mu)^{n-r} \quad \text{for } y = \frac{r}{n},\ r = 0, 1, 2, \ldots, n \\
\mathrm{E}(Y) &= \mu \\
\mathrm{Var}(Y) &= \frac{\mu(1-\mu)}{n}
\end{aligned}
$$

Exponential Distribution

$$
\begin{aligned}
f(y) &= \frac{1}{\mu} \exp\left(-\frac{y}{\mu}\right) \quad \text{for } 0 < y < \infty \\
\mathrm{E}(Y) &= \mu \\
\mathrm{Var}(Y) &= \mu^2
\end{aligned}
$$

The exponential distribution is a special case of the gamma where $\nu = 1$.

Gamma Distribution

$$
\begin{aligned}
f(y) &= \frac{1}{\Gamma(\nu) y} \left(\frac{y\nu}{\mu}\right)^{\nu} \exp\left(-\frac{y\nu}{\mu}\right) \quad \text{for } 0 < y < \infty \\
\phi &= \frac{1}{\nu} \\
\mathrm{E}(Y) &= \mu \\
\mathrm{Var}(Y) &= \frac{\mu^2}{\nu}, \quad \nu > 0
\end{aligned}
$$

For the gamma distribution, $\nu = \frac{1}{\phi}$ is the estimated dispersion parameter that is displayed in the output. The parameter ν is sometimes called the gamma index parameter.

Generalized Poisson Distribution

$$
\begin{aligned}
\xi &= 1 - \exp(-\phi), \quad \phi \geq 0 \\
\mu^* &= \mu - \xi(\mu - y) \\
f(y) &= (\mu^*)^{(y-1)} \frac{((1-\xi)\mu)}{\Gamma(y+1)} \exp(-\mu^*) \quad \text{for } y = 0, 1, 2, \ldots \\
\mathrm{E}(Y) &= \mu \\
\mathrm{Var}(Y) &= \frac{\mu}{(1-\xi)^2}
\end{aligned}
$$

The generalized Poisson distribution provides an overdispersed alternative to the Poisson distribution; $\phi = \xi = 0$ produces the mass function of a regular Poisson random variable. For more information about the generalized Poisson distribution and a comparison with the negative binomial distribution, see Joe and Zhu (2005). For the generalized Poisson distribution, ϕ is the estimated dispersion parameter that is displayed in the output.

Geometric Distribution

$$
\begin{aligned}
f(y) &= \frac{\mu^y}{(1+\mu)^{y+1}} \quad \text{for } y = 0, 1, 2, \ldots \\
\mathrm{E}(Y) &= \mu \\
\mathrm{Var}(Y) &= \mu + \mu^2
\end{aligned}
$$

The geometric distribution is a special case of the negative binomial where $\phi = 1$.

Inverse Gaussian Distribution

$$
\begin{aligned}
f(y) &= \frac{1}{\sqrt{2\pi y^3 \sigma}} \exp\left[-\frac{1}{2y} \left(\frac{y-\mu}{\mu\sigma} \right)^2 \right] \quad \text{for } 0 < y < \infty \\
\phi &= \sigma^2 \\
\mathrm{Var}(Y) &= \phi\mu^3
\end{aligned}
$$

Lognormal Distribution

$$
\begin{aligned}
f(y) &= \frac{1}{\sqrt{2\pi}\sigma y}\exp\left[-\frac{1}{2}\left(\frac{\ln(y)-\mu}{\sigma}\right)^2\right] \quad \text{for } 0 < y < \infty \\
\phi &= \sigma^2 \\
\mathrm{E}(Y) &= \exp(\mu)\sqrt{\exp(\phi)} \\
\mathrm{Var}(Y) &= \exp(2\mu)\exp\{\phi\}(\exp(\phi)-1)
\end{aligned}
$$

If Y has the preceding lognormal distribution, then $X = \log(Y)$ has a normal distribution with mean μ and variance σ^2.

Multinomial Distribution

$$
f(y_1, y_2, \ldots, y_k) = \frac{m!}{y_1! y_2! \cdots y_k!} p_1^{y_1} p_2^{y_2} \cdots p_k^{y_k}
$$

Negative Binomial Distribution

$$
\begin{aligned}
f(y) &= \frac{\Gamma(y+1/k)}{\Gamma(y+1)\Gamma(1/k)}\frac{(k\mu)^y}{(1+k\mu)^{y+1/k}} \quad \text{for } y = 0, 1, 2, \ldots \\
\phi &= k \\
\mathrm{E}(Y) &= \mu \\
\mathrm{Var}(Y) &= \mu + \phi\mu^2
\end{aligned}
$$

For the negative binomial distribution, k is the estimated dispersion parameter that is displayed in the output.

Normal Distribution

$$
\begin{aligned}
f(y) &= \frac{1}{\sqrt{2\pi}\sigma}\exp\left[-\frac{1}{2}\left(\frac{y-\mu}{\sigma}\right)^2\right] \quad \text{for } -\infty < y < \infty \\
\phi &= \sigma^2 \\
\mathrm{E}(Y) &= \mu \\
\mathrm{Var}(Y) &= \phi
\end{aligned}
$$

Poisson Distribution

$$\begin{aligned} f(y) &= \frac{\mu^y \mathrm{e}^{-\mu}}{y!} \quad \text{for } y = 0, 1, 2, \ldots \\ \mathrm{E}(Y) &= \mu \\ \mathrm{Var}(Y) &= \mu \end{aligned}$$

(Shifted) *t* Distribution

$$\begin{aligned} z &= \frac{\Gamma(0.5(\nu+1))}{\sqrt{\pi\nu\phi}\,\Gamma(0.5\nu)} \\ f(y) &= z\left(1 + \frac{(y-\mu)^2}{\nu\phi}\right)^{-0.5(\nu+1)} \quad \text{for } -\infty < y < \infty \\ \mathrm{E}(Y) &= \mu \\ \mathrm{Var}(Y) &= \phi\nu/(\nu-2), \quad \nu \geq 3 \end{aligned}$$

You can specify the degrees of freedom parameter ν in the DISTRIBUTION=*t*(ν) option. If you do not specify it, a value of $\nu = 3$ is used.

Note that this form of the *t* distribution is not a noncentral distribution, but that of a shifted central *t* random variable.

Tweedie Distribution

The Tweedie model is a generalized linear model from the exponential family. The Tweedie distribution is characterized by three parameters: the mean μ, the dispersion ϕ, and the power p. The variance of the distribution is $\phi\mu^p$. For values of p in the range $1 < p < 2$, a Tweedie random variable can be represented as a Poisson sum of gamma distributed random variables. That is,

$$Y = \sum_{i=1}^{N} Y_i$$

where N has a Poisson distribution that has mean $\lambda = \frac{\mu^{2-p}}{\phi(2-p)}$ and the Y_is have independent, identical gamma distributions, each of which has an expected value $\mathrm{E}(Y_i) = \phi(2-p)\mu^{p-1}$ and an index parameter $\nu_i = \frac{2-p}{p-1}$.

In this case, Y has a discrete mass at 0, $\Pr(Y = 0) = \Pr(N = 0) = \exp(-\lambda)$, and the probability density of Y, $f(y)$, is represented by an infinite series for $y > 0$. The GENSELECT procedure restricts the power parameter to satisfy $1.1 <= p$ for numerical stability in model fitting. The Tweedie distribution does not have a general closed form representation for all values of p. For more information about the Tweedie distribution, see Frees (2010).

The distribution mean and variance are:

$$\begin{aligned} \mathrm{E}(Y) &= \mu \\ \mathrm{Var}(Y) &= \phi\mu^p \end{aligned}$$

Weibull Distribution

$$\begin{aligned} f(y) &= \frac{1}{\mu\phi}\left(\frac{y}{\mu}\right)^{\frac{1}{\phi}-1}\exp\left(-\frac{y}{\mu}\right)^{\frac{1}{\phi}} \quad \text{for } 0 < y < \infty \\ \mathrm{E}(Y) &= \mu\Gamma(1+\phi) \\ \mathrm{Var}(Y) &= \mu^2[\Gamma(1+2\phi) - \Gamma^2(1+\phi)], \quad \phi > 0 \end{aligned}$$

Log-Likelihood Functions

The GENSELECT procedure forms the log-likelihood functions of the various models as

$$L(\boldsymbol{\mu};\mathbf{y}) = \sum_{i=1}^{n} f_i\, l(\mu_i; y_i, w_i)$$

where $l(\mu_i; y_i, w_i)$ is the log-likelihood contribution of the ith observation that has weight w_i, and f_i is the value of the frequency variable. For the determination of w_i and f_i, see the WEIGHT and FREQ statements. The individual log-likelihood contributions for the various distributions are as follows.

In the following, the mean parameter μ_i for each observation i is related to the regression parameters $\boldsymbol{\beta}_i$ through the linear predictor $\eta_i = \mathbf{x}_i'\boldsymbol{\beta}$ by

$$\mu_i = g^{-1}(\eta_i)$$

where g is the link function.

Beta Distribution

$$\begin{aligned} l(\mu_i; y_i, w_i) = \log&\left\{\frac{\Gamma(\phi/w_i)}{\Gamma(\mu_i\phi/w_i)\Gamma((1-\mu_i)\phi/w_i)}\right\} \\ &+ (\mu_i\phi/w_i - 1)\log\{y_i\} \\ &+ ((1-\mu_i)\phi/w_i - 1)\log\{1-y_i\} \end{aligned}$$

where ϕ is the dispersion parameter that is displayed in the output.

Binary Distribution

$$\begin{aligned} \eta_i &= \mathbf{x}_i'\boldsymbol{\beta} \\ \mu_i &= g^{-1}(\eta_i) \\ l(\mu_i; y_i) &= y_i \log\{\mu_i\} + (1 - y_i) \log\{1 - \mu_i\} \end{aligned}$$

Here, μ_i is the probability of an event, and the variable y_i takes the value 1 for an event and 0 for a nonevent. The inverse link function $g^{-1}(\cdot)$ maps from the scale of the linear predictor η_i to the scale of the mean. For example, for the logit link (the default),

$$\mu_i = \frac{\exp\{\eta_i\}}{1 + \exp\{\eta_i\}}$$

You can control which binary outcome in your data is modeled as the event by specifying the *response-options* in the MODEL statement, and you can choose the link function by specifying the LINK= option in the MODEL statement.

If you specify a WEIGHT statement and w_i denotes the weight for the current observation, the log-likelihood function is computed as

$$l(\mu_i; y_i, w_i) = w_i l(\mu_i; y_i)$$

Binomial Distribution

$$\begin{aligned} \eta_i &= \mathbf{x}_i'\boldsymbol{\beta} \\ \mu_i &= g^{-1}(\eta_i) \\ l(\mu_i; y_i, w_i) &= w_i \left(y_i \log\{\mu_i\} + (n_i - y_i) \log\{1 - \mu_i\}\right) \\ &\quad + w_i \left(\log\{\Gamma(n_i + 1)\} - \log\{\Gamma(y_i + 1)\} - \log\{\Gamma(n_i - y_i + 1)\}\right) \end{aligned}$$

where y_i and n_i are the values of the events and trials of the ith observation, respectively. The value μ_i measures the probability of events (successes) in the underlying Bernoulli distribution whose aggregate follows the binomial distribution.

Exponential Distribution

$$l(\mu_i; y_i, w_i) = w_i \log\left\{\frac{w_i y_i}{\mu_i}\right\} - \frac{w_i y_i}{\mu_i} - \log\{y_i \Gamma(w_i)\}$$

Gamma Distribution

$$\begin{aligned}\eta_i &= \mathbf{x}_i'\boldsymbol{\beta}\\ \mu_i &= g^{-1}(\eta_i)\\ l(\mu_i; y_i, w_i) &= \frac{w_i}{\phi}\log\left(\frac{w_i y_i}{\phi\mu_i}\right) - \frac{w_i y_i}{\phi\mu_i} - \log(y_i) - \log\left(\Gamma\left(\frac{w_i}{\phi}\right)\right)\end{aligned}$$

For the gamma distribution, $\nu = \frac{1}{\phi}$ is the estimated dispersion parameter that is displayed in the output.

Generalized Poisson Distribution

$$\begin{aligned}\xi_i &= (1 - \exp\{-\phi\}/w_i)\\ \mu_i^* &= \mu_i - \xi(\mu_i - y_i)\\ l(\mu_i^*; y_i, w_i) &= \log\{\mu_i^* - \xi_i y_i\} + (y_i - 1)\log\{\mu_i^*\}\\ &\quad - \mu_i^* - \log\{\Gamma(y_i + 1)\}\end{aligned}$$

where ϕ is the dispersion parameter that is displayed in the output.

Geometric Distribution

$$\begin{aligned}l(\mu_i; y_i, w_i) &= y_i \log\left\{\frac{\mu_i}{w_i}\right\} - (y_i + w_i)\log\left\{1 + \frac{\mu_i}{w_i}\right\}\\ &\quad + \log\left\{\frac{\Gamma(y_i + w_i)}{\Gamma(w_i)\Gamma(y_i + 1)}\right\}\end{aligned}$$

Inverse Gaussian Distribution

$$\begin{aligned}\eta_i &= \mathbf{x}_i'\boldsymbol{\beta}\\ \mu_i &= g^{-1}(\eta_i)\\ l(\mu_i; y_i, w_i) &= -\frac{1}{2}\left[\frac{w_i(y_i - \mu_i)^2}{y_i\mu_i^2\phi} + \log\left(\frac{\phi y_i^3}{w_i}\right) + \log(2\pi)\right]\end{aligned}$$

where ϕ is the dispersion parameter that is displayed in the output.

Lognormal Distribution

$$\begin{aligned}\eta_i &= \mathbf{x}_i'\boldsymbol{\beta}\\ \mu_i &= g^{-1}(\eta_i)\\ l(\mu_i; y_i, w_i) &= -\frac{1}{2}\left[2\log\{y_i\} + \frac{w_i(y_i - \mu_i)^2}{\phi} + \log\left(\frac{\phi}{w_i}\right) + \log(2\pi)\right]\end{aligned}$$

where ϕ is the dispersion parameter that is displayed in the output. If $X = \log\{Y\}$ has a normal distribution with mean μ and variance ϕ, then Y has the log-likelihood function $l(\mu_i; y_i, w_i)$.

Multinomial Distribution

The multinomial distribution that the GENSELECT procedure models is a generalization of the binary distribution; it is the distribution of a single draw from a discrete distribution that has J possible values. Thus, the log-likelihood function for the ith observation is

$$l(\boldsymbol{\pi}_i; \mathbf{y}_i, w_i) = w_i \sum_{j=1}^{J} y_{ij} \log\{\pi_{ij}\}$$

In this expression, J denotes the number of response categories (the number of possible outcomes) and π_{ij} is the probability that the ith observation takes on the response value associated with category j. The category probabilities must satisfy

$$\sum_{j=1}^{J} \pi_j = 1$$

and the constraint is satisfied by modeling $J - 1$ categories.

If your response Y has more than two values and they can be ordered (for example, $Y \in \{1, \ldots, J-1, J\}$), then the GENSELECT procedure fits ordinal response models of the form

$$g(\pi_j \mid \mathbf{x}) = \alpha_j + \boldsymbol{\beta}'\mathbf{x}, \quad j = 1, \ldots, J-1$$

where g is the link function and $\pi_j = \Pr(Y \leq j)$ are cumulative probabilities of the ordered response categories.

If your response Y has more than two values and they have no natural ordering, then the GENSELECT procedure fits a generalized or baseline-category logit model, which has the form

$$\log\left(\frac{\Pr(Y = j \mid \mathbf{x})}{\Pr(Y = J \mid \mathbf{x})}\right) = \alpha_j + \boldsymbol{\beta}_j'\mathbf{x}, \quad j = 1, \ldots, J-1$$

where the $\boldsymbol{\beta}_1, \ldots, \boldsymbol{\beta}_{J-1}$ are $J - 1$ vectors of slope parameters. These models are a special case of the discrete choice or conditional logit models introduced by McFadden (1974).

In models that have ordered response categories, the probabilities are expressed in cumulative form, so the last category is redundant. In generalized logit models (multinomial models that have unordered categories), one category is chosen as the reference category, and the linear predictor in the reference category is set to 0. For more information, see the REF= *response-option* in the MODEL statement.

Negative Binomial Distribution

$$\begin{aligned}
\eta_i &= \mathbf{x}_i'\boldsymbol{\beta} \\
\mu_i &= g^{-1}(\eta_i) \\
l(\mu_i; y_i, w_i) &= y_i \log\left(\frac{k\mu_i}{w_i}\right) - (y_i + w_i/k)\log\left(1 + \frac{k\mu_i}{w_i}\right) + \log\left(\frac{\Gamma(y_i + w_i/k)}{\Gamma(y_i + 1)\Gamma(w_i/k)}\right)
\end{aligned}$$

where k is the negative binomial dispersion parameter that is displayed in the output.

Normal Distribution

$$\begin{aligned} \eta_i &= \mathbf{x}_i'\boldsymbol{\beta} \\ \mu_i &= g^{-1}(\eta_i) \\ l(\mu_i; y_i, w_i) &= -\frac{1}{2}\left[\frac{w_i(y_i-\mu_i)^2}{\phi} + \log\left(\frac{\phi}{w_i}\right) + \log(2\pi)\right] \end{aligned}$$

where ϕ is the dispersion parameter that is displayed in the output.

Poisson Distribution

$$\begin{aligned} \eta_i &= \mathbf{x}_i'\boldsymbol{\beta} \\ \mu_i &= g^{-1}(\eta_i) \\ l(\mu_i; y_i, w_i) &= w_i[y_i \log(\mu_i) - \mu_i - \log(y_i!)] \end{aligned}$$

t Distribution

$$\begin{aligned} z_i &= -0.5\log\{\phi/w_i\} + \log\{\Gamma(0.5(\nu+1)\} \\ &\quad - \log\{\Gamma(0.5\nu)\} - 0.5 \times \log\{\pi\nu\} \\ l(\mu_i; y_i, w_i) &= -\left(\frac{\nu+1}{2}\right)\log\left\{1 + \frac{w_i}{\nu}\frac{(y_i-\mu_i)^2}{\phi}\right\} + z_i \end{aligned}$$

where ϕ is the dispersion parameter that is displayed in the output.

Tweedie Distribution

The Tweedie distribution does not in general have a closed form log-likelihood function in terms of the mean, dispersion, and power parameters. The form of the log likelihood is

$$L(\boldsymbol{\mu}; \mathbf{y}) = \sum_{i=1}^{n} f_i\, l(\mu_i; y_i, w_i)$$

where

$$l(\mu_i, y_i, w_i) = \log(f(y_i; \mu_i, p, \frac{\phi}{w_i}))$$

and $f(y, \mu, p, \phi)$ is the Tweedie probability distribution, which is described in the section "Tweedie Distribution" on page 753. Evaluation of the Tweedie log likelihood for model fitting is performed numerically as described in Dunn and Smyth (2005, 2008).

Quasi-likelihood

The extended quasi-likelihood (EQL) is constructed according to the definition of McCullagh and Nelder (1989, Chapter 9) as

$$Q_p(\mathbf{y}, \boldsymbol{\mu}, \phi, p) = \sum_i q(y_i, \mu_i, \phi, p)$$

where the contribution from an observation is

$$q(y_i, \mu_i, \phi, p) = -0.5 \log(2\pi \frac{\phi}{w_i} y_i^p) - w_i \left(\frac{y_i^{2-p} - (2-p) y_i \mu_i^{1-p} + (1-p)\mu_i^{2-p}}{(1-p)(1-p)} \right) / \phi$$

where $1 < p < 2$. This EQL is used in computing initial values for the iterative maximization of the Tweedie log likelihood, as specified using the OPTMETHOD= Tweedie option in Table 14.7. If you specify the OPTMETHOD=EQL *Tweedie-optimization-option* in Table 14.7, then the parameter estimates are computed by using the EQL instead of the log likelihood.

Weibull Distribution

$$l(\mu_i; y_i, w_i) = -w_i \left\{ \frac{\phi - 1}{\phi} \log\left(\frac{y_i}{\mu_i}\right) + \log(\mu_i \phi) + \exp\left[\log\left(\frac{y_i}{\mu_i}\right) / \phi \right] \right\}$$

where ϕ is the dispersion parameter that is displayed in the output.

Existence of Maximum Likelihood Estimates

The likelihood equation for a logistic regression model does not always have a finite solution. Sometimes there is a nonunique maximum on the boundary of the parameter space, at infinity. The existence, finiteness, and uniqueness of maximum likelihood estimates for the logistic regression model depend on the patterns of data points in the observation space (Albert and Anderson 1984; Santner and Duffy 1986).

Consider a binary response model. Let Y_j be the response of the jth subject, and let $\mathbf{x}_j$ be the vector of explanatory variables (including the constant 1 that is associated with the intercept). There are three mutually exclusive and exhaustive types of data configurations:

Complete separation There is a complete separation of data points if there exists a vector $\mathbf{b}$ that correctly allocates all observations to their response groups; that is,

$$\begin{cases} \mathbf{b}'\mathbf{x}_j > 0 & Y_j = 0 \\ \mathbf{b}'\mathbf{x}_j < 0 & Y_j = 1 \end{cases}$$

This configuration produces nonunique infinite estimates. If the iterative process of maximizing the likelihood function is allowed to continue, then the log likelihood diminishes to 0 and the dispersion matrix becomes unbounded.

Quasi-complete separation The data are not completely separable, but there is a vector $\mathbf{b}$ such that

$$\begin{cases} \mathbf{b}'\mathbf{x}_j \geq 0 & Y_j = 0 \\ \mathbf{b}'\mathbf{x}_j \leq 0 & Y_j = 1 \end{cases}$$

and equality holds for at least one subject in each response group. This configuration also yields nonunique infinite estimates. If the iterative process of maximizing the likelihood function is allowed to continue, then the dispersion matrix becomes unbounded and the log likelihood diminishes to a nonzero constant.

Overlap If neither complete nor quasi-complete separation exists in the sample points, there is an overlap of sample points. In this configuration, the maximum likelihood estimates exist and are unique.

The GENSELECT procedure uses a simple empirical approach to recognize the data configurations that lead to infinite parameter estimates. The basis of this approach is that any convergence method of maximizing the log likelihood must yield a solution that indicates complete separation, if such a solution exists. Upon convergence, if the predicted response equals the observed response for every observation, there is a complete separation of data points.

If the data are not completely separated, if an observation is identified to have an extremely large probability (≥ 0.95) of predicting the observed response, and if there have been at least eight iterations, then there are two possible situations. First, there is overlap in the data set, the observation is an atypical observation of its own group, and the iterative process stopped when a maximum was reached. Second, there is quasi-complete separation in the data set, and the asymptotic dispersion matrix is unbounded. If any of the diagonal elements of the dispersion matrix for the standardized observation vector (all explanatory variables standardized to zero mean and unit variance) exceeds 5,000, then PROC GENSELECT declares quasi-complete separation; if any of the diagonal elements exceeds 1,000, then the procedure displays a message indicating that quasi-complete separation might be detectable by increasing the number of iterations. If either complete separation or quasi-complete separation is detected, a note is displayed in the procedure output.

Checking for quasi-complete separation is less foolproof than checking for complete separation. If neither type of separation is discovered and your parameter estimates have large standard errors, then your data might be separable. The NOCHECK option in the MODEL statement turns off the process of checking for infinite parameter estimates; the MINITER= option in the PROC GENSELECT statement increases the number of iterations.

The LASSO Method of Model Selection

LASSO Selection

The GENSELECT procedure implements the group LASSO method, which is described in the section "Group LASSO Selection" on page 87 in Chapter 2, "Shared Concepts." The current section provides some background about the LASSO method that you need in order to understand the group LASSO method.

LASSO (least absolute shrinkage and selection operator) selection arises from a constrained form of ordinary least squares regression in which the sum of the absolute values of the regression coefficients is constrained to be smaller than a specified parameter. More precisely, let $\mathbf{X} = (\mathbf{x}_1, \mathbf{x}_2, \ldots, \mathbf{x}_m)$ denote the matrix of covariates, and let $\mathbf{y}$ denote the response. Then for a given parameter t, the LASSO regression coefficients $\boldsymbol{\beta} = (\beta_1, \beta_2, \ldots, \beta_m)$ are the solution to the constrained least squares problem:

$$\min ||\mathbf{y} - \mathbf{X}\boldsymbol{\beta}||^2 \qquad \text{subject to} \qquad \sum_{j=1}^{m} |\beta_j| \leq t$$

For generalized linear models, the LASSO regression coefficients $\boldsymbol{\beta} = (\beta_1, \beta_2, \ldots, \beta_m)$ are the solution to the constrained optimization problem,

$$\min\{-L(\boldsymbol{\mu}; \mathbf{y})\} \qquad \text{subject to} \qquad \sum_{j=1}^{m} |\beta_j| \leq t$$

where L is the log-likelihood function defined in the section "Log-Likelihood Functions" on page 754.

Provided that the LASSO parameter t is small enough, some of the regression coefficients will be exactly zero. Hence, you can think of the LASSO method as selecting a subset of the regression coefficients for each LASSO parameter. By increasing the LASSO parameter in discrete steps, you obtain a sequence of regression coefficients for which the nonzero coefficients at each step correspond to selected parameters. For more information about the LASSO method, see, for example, Hastie, Tibshirani, and Friedman (2009).

Some distributions involve a dispersion parameter (the parameter ϕ in the expressions for the log likelihood). These parameters are not estimated by the LASSO optimization algorithm, and they are set to either the default value or a value that you specify. You can use the MODEL statement option PHI= to set the dispersion to a fixed value.

Generalized Estimating Equations

The analysis of correlated data that arise from repeated measurements when the measurements are assumed to be multivariate normal has been studied extensively. However, the normality assumption might not always be reasonable; for example, you must use a different methodology in the data analysis when the responses are discrete and correlated. Generalized estimating equations (GEEs) provide a practical method with reasonable statistical efficiency to analyze such data.

Liang and Zeger (1986) introduced GEEs as a method of dealing with correlated data when, except for the correlation among responses, the data can be modeled as a generalized linear model. For example, in many cases you can model correlated binary and count data in this way. For more information about GEEs, see Hardin and Hilbe (2003), Diggle, Liang, and Zeger (1994), and Lipsitz et al. (1994).

Let y_{ij}, $j = 1, \ldots, n_i$, $i = 1, \ldots, K$, represent the jth measurement on the ith subject. There are n_i measurements on subject i and $\sum_{i=1}^{K} f_i\, n_i$ total measurements, where f_i is the cluster frequency that you specify in the FREQ statement. If you omit the FREQ statement, then $f_i = 1$ for all observations. The frequencies must be the same for all observations within each cluster.

You model correlated data by using the same link function and linear predictor specification that you use to model independent data. You use the same variance functions as in the independent case, but you must also specify a structure for the correlation between the repeated measurements. In the following material, $v(\mu)$ denotes the variance function for the specified distribution. Note that for the negative binomial distribution, the variance function is defined as $v(\mu) = \mu + k\mu^2$, where k is the maximum likelihood estimate of the negative binomial dispersion parameter k or the fixed value of k that you specify using the PHI= option in the MODEL statement.

Let the vector of measurements on the ith subject be $\mathbf{Y}_i = [y_{i1}, \ldots, y_{in_i}]'$, where the corresponding vector of means is $\boldsymbol{\mu}_i = [\mu_{i1}, \ldots, \mu_{in_i}]'$, and let $\mathbf{V}_i$ be the covariance matrix of $\mathbf{Y}_i$. Let the vector of independent, or explanatory, variables for the jth measurement on the ith subject be $\mathbf{x}_{ij} = [x_{ij1}, \ldots, x_{ijp}]'$. The generalized estimating equation of Liang and Zeger (1986) for estimating the $p \times 1$ vector of regression parameters $\boldsymbol{\beta}$ is an extension of the independence estimating equation to correlated data and is given by

$$\mathbf{S}(\boldsymbol{\beta}) = \sum_{i=1}^{K} f_i \mathbf{D}_i' \mathbf{V}_i^{-1} (\mathbf{Y}_i - \boldsymbol{\mu}_i(\boldsymbol{\beta})) = \mathbf{0}$$

where

$$\mathbf{D}_i = \frac{\partial \boldsymbol{\mu}_i}{\partial \boldsymbol{\beta}}$$

The relationship between the linear predictor and the mean is specified by

$$g(\mu_{ij}) = \mathbf{x}_{ij}{}'\boldsymbol{\beta}$$

where g is the link function, and so the $p \times n_i$ matrix of partial derivatives of the mean with respect to the regression parameters for the ith subject is given by

$$\mathbf{D}_i' = \frac{\partial \boldsymbol{\mu}_i'}{\partial \boldsymbol{\beta}} = \begin{bmatrix} \frac{x_{i11}}{g'(\mu_{i1})} & \cdots & \frac{x_{in_i1}}{g'(\mu_{in_i})} \\ \vdots & & \vdots \\ \frac{x_{i1p}}{g'(\mu_{i1})} & \cdots & \frac{x_{in_ip}}{g'(\mu_{in_i})} \end{bmatrix}$$

Working Correlation Matrix

Let $\mathbf{R}_i(\boldsymbol{\alpha})$ be an $n_i \times n_i$ "working" correlation matrix that is fully specified by the vector of parameters $\boldsymbol{\alpha}$. The covariance matrix of $\mathbf{Y}_i$ is modeled as

$$\mathbf{V}_i = \phi \mathbf{A}_i^{\frac{1}{2}} \mathbf{W}_i^{-\frac{1}{2}} \mathbf{R}(\boldsymbol{\alpha}) \mathbf{W}_i^{-\frac{1}{2}} \mathbf{A}_i^{\frac{1}{2}}$$

where $\mathbf{A}_i$ is an $n_i \times n_i$ diagonal matrix whose jth diagonal element is $v(\mu_{ij})$, and $\mathbf{W}_i$ is an $n_i \times n_i$ diagonal matrix whose jth diagonal is w_{ij}, where w_{ij} is a weight specified in the WEIGHT statement. If there is no WEIGHT statement, then $w_{ij} = 1$ for all i and j. If $\mathbf{R}_i(\boldsymbol{\alpha})$ is the true correlation matrix of $\mathbf{Y}_i$, then $\mathbf{V}_i$ is the true covariance matrix of $\mathbf{Y}_i$.

The working correlation matrix is usually unknown and must be estimated. You estimate it in the iterative fitting process by using the current value of the parameter vector $\boldsymbol{\beta}$ to compute appropriate functions of the Pearson residual

$$e_{ij} = \frac{y_{ij} - \mu_{ij}}{\sqrt{v(\mu_{ij})/w_{ij}}}$$

If you specify the working correlation as $\mathbf{R_0} = \mathbf{I}$, which is the identity matrix, the GEE reduces to the independence estimating equation.

Table 14.15 shows the working correlation types that the GENSELECT procedure supports and the estimators that are used to estimate the working correlations.

Table 14.15 Working Correlation Structures and Correlation Parameter Estimators

Working Correlation Structure	Estimator
Autoregressive	
AR(1)	
$\text{Corr}(Y_{ij}, Y_{i,j+t}) = \alpha^t$ for $t = 0, 1, 2, \ldots, n_i - j$	$\hat{\alpha} = \frac{1}{(K_1 - p)\phi} \sum_{i=1}^{K} f_i \sum_{j \le n_i - 1} e_{ij} e_{i,j+1}$ $K_1 = \sum_{i=1}^{K} f_i (n_i - 1)$
Exchangeable	
$\text{Corr}(Y_{ij}, Y_{ik}) = \begin{cases} 1 & j = k \\ \alpha & j \neq k \end{cases}$	$\hat{\alpha} = \frac{1}{(N^* - p)\phi} \sum_{i=1}^{K} f_i \sum_{j<k} e_{ij} e_{ik}$ $N^* = 0.5 \sum_{i=1}^{K} f_i n_i (n_i - 1)$
Independence	
$\text{Corr}(Y_{ij}, Y_{ik}) = \begin{cases} 1 & j = k \\ 0 & j \neq k \end{cases}$	The working correlation is not estimated in this case.
***m*-dependent**	
$\text{Corr}(Y_{ij}, Y_{i,j+t}) = \begin{cases} 1 & t = 0 \\ \alpha_t & t = 1, 2, \ldots, m \\ 0 & t > m \end{cases}$	$\hat{\alpha}_t = \frac{1}{(K_t - p)\phi} \sum_{i=1}^{K} f_i \sum_{j \le n_i - t} e_{ij} e_{i,j+t}$ $K_t = \sum_{i=1}^{K} f_i (n_i - t)$
Unstructured	
$\text{Corr}(Y_{ij}, Y_{ik}) = \begin{cases} 1 & j = k \\ \alpha_{jk} & j \neq k \end{cases}$	$\hat{\alpha}_{jk} = \frac{1}{(K - p)\phi} \sum_{i=1}^{K} f_i e_{ij} e_{ik}$

Dispersion Parameter

The dispersion parameter ϕ is estimated by

$$\hat{\phi} = \frac{1}{N - p} \sum_{i=1}^{K} f_i \sum_{j=1}^{n_i} e_{ij}^2$$

where $N = \sum_{i=1}^{K} f_i n_i$ is the total number of measurements and p is the number of regression parameters.

PROC GENSELECT reports $\hat{\phi}$ as the dispersion parameter in the output table "Analysis of GEE Parameter Estimates Model-Based Standard Error Estimates." The dispersion parameter is not included for models that use the binomial, binary, or Poisson distribution. If a fixed-scale parameter is specified using the PHI= option in the MODEL statement, then the fixed value is used in estimating the model-based covariance matrix and standard errors.

Fitting Algorithm

The following algorithm fits the specified model by using GEEs. Note that this is not in general a likelihood-based method of estimation; inferences based on likelihoods are not possible for GEE methods.

1. Compute an initial estimate of $\boldsymbol{\beta}$ by using an ordinary generalized linear model, assuming independence.
2. Compute the working correlations $\mathbf{R}$ on the basis of the standardized residuals, the current $\boldsymbol{\beta}$, and the assumed structure of $\mathbf{R}$.
3. Compute an estimate of the covariance:

$$\mathbf{V}_i = \phi \mathbf{A}_i^{\frac{1}{2}} \mathbf{W}_i^{-\frac{1}{2}} \hat{\mathbf{R}}(\boldsymbol{\alpha}) \mathbf{W}_i^{-\frac{1}{2}} \mathbf{A}_i^{\frac{1}{2}}$$

4. Update $\boldsymbol{\beta}$:

$$\boldsymbol{\beta}_{r+1} = \boldsymbol{\beta}_r + \left[\sum_{i=1}^{K} f_i \frac{\partial \boldsymbol{\mu}_i}{\partial \boldsymbol{\beta}}' \mathbf{V}_i^{-1} \frac{\partial \boldsymbol{\mu}_i}{\partial \boldsymbol{\beta}} \right]^{-1} \left[\sum_{i=1}^{K} f_i \frac{\partial \boldsymbol{\mu}_i}{\partial \boldsymbol{\beta}}' \mathbf{V}_i^{-1} (\mathbf{Y}_i - \boldsymbol{\mu}_i) \right]$$

5. Repeat steps 2–4 until convergence.

Missing Data

See Diggle, Liang, and Zeger (1994, Chapter 11) for a discussion of missing values in longitudinal data. Suppose you intend to take measurements $Y_{i1}, \ldots, Y_{in}$ for the ith unit. Missing values for which Y_{ij} are missing whenever Y_{ik} is missing for all $j \geq k$ are called *dropouts*. Otherwise, missing values that are intermixed with nonmissing values are called *intermittent* missing values. PROC GENSELECT can estimate the working correlation from data that contain both types of missing values by using the *all available pairs* method, in which all nonmissing pairs of data are used in the moment estimators of the working correlation parameters that are defined previously. The resulting covariances and standard errors are valid under the missing completely at random (MCAR) assumption.

For example, for the unstructured working correlation model,

$$\hat{\alpha}_{jk} = \frac{1}{(K' - p)\phi} \sum f_i e_{ij} e_{ik}$$

where the sum is over the units that have nonmissing measurements at times j and k, and K' is the number of units that have nonmissing measurements at j and k. Estimates of the parameters for other working correlation types are computed in a similar manner, using available nonmissing pairs in the appropriate moment estimators.

The contribution of the ith unit to the parameter update equation is computed by omitting the elements of $(\mathbf{Y}_i - \boldsymbol{\mu}_\mathbf{i})$, the columns of $\mathbf{D}_i' = \frac{\partial \boldsymbol{\mu}}{\partial \boldsymbol{\beta}}'$, and the rows and columns of $\mathbf{V}_i$ that correspond to missing measurements.

Parameter Estimate Covariances

The *model-based* estimator of $\mathrm{Cov}(\hat{\boldsymbol{\beta}})$ is given by

$$\boldsymbol{\Sigma}_m(\hat{\boldsymbol{\beta}}) = \mathbf{I}_0^{-1}$$

where

$$\mathbf{I}_0 = \sum_{i=1}^{K} f_i \frac{\partial \boldsymbol{\mu}_i}{\partial \boldsymbol{\beta}}' \mathbf{V}_i^{-1} \frac{\partial \boldsymbol{\mu}_i}{\partial \boldsymbol{\beta}}$$

This is a consistent estimator of the covariance matrix of $\hat{\boldsymbol{\beta}}$ if the mean model and the working correlation matrix are correctly specified.

The estimator

$$\boldsymbol{\Sigma}_e = \mathbf{I}_0^{-1}\mathbf{I}_1\mathbf{I}_0^{-1}$$

is called the *empirical*, or *robust*, estimator of the covariance matrix of $\hat{\boldsymbol{\beta}}$, where

$$\mathbf{I}_1 = \sum_{i=1}^{K} f_i \frac{\partial \boldsymbol{\mu}_i}{\partial \boldsymbol{\beta}}' \mathbf{V}_i^{-1}\mathrm{Cov}(\mathbf{Y}_i)\mathbf{V}_i^{-1} \frac{\partial \boldsymbol{\mu}_i}{\partial \boldsymbol{\beta}}$$

It has the property of being a consistent estimator of the covariance matrix of $\hat{\boldsymbol{\beta}}$, even if the working correlation matrix is misspecified—that is, if $\mathrm{Cov}(\mathbf{Y}_i) \neq \mathbf{V}_i$. For further information about the robust variance estimate, see Zeger, Liang, and Albert (1988), Royall (1986), and White (1982). In computing $\boldsymbol{\Sigma}_e$, the parameters $\boldsymbol{\beta}$ and ϕ are replaced by estimates, and $\mathrm{Cov}(\mathbf{Y}_i)$ is replaced by the estimate

$$(\mathbf{Y}_i - \boldsymbol{\mu}_i(\hat{\boldsymbol{\beta}}))(\mathbf{Y}_i - \boldsymbol{\mu}_i(\hat{\boldsymbol{\beta}}))'$$

Quasi-likelihood Information Criterion

The quasi-likelihood information criterion (QIC) was developed by Pan (2001) as a modification of the Akaike information criterion (AIC) to apply to models that are fit by GEEs.

Define the quasi-likelihood under the independence working correlation assumption, which is evaluated using the parameter estimates under the working correlation R as

$$Q(\hat{\boldsymbol{\beta}}(R), \phi) = \sum_{i=1}^{K} f_i \sum_{j=1}^{n_i} Q(\hat{\boldsymbol{\beta}}(R), \phi; (Y_{ij}, \mathbf{X}_{ij}))$$

where the quasi-likelihood contribution of the jth observation in the ith cluster is defined in the section "Quasi-likelihood Functions" on page 766 and $\hat{\boldsymbol{\beta}}(R)$ are the parameter estimates obtained from GEEs that use the working correlation R.

QIC is defined as

$$\mathrm{QIC}(R) = -2Q(\hat{\boldsymbol{\beta}}(R), \phi) + 2\mathrm{trace}(\hat{\Omega}_I \hat{V}_R)$$

where $\hat{V}_R$ is the robust covariance estimate and $\hat{\Omega}_I$ is the inverse of the model-based covariance estimate under the independence working correlation assumption, evaluated at $\hat{\boldsymbol{\beta}}(R)$, which are the parameter estimates obtained from GEEs that use the working correlation R.

PROC GENSELECT also computes an approximation to QIC(R), which Pan (2001) defines as

$$\mathrm{QIC}_{\boldsymbol{u}}(R) = -2Q(\hat{\boldsymbol{\beta}}(R), \phi) + 2p$$

where p is the number of regression parameters.

Pan (2001) notes that QIC is appropriate for selecting regression models and working correlations, whereas $\mathrm{QIC}_{\boldsymbol{u}}$ is appropriate only for selecting regression models.

Quasi-likelihood Functions

For detailed discussions of quasi-likelihood functions, see McCullagh and Nelder (1989) and Hardin and Hilbe (2003). The contribution of observation j in cluster i to the quasi-likelihood function that is evaluated at the regression parameters $\boldsymbol{\beta}$ is given by $Q(\boldsymbol{\beta}, \phi; (Y_{ij}, \mathbf{X}_{ij})) = \frac{Q_{ij}}{\phi}$, where Q_{ij} is defined in the following list. These are used in the computation of the quasi-likelihood information criteria (QIC) for the goodness of fit of models that are fit using GEEs. The w_{ij} are prior weights, if any, that are specified in the WEIGHT or FREQ statement. Note that the definition here of the quasi-likelihood for the negative binomial differs from that given in McCullagh and Nelder (1989). The definition here allows the negative binomial quasi-likelihood to approach the Poisson as $k \to 0$.

- Binomial

$$Q_{ij} = w_{ij}[r_{ij}\log(p_{ij}) + (n_{ij} - r_{ij})\log(1 - p_{ij})]$$

- Gamma

$$Q_{ij} = -w_{ij}\left[\frac{y_{ij}}{\mu_{ij}} + \log(\mu_{ij})\right]$$

- Inverse Gaussian

$$Q_{ij} = \frac{w_{ij}(\mu_{ij} - .5y_{ij})}{\mu_{ij}^2}$$

- Negative binomial

$$Q_{ij} = w_{ij}\left[\log\Gamma\left(y_{ij} + \frac{1}{k}\right) - \log\Gamma\left(\frac{1}{k}\right) + y_{ij}\log\left(\frac{k\mu_{ij}}{1 + k\mu_{ij}}\right) + \frac{1}{k}\log\left(\frac{1}{1 + k\mu_{ij}}\right)\right]$$

- Normal

$$Q_{ij} = -\frac{1}{2}w_{ij}(y_{ij} - \mu_{ij})^2$$

- Poisson

$$Q_{ij} = w_{ij}(y_{ij}\log(\mu_{ij}) - \mu_{ij})$$

GEE analysis is not supported when you perform model selection, when you perform a partitioned analysis, or when you specify parameter restrictions.

Using a Preexisting Table Order

You can add group and order information to a table by using the **partition** action in the **table** action set. If you want to use the group and order information in a table to achieve a reproducible processing order and you also want to do a repeated measures analysis, the group information must follow specific rules. In particular, the variables that you specify in the **groupBy** parameter of the **partition** action must match the variables that you specify in the SUBJECT option of the REPEATED statement.

There are some variations to this requirement, depending on which type of subject effect you specify. If you specify a single-variable subject effect or an interaction subject effect, you must use all these variables in the **groupBy** parameter of the **partition** action. If you specify a nested subject effect, you must include the nested variable in the **groupBy** parameter. You can also include the nesting variables in the **groupBy** parameter, but you cannot include any other variables in the **groupBy** parameter.

If you use an order-sensitive working correlation structure, you do not need to use the variables that form the within-subject effect in the **orderBy** parameter of the **partition** action. These sets of variables can overlap, but it is not required that the preexisting table order correspond to the ordering for the within-subject effect.

Partition Fit Statistics

Specifying a PARTITION statement modifies the display of many tables by adding separate rows or columns for the training, validation, and test data tables. In addition, the "Fit Statistics" table displays the average square error, which is useful for assessing the model and which should be very similar for the different roles when the training data are representative of the other data partitions. For more information, see the section "Model Fit and Assessment Statistics" on page 767.

Model Fit and Assessment Statistics

The statistics that are defined in this section are useful for assessing the fit of the model to your data; they are displayed in the "Fit Statistics" table. The statistics are computed for each data role when you specify a PARTITION statement.

Information Criteria

The calculation of the information criteria uses the following formulas, where p denotes the number of effective parameters in the candidate model, F denotes the sum of frequencies used, and l is the log likelihood evaluated at the converged estimates:

$$\begin{aligned} \text{AIC} &= -2l + 2p \\ \text{AICC} &= \begin{cases} -2l + 2pF/(F-p-1) & \text{when } F > p+2 \\ -2l + 2p(p+2) & \text{otherwise} \end{cases} \\ \text{SBC} &= -2l + p\log(F) \end{aligned}$$

If you do not specify a FREQ statement, F equals n, the number of observations used.

These measures are most useful for comparing competing models that are not necessarily nested—that is, models that cannot be reduced to one another by simple constraints on the parameter space. Smaller values of the measures indicate better models.

Average Square Error

The average square error (ASE) is the average of the squared differences between the responses and the predictions. When you have a discrete number of response levels, the ASE is modified as shown in Table 14.16 (Brier 1950; Murphy 1973); it is also called the Brier score or Brier reliability.

Table 14.16 Average Square Error Computations

Response Type	ASE (Brier Score)
Binary	$\frac{1}{F}\sum_i f_i(y_i(1-\widehat{\pi}_i)^2 + (1-y_i)\widehat{\pi}_i^2)$
Binomial	$\frac{1}{F}\sum_i f_i(r_i/t_i - \widehat{\pi}_i)^2$
Multinomial	$\frac{1}{F}\sum_i f_i \sum_j (y_{ij} - \widehat{\pi}_{ij})^2$

In Table 14.16, $F = \sum_i f_i$, r_i is the number of events, t_i is the number of trials in binomial response models, $y_i = 1$ for events and 0 for nonevents in binary response models, and $\widehat{\pi}_i$ is the predicted probability of an event. For polytomous response models, $y_{ij} = 1$ if the ith observation has response level j, and π_{ij} is the model-predicted probability of response level j for observation i.

Predicted Values and Regression Diagnostics

You can produce observationwise predicted values, confidence limits, and regression diagnostics that were developed by Williams (1987) and Pregibon (1981) by specifying the OUTPUT statement. For multinomial response data, you can likewise produce observationwise predicted probabilities, confidence limits, and raw residuals.

Given a vector of covariates $\mathbf{x}_i$ for the ith observation in your data table, and the model-predicted parameter estimates $\hat{\boldsymbol{\beta}}$, you can write the linear predictor $\hat{\eta}_i = \mathbf{x}_i'\hat{\boldsymbol{\beta}}$. The predicted mean of the ith observation $\hat{\mu}_i(\hat{\boldsymbol{\beta}})$, or the model-predicted event probability $\hat{p}_i$, is $\mu_i(\hat{\boldsymbol{\beta}}) = \hat{p}_i = g^{-1}(\hat{\eta}_i)$, where you select the link function g by specifying the LINK= option. The variance function of the distribution is $V(\mu)$, and $\hat{\boldsymbol{\Sigma}}$ is the estimated covariance of $\hat{\boldsymbol{\beta}}$. Denote the frequency of the ith observation as f_i and the weight as w_i.

For ordinal response models, the predicted cumulative probabilities are computed by using the appropriate model-predicted intercept parameters $\hat{\alpha}_j$ and letting $\hat{\boldsymbol{\beta}}$ consist of the slope parameters: $\hat{\eta}_{ij} = g(\Pr(Y \le j\,|\mathbf{x}_i) = \hat{\alpha}_j + \mathbf{x}_i'\hat{\boldsymbol{\beta}}$ and $\hat{\pi}_{ij} = \Pr(Y \le j\,|\mathbf{x}_i) = g^{-1}(\hat{\eta}_{ij})$ for $1 \le j < J$.

For nominal response models, the predicted probabilities are computed by using the appropriate model-predicted intercept parameters $\hat{\alpha}_j$ and by letting $\hat{\boldsymbol{\beta}}_j$ consist of the slope parameters: $\hat{\eta}_{ij} = g(\Pr(Y = j\,|\mathbf{x}_i) = \hat{\alpha}_j + \mathbf{x}_i'\hat{\boldsymbol{\beta}}_j$ and $\hat{\pi}_{ij} = \Pr(Y = j\,|\mathbf{x}_i) = g^{-1}(\hat{\eta}_{ij})$ for $1 \le j < J$.

If you perform elastic net or LASSO selection, or if you specify the NOSTDERR or NOSTDERR option, then your analysis does not generate a covariance matrix, and you can produce only the predicted probabilities (individual, cumulative, and posterior when available) and the raw, Pearson, deviance, and working residuals.

Confidence Intervals

Approximate confidence intervals for predicted values can be computed as follows. You estimate the variance of the linear predictor by using the following formula:

$$\hat{\sigma}_x^2 = \mathbf{x}_i' \hat{\mathbf{\Sigma}} \mathbf{x}_i$$

For multinomial models, the variance also depends on the response function. Let $\boldsymbol{\delta}_j$ be a $(J-1)$ column vector whose jth entry is equal to 1 and all other entries are equal to 0. Redefine $\mathbf{x}_i = (\boldsymbol{\delta}_j', \mathbf{x}_i')'$, $\hat{\eta}_i = \hat{\eta}_{ij}$, and $\hat{\pi}_i = \hat{\pi}_{ij}$. Then

$$\hat{\sigma}^2(\hat{\eta}_i) = \mathbf{x}_i' \hat{\mathbf{\Sigma}} \mathbf{x}_i$$

The asymptotic $100(1-\alpha)\%$ confidence interval for η_i is

$$\left(\hat{\eta}_i - z_{\alpha/2}\hat{\sigma}(\hat{\eta}_i),\ \hat{\eta}_i + z_{\alpha/2}\hat{\sigma}(\hat{\eta}_i) \right)$$

where $z_{\alpha/2}$ is the $100(1-\alpha/2)$th percentile point of a standard normal distribution.

The predicted value and the $100(1-\alpha)\%$ confidence limits for p_i are obtained by back-transforming the corresponding measures for the linear predictor. So the confidence limits for p_i are

$$\left(g^{-1}\left[\hat{\eta}_i - z_{\alpha/2}\hat{\sigma}(\hat{\eta}_i)\right],\ g^{-1}\left[\hat{\eta}_i + z_{\alpha/2}\hat{\sigma}(\hat{\eta}_i)\right] \right)$$

Hat-Matrix Diagonals

The diagonal elements of the hat matrix are useful in detecting extreme points in the design space, where they tend to have larger values. For the generalized linear model, the variance of the ith individual observation is

$$v_i = \frac{\phi V(\mu_i)}{f_i w_i}$$

For the ith observation, let

$$w_{ei} = v_i^{-1}(g'(\mu_i))^{-2}$$

where $g'(\mu_i)$ is the derivative of the link function evaluated at μ_i. Let $\mathbf{W}$ be the diagonal matrix, with w_{ei} denoting the ith diagonal element, which is used in computing the expected information matrix. Define the leverage, or hat-matrix diagonal, h_i, as the ith diagonal element of the matrix

$$\mathbf{W}^{\frac{1}{2}}\mathbf{X}(\mathbf{X}'\mathbf{W}\mathbf{X})^{-1}\mathbf{X}'\mathbf{W}^{\frac{1}{2}}$$

For binary or binomial models, if the estimated probability is extreme (less than 0.1 and greater than 0.9, approximately), then the hat-matrix diagonal might be greatly reduced in value. Consequently, when an observation has a very large or very small estimated probability, its leverage is not a good indicator of the observation's distance from the design space (Hosmer and Lemeshow 2000, p. 171).

Residuals

Residuals are useful in identifying observations that are not explained well by the model. For the binomial distribution, the raw residual is defined as

$$r_i = y_i/t_i - \hat{p}_i$$

where y_i is the number of event responses out of t_i trials for the ith observation. For single-trial syntax, $t_i = 1$ and $y_i = 1$ if the ordered response is 1 and $y_i = 0$ otherwise. For multinomial response data, the raw residual is

$$y_{ij} - \widehat{\pi}_{ij}$$

where $y_{ij} = 1$ if the ith observation has response level j and $y_{ij} = 0$ otherwise, and $\hat{\pi}_{ij}$ are the model-predicted probabilities of response level j for observation i.

For other generalized linear models, the raw residual is

$$r_i = y_i - \hat{p}_i$$

where y_i is the observed response and $\hat{p}_i$ is the predicted value. However, if you also specify the DIST=LOGNORMAL option, the raw residual is

$$r_i = \log(y_i) - \hat{p}_i$$

The Pearson residual is the square root of the ith observation's contribution to Pearson's chi-square:

$$r_{Pi} = r_i \sqrt{\frac{f_i w_i}{V(\mu_i)}}$$

The deviance residual is the square root of the contribution of the ith observation to the deviance, with the sign of the raw residual,

$$r_{Di} = (\text{sign}(r_i))\sqrt{d_i}$$

For example, for the binomial distribution,

$$d_i = 2 f_i w_i t_i \left[y_i/t_i \log\left(\frac{y_i/t_i}{\mu_i}\right) + (1 - y_i/t_i) \log\left(\frac{1 - y_i/t_i}{1 - \mu_i}\right)\right]$$

The working residual is

$$r_{Wi} = r_i \left(\frac{\partial \mu_i}{\partial \eta_i}\right)^{-1}$$

The Pearson residuals, standardized to have unit asymptotic variance, are

$$r_{SPi} = \frac{r_{Pi}}{\sqrt{1 - h_i}}$$

The deviance residuals, standardized to have unit asymptotic variance, are

$$r_{SDi} = \frac{r_{Di}}{\sqrt{1 - h_i}}$$

The likelihood residuals, which estimate components of a likelihood ratio test of deleting an individual observation, are a weighted combination of the standardized Pearson and deviance residuals,

$$r_{Li} = \text{sign}(r_i)\sqrt{h_i r_{SPi}^2 + (1 - h_i) r_{SDi}^2}$$

Other Regression Diagnostics

The CBAR statistic is a confidence interval displacement diagnostic that provides a scalar measure of the influence of an individual observation on $\widehat{\boldsymbol{\beta}}$. This diagnostic is based on the same idea as Cook's distance in linear regression theory (Cook and Weisberg 1982), but it uses the one-step estimate:

$$\overline{C}_i = r_{Pi}^2 h_i/(1-h_i)$$

The DIFDEV and DIFCHISQ statistics are diagnostics for detecting ill-fitted observations—observations that contribute heavily to the disagreement between the data and the predicted values of the fitted model. DIFDEV is the change in the deviance that results from deleting an individual observation, and DIFCHISQ is the change in the Pearson chi-square statistic that results from the same deletion. By using the one-step estimate, DIFDEV and DIFCHISQ for the ith observation are computed as follows:

$$\begin{aligned} \text{DIFDEV}_i &= r_{Di}^2 + \overline{C}_i \\ \text{DIFCHISQ}_i &= \overline{C}_i/h_i \end{aligned}$$

Diagnostics for Models Fit by Generalized Estimating Equations (GEEs)

The diagnostic statistics in this section were developed by Preisser and Qaqish (1996). See the section "Generalized Estimating Equations" on page 761 for further information and notation for generalized estimating equations (GEEs). The following additional notation is used in this section.

Partition the design matrix $\mathbf{X}$ and response vector $\mathbf{Y}$ by cluster; that is, let $\mathbf{X} = (X_1', \ldots, X_K')'$ and $\mathbf{Y} = (Y_1', \ldots, Y_K')'$, corresponding to the K clusters.

Let n_i be the number of responses for cluster i, and denote the total number of observations as $N = \sum_{i=1}^{K} n_i$. Denote the $n_i \times n_i$ diagonal matrix as A_i, where $V(\mu_{ij})$ is the jth diagonal element. If there is a WEIGHT statement, the diagonal element of A_i is $V(\mu_{ij})/w_{ij}$, where w_{ij} is the specified weight of the jth observation in the ith cluster. Let $\mathbf{B}$ be the $N \times N$ diagonal matrix with $g'(\mu_{ij})$ as diagonal elements, $i = 1, \ldots, K$, $j = 1, \ldots, n_i$. Let $\mathbf{B}_i$ be the $n_i \times n_i$ diagonal matrix that corresponds to cluster i, where $g'(\mu_{ij})$ is the jth diagonal element.

Let $\mathbf{W}$ be the $N \times N$ block diagonal weight matrix whose ith block, corresponding to the ith cluster, is the $n_i \times n_i$ matrix

$$\mathbf{W}_{ei} = \mathbf{B}_i^{-1}\mathbf{A}_i^{-\frac{1}{2}}\mathbf{R}_i^{-1}(\hat{\boldsymbol{\alpha}})\mathbf{A}_i^{-\frac{1}{2}}\mathbf{B}_i^{-1}$$

where $\mathbf{R}_i(\hat{\boldsymbol{\alpha}})$ is the working correlation matrix for cluster i that is computed using the estimated correlation parameters $\hat{\boldsymbol{\alpha}}$.

Let

$$\mathbf{Q}_i = \mathbf{X}_i(\mathbf{X}'\mathbf{W}\mathbf{X})^{-1}\mathbf{X}_i'$$

where $\mathbf{X}_i$ is the $n_i \times p$ design matrix that corresponds to cluster i.

The cluster leverage statistic represents the leverage of cluster i and is contained in the matrix $\mathbf{H}_i = \mathbf{Q}_i\mathbf{W}_{ei}$. The leverage of cluster i is summarized by the trace of $\mathbf{H}_i$:

$$ch_i = \text{tr}(\mathbf{H}_i)$$

The leverage h_t of the tth observation in the ith cluster is the tth diagonal element of $\mathbf{H}_i$.

Joint Tests and Type 3 Tests

Linear hypotheses for $\boldsymbol{\beta}$ are expressed in matrix form as

$$H_0: \mathbf{L}\boldsymbol{\beta} = \mathbf{c}$$

where $\mathbf{L}$ is a matrix of coefficients for the linear hypotheses and $\mathbf{c}$ is a vector of constants. The vector of regression coefficients $\boldsymbol{\beta}$ includes slope parameters and intercept parameters. The Wald chi-square statistic for testing H_0 is computed as

$$\chi^2_W = (\mathbf{L}\widehat{\boldsymbol{\beta}} - \mathbf{c})'[\mathbf{L}\widehat{\mathbf{V}}(\widehat{\boldsymbol{\beta}})\mathbf{L}']^{-1}(\mathbf{L}\widehat{\boldsymbol{\beta}} - \mathbf{c})$$

where $\widehat{\mathbf{V}}(\widehat{\boldsymbol{\beta}})$ is the estimated covariance matrix. Under H_0, χ^2_W has an asymptotic chi-square distribution with r degrees of freedom, where r is the rank of $\mathbf{L}$.

For models that use less-than-full-rank parameterization (as specified by the PARAM=GLM option in the CLASS statement), a Type 3 test of an effect of interest (main effect or interaction) is a test of the Type III estimable functions that are defined for that effect. When the model contains no missing cells, the Type 3 test of a main effect is equivalent to testing the hypothesis of equal marginal means. For more information about Type III estimable functions, see the chapter "The GLM Procedure" and the section "The Four Types of Estimable Functions" in *SAS/STAT User's Guide*. Also see Littell, Freund, and Spector (1991).

For models that use full-rank parameterization, all parameters are estimable when there are no missing cells, so it is unnecessary to define estimable functions. The standard test of an effect of interest in this case is the joint test that the values of the parameters associated with that effect are 0. For a model that uses effects parameterization (as specified by the PARAM=EFFECT option in the CLASS statement), the joint test for a main effect is equivalent to testing the equality of marginal means. For a model that uses reference parameterization (as specified by the PARAM=REF option in the CLASS statement), the joint test is equivalent to testing the equality of cell means at the reference level of the other model effects. For more information about the coding scheme and the associated interpretation of results, see Muller and Fetterman (2002, Chapter 14).

If there is no interaction term, the Type 3 test of an effect for a model that uses GLM parameterization is the same as the joint test of the effect for the model that uses full-rank parameterization. In this situation, the joint test is also called the Type 3 test. For a model that contains an interaction term and no missing cells, the Type 3 test of a component main effect under GLM parameterization is the same as the joint test of the component main effect under effect parameterization. Both test the equality of cell means. But this Type 3 test differs from the joint test under reference parameterization, which tests the equality of cell means at the reference level of the other component main effect. If some cells are missing, you can obtain meaningful tests only by testing a Type III estimation function, so in this case you should use GLM parameterization.

The results of a Type 3 test or a joint test do not depend on the order in which you specify the terms in the MODEL statement.

A Type 3 test is not available for models that you fit by using the GEE method.

Multithreading

The GENSELECT procedure allocates data to different threads and calculates the likelihood function, gradient, and Hessian by accumulating the values from all threads. For more information about how PROC GENSELECT uses threads, see the section "Multithreading" on page 102 in Chapter 2, "Shared Concepts."

Optimization Algorithms

Several optimization techniques are available in PROC GENSELECT. You can choose a particular optimizer by using the TECHNIQUE= option in the PROC GENSELECT statement. Table 14.17 summarizes the optimization techniques available in PROC GENSELECT.

Table 14.17 Optimization Techniques

TECHNIQUE=	Algorithm
TRUREG	Trust region method
NEWRAP	Newton-Raphson method with line search
NRRIDG	Newton-Raphson method with ridging
QUANEW	Quasi-Newton methods
DBLDOG	Double-dogleg method
CONGRA	Conjugate gradient methods
LBFGS	Limited-memory BFGS quasi-Newton method
NMSIMP	Nelder-Mead simplex method

There is no algorithm for optimizing general nonlinear functions that always finds the global optimum for a general nonlinear optimization problem in a reasonable amount of time. Because no single optimization technique is always superior to others, PROC GENSELECT provides a variety of optimization techniques that work well in various circumstances. However, you can devise problems for which none of the techniques in PROC GENSELECT can find the correct solution. Moreover, nonlinear optimization can be computationally expensive in terms of time and memory, so you must be careful when matching an algorithm to a problem. The section "Choosing an Optimization Algorithm" on page 103 in Chapter 2, "Shared Concepts," is helpful in choosing a suitable optimization algorithm.

In a GEE analysis, these optimization options control the first stage of estimation that produces the initial values for the GEE fit.

Displayed Output

The following sections describe the output that PROC GENSELECT produces. The output is organized into various tables, which are discussed in their order of appearance.

Store Information

The "Store Information" table displays basic information about the stored model: the item store name, the names of the library and data table used to create the model, the names of the action and procedure that created the item store, and the date when the model was stored. This table is not displayed when you fit a model.

Store Text

The "Store Text" table displays notes that are stored along with the stored model. This table is not displayed when you fit a model.

Model Information

The "Model Information" table displays basic information about the model, such as the response variable, the frequency variable, the link function, and the model category that the GENSELECT procedure selected based on your input and options. The "Model Information" table also displays the distribution of the data that is assumed by the GENSELECT procedure. For information about how the procedure determines the response distribution, see the section "Response Distributions" on page 748. If you specify the CODE statement, then the table displays the name of the variable in the scoring code that contains the classifications. If you do not also specify the PCATALL option, then the table also displays the name of the variable in the scoring code that contains the predicted probabilities.

Number of Observations

The "Number of Observations" table displays the number of observations read from the input data table and the number of observations used in the analysis. If a FREQ statement is present, the table displays the sum of the frequencies that are read and used. If the events/trials syntax is used, the number of events and trials is also displayed. If you specify a PARTITION statement, the table displays the values for each role.

Response Profile

The "Response Profile" table displays the ordered value from which the GENSELECT procedure determines the probability being modeled as an event in a binary model and displays the ordering of categories in a multinomial model. For each response category level, the frequency used in the analysis is reported. You can affect the ordering of the response values by specifying *response-options* in the MODEL statement. For a binary model, the note that follows the "Response Profile" table indicates which outcome is modeled as the event. For an ordinal multinomial model, the note that follows the "Response Profile" table indicates how the ordered response levels are accumulated; for a nominal multinomial model, the note indicates the reference response level. If you specify a PARTITION statement, the table displays the values for each role.

Class Level Information

The "Class Level Information" table lists the levels of every variable specified in the CLASS statement. You should check this information to make sure that the data are correct. You can adjust the order of the CLASS variable levels by specifying the ORDER= option in the CLASS statement. You can suppress the "Class Level Information" table completely or partially by specifying the NOCLPRINT= option in the PROC GENSELECT statement.

If the classification variables use a nonsingular parameterization, the "Class Level Information" table also displays the reference value for each variable.

Selection Information

When you specify the SELECTION statement, the GENSELECT procedure by default produces a series of tables that display information about the model selection. The "Selection Information" table informs you about the model selection method, selection and stop criteria, and other parameters that govern the selection. You can suppress this table by specifying DETAILS=NONE in the SELECTION statement.

Iteration History

When you specify the ITHIST option in the PROC GENSELECT statement, the "Iteration History" table displays, for each iteration of the optimization, the number of function evaluations (including gradient and Hessian evaluations), the value of the objective function, the change in the objective function from the previous iteration, and the absolute value of the largest (projected) gradient element. The objective function that is used in the optimization in the GENSELECT procedure is normalized by default to enable comparisons across data tables that have different sampling intensity. You can control normalization by specifying the NORMALIZE= option in the PROC GENSELECT statement.

Convergence Status

The convergence status table is a small ODS table in the default output. In the listing, it appears as a message that indicates whether the optimization succeeded and which convergence criterion was met. If the optimization fails, the message indicates the reason for the failure. If you save the convergence status table to an output data set, a numeric Status variable is added that enables you to assess convergence programmatically. The values of the Status variable indicate the following:

0 Convergence was achieved, or an optimization was not performed (because TECHNIQUE=NONE is specified).

1 The objective function could not be improved.

2 Convergence was not achieved because of a user interruption or because a limit was exceeded, such as the maximum number of iterations or the maximum number of function evaluations. To modify these limits, see the MAXITER=, MAXFUNC=, and MAXTIME= options in the PROC GENSELECT statement.

3 Optimization failed to converge because function or derivative evaluations failed at the starting values or during the iterations or because a feasible point that satisfies the parameter constraints could not be found in the parameter space.

Entry and Removal Candidates

When you specify DETAILS=ALL or DETAILS=STEPS in the SELECTION statement, the GENSELECT procedure produces the "Entry Candidates" or "Removal Candidates" table, which displays the effect names and values of the criterion used to select entering or departing effects at each step of the selection process. For each step, the effects are displayed in sorted order from best to worst of the selection criterion.

Selection Summary

When you specify the SELECTION statement, the GENSELECT procedure produces the "Selection Summary" table, which displays information about which effects were added to or removed from the model in the various steps of the model selection process. The statistic that led to the entry or removal decision is also displayed. You can request further details about the model selection steps by specifying DETAILS=STEPS or DETAILS=ALL in the SELECTION statement. You can suppress the display of the "Selection Summary" table by specifying DETAILS=NONE in the SELECTION statement.

If you specify the LASSO selection method, then this table displays information about which effect was added to or removed from the model, the number of effects in the model, the lambda value, and the information criteria.

Stop Reason

When you specify the SELECTION statement, the GENSELECT procedure produces a simple table that tells you why model selection stopped.

Selection Reason

When you specify the SELECTION statement, the GENSELECT procedure produces a simple table that tells you why the final model was selected.

Selected Effects

When you specify the SELECTION statement, the GENSELECT procedure produces a simple table that tells you which effects were included in the final model.

Dimensions

The "Dimensions" table displays size measures that are derived from the model and the environment. It displays the number of columns in the current design matrix, the number of effects in the current design, the largest number of design columns associated with an effect, the rank of the matrix, and the number of parameters in the current model, including any dispersion parameters.

Fit Statistics

The "Fit Statistics" table displays a variety of likelihood-based measures of fit. All statistics are presented in "smaller is better" form. The values that the "Fit Statistics" table displays are not based on a normalized log-likelihood function. If you specify a PARTITION statement or the PARTFIT option, the table displays the values for each role along with statistics for comparing the training, validation, and testing results.

For more information about the statistics displayed in this table, see the section "Model Fit and Assessment Statistics" on page 767.

This table is not produced in a GEE analysis.

Parameter Estimates

The parameter estimates, their estimated (asymptotic) standard errors, and p-values for the hypothesis that the parameter is 0 are presented in the "Parameter Estimates" table. If you request confidence intervals by specifying the CLB option in the MODEL statement, confidence limits are produced for the estimates.

This table is not produced by default in a GEE analysis. You can produce this table by specifying the PRINTMLE option in the REPEATED statement. In this case, the table is labeled "Analysis of Initial Parameter Estimates."

Parameter Estimates Covariance Matrix

When you specify the COVB option in the PROC GENSELECT statement, the GENSELECT procedure displays the covariance matrix of the parameter estimates. The covariance matrix is computed as the inverse of the negative of the matrix of second derivatives of the log-likelihood function with respect to the model parameters (the Hessian matrix), evaluated at the parameter estimates.

This table is not produced in a GEE analysis.

Parameter Estimates Correlation Matrix

When you specify the CORRB option in the PROC GENSELECT statement, the GENSELECT procedure displays the correlation matrix of the parameter estimates.

This table is not produced in a GEE analysis.

GEE Model Information

The "GEE Model Information" table displays basic information about the GEE model, including the subject effects, any within-subject effects, the working correlation type, and details about the size of the working correlation matrix.

GEE Parameter Estimates Covariance Matrix Using Model-Based Covariance

The "GEE Parameter Estimates Covariance Matrix Using Model-Based Covariance" table displays the parameter estimates covariance matrix from the GEE analysis that uses the model-based covariance estimate. For more information about the covariance estimates that are used for GEE analysis, see the section "Parameter Estimate Covariances" on page 765.

This table is not displayed unless you specify the MCOVB or COVB option in the REPEATED statement.

GEE Parameter Estimates Correlation Matrix Using Model-Based Covariance

The "GEE Parameter Estimates Correlation Matrix Using Model-Based Covariance" table displays the parameter estimates correlation matrix from the GEE analysis that uses the model-based covariance estimate. For more information about the covariance estimates that are used for GEE analysis, see the section "Parameter Estimate Covariances" on page 765.

This table is not displayed unless you specify the MCORRB or CORRB option in the REPEATED statement.

GEE Parameter Estimates Covariance Matrix Using Empirical Covariance

The "GEE Parameter Estimates Covariance Matrix Using Empirical Covariance" table displays the parameter estimates covariance matrix from the GEE analysis that uses the empirical covariance estimate. For more information about the covariance estimates that are used for GEE analysis, see the section "Parameter Estimate Covariances" on page 765.

This table is not displayed unless you specify the ECOVB or COVB option in the REPEATED statement.

GEE Parameter Estimates Correlation Matrix Using Empirical Covariance

The "GEE Parameter Estimates Correlation Matrix Using Empirical Covariance" table displays the parameter estimates correlation matrix from the GEE analysis that uses the empirical covariance estimate. For more information about the covariance estimates that are used for GEE analysis, see the section "Parameter Estimate Covariances" on page 765.

This table is not displayed unless you specify the ECORRB or CORRB option in the REPEATED statement.

GEE Working Correlation Matrix

The "GEE Working Correlation Matrix" table displays the correlation matrix of the repeated measures. Its dimension depends on the number of repeated measures and any within-subject effects.

This table is not displayed unless you specify the CORRW option in the REPEATED statement.

GEE Exchangeable Correlation

The "GEE Exchangeable Correlation" table displays the exchangeable correlation parameter. For more information about the working correlation structures, see the section "Working Correlation Matrix" on page 762.

This table is not displayed unless you specify TYPE=EXCH and the CORRW option in the REPEATED statement.

GEE Fit Criteria

The "GEE Fit Criteria" table displays the information criteria for the GEE model. For more information about the fit statistics that are used with GEE, see the section "Quasi-likelihood Information Criterion" on page 765.

GEE Parameter Estimates Using Empirical Standard Errors

The "GEE Parameter Estimates Using Empirical Standard Errors" table presents the parameter estimates from the GEE analysis. The table displays the standard errors that are derived from the empirical covariance matrix. The table includes the parameter estimates, their estimated standard errors, and p-values for the hypothesis that the parameter is 0. If you request confidence intervals by specifying the CLB option in the MODEL statement, confidence limits are produced for the estimates.

For more information about the covariance estimates that are used for GEE analysis, see the section "Parameter Estimate Covariances" on page 765.

GEE Parameter Estimates Using Model-Based Standard Errors

The "GEE Parameter Estimates Using Model-Based Standard Errors" table presents the parameter estimates from the GEE analysis. The table displays the standard errors that are derived from the model-based covariance matrix. The table includes the parameter estimates, their estimated standard errors, and p-values for the hypothesis that the parameter is 0. If you request confidence intervals by specifying the CLB option in the MODEL statement, confidence limits are produced for the estimates.

This table is not produced unless you specify the MODELSE option in the REPEATED statement. For more information about the covariance estimates that are used for GEE analysis, see the section "Parameter Estimate Covariances" on page 765.

Model Analysis of Variance (Type III)

When you specify the TYPE3 option in the MODEL statement, the procedure produces the "Model Analysis of Variance (Type III)" table. This table displays tests that all parameters for a particular effect are 0. For more information, see the section "Joint Tests and Type 3 Tests" on page 772.

This table is not produced in a GEE analysis.

Postfit Information

The "Postfit Information" table displays the name of the data table that the stored model uses to create the results that are displayed in the Restore section of the output, the number of observations that are read from this data table, and the number of observations that are used in the analyses. If you specify a FREQ statement, the table displays the sum of the frequencies that are read and used. If you specify a WEIGHT statement, the table displays the sum of $f_i w_i$ that are read and used. If the stored model is created using a PARTITION statement, the table displays the values for each role. This table is not displayed when you fit a model. This table is followed by "Response Profile" and "Fit Statistics" tables that are computed by using the input data table.

Score Code Variables for Predicted Values

When you specify the PCATALL option in the CODE statement and you specify the DISTRIBUTION=BINARY option in the MODEL statement, the GENSELECT procedure produces the "Score Code Variables for Predicted Probability" table. For each level of the response variable, this table displays the corresponding variable in the scoring code that contains the predicted probability.

Timing

The "Timing" table displays the amount of time (in seconds) that PROC GENSELECT required to perform different tasks in the analysis.

OutputCasTables Table

The OutputCasTables table is a special table that has information about each CAS table that is created during a CAS action execution. The information for each CAS table consists of the CAS table name, the caslib in which the table resides, and the number of columns and rows in the CAS table. Because this table is not a typical ODS table that contains analytical results, you cannot include it in the *table-spec-list* in the DISPLAYOUT statement.

ODS Table Names

Each table that the GENSELECT procedure creates has a name associated with it. You must use this name to refer to the table when you use the DISPLAY statement, the DISPLAYOUT statement, or ODS statements. These names are listed in Table 14.18.

The EFFECT and LSMEANS statements also create tables that are not listed in Table 14.18. For information about these tables, see the corresponding sections of Chapter 2, "Shared Concepts."

Table 14.18 ODS Tables Produced by PROC GENSELECT

Table Name	Description	Statement	Options
ClassInfo	Level information from the CLASS statement	CLASS	Default
ConvergenceStatus	Status of optimization at conclusion of optimization	PROC GENSELECT	Default
CorrB	Correlation matrix of parameter estimates	PROC GENSELECT	CORRB
CovB	Covariance matrix of parameter estimates	PROC GENSELECT	COVB
Dimensions	Model dimensions	PROC GENSELECT	Default
EntryCandidates	Details about candidates for entry into the model	SELECTION	METHOD=FORWARD DETAILS=STEP
FitStatistics	Fit statistics	PROC GENSELECT	Default
GEEEmpPEst	GEE parameter estimates using empirical standard errors	REPEATED	Default
GEEExchCorr	Exchangeable correlation parameter	REPEATED	TYPE=EXCH
GEEFitCriteria	Measures of fit for GEE models	REPEATED	Default
GEEModInfo	Information about GEE model	REPEATED	Default
GEEModPEst	GEE parameter estimates using model-based standard errors	REPEATED	MODELSE
GEENCorr	Correlation matrix of GEE parameter estimates using model-based covariance	REPEATED	CORRB or MCORRB
GEENCov	Covariance matrix of GEE parameter estimates using model-based covariance	REPEATED	COVB or MCOVB
GEERCorr	Correlation matrix of GEE parameter estimates using empirical covariance	REPEATED	CORRB or ECORRB
GEERCov	Covariance matrix of GEE parameter estimates using empirical covariance	REPEATED	COVB or ECOVB
GEEWCorr	Working correlation matrix of repeated measures	REPEATED	CORRW

Table 14.18 *continued*

Table Name	Description	Statement	Options
IterHistory	Iteration history	PROC GENSELECT	ITHIST
ModelInfo	Information about the modeling environment	PROC GENSELECT	Default
ModelAnova	Model analysis of variance (Type III)	MODEL	TYPE3
NObs	Number of observations read and used, and number of events and trials, if applicable	PROC GENSELECT	Default
OutputCasTables	See the section "OutputCasTables Table" on page 779	OUTPUT DISPLAYOUT	OUT=
ParameterEstimates	Solutions for the parameter estimates associated with effects in MODEL statements	PROC GENSELECT REPEATED	Default PRINTMLE
PostfitInfo	Input data table name and number of observations read and used for the restored model	PROC GENSELECT	RESTORE= and DATA=
PredProbName	Displays the predicted probability variable in the scoring code associated with each response level	CODE	PCATALL
RemovalCandidates	Details about candidates for removal from the model	SELECTION	METHOD=BACKWARD DETAILS=STEP
ResponseProfile	Response categories for binary and multinomial data	Default	
SelectedEffects	List of effects selected for the model	SELECTION	Default
SelectionInfo	Information about the settings for model selection	SELECTION	Default
SelectionReason	Reason why the particular model was selected	SELECTION	Default
SelectionSummary	Summary information about model selection steps	SELECTION	Default
StopReason	Reason for termination of model selection	SELECTION	Default
StoreInfo	Information about the restored model	PROC GENSELECT	RESTORE=
StoreText	Notes stored along with the model	PROC GENSELECT	RESTORE=
Timing	Absolute and relative times for tasks performed by the procedure	PROC GENSELECT	Default

ODS Graphics

Statistical procedures use ODS Graphics to create graphs as part of their output. ODS Graphics is described in detail in the "Statistical Graphics Using ODS" chapter in *SAS/STAT User's Guide*.

Before you create graphs, ODS Graphics must be enabled (for example, by using the ODS GRAPHICS ON statement). For more information about enabling and disabling ODS Graphics, see the section "Enabling and Disabling ODS Graphics" in that chapter.

The overall appearance of graphs is controlled by ODS styles. Styles and other aspects of using ODS Graphics are discussed in the section "A Primer on ODS Statistical Graphics" in that chapter.

When ODS Graphics is enabled, the SELECTION statement can produce plots to help evaluate the selection process. For information about these plots, see the section "Model Selection Plots" on page 93 in Chapter 2, "Shared Concepts."

PROC GENSELECT assigns a name to each graph that it creates using ODS. You can use these names to reference the graphs when using ODS. The names are listed in Table 14.19.

Table 14.19 Graphs Produced by PROC GENSELECT

ODS Graph Name	Plot Description	PLOTS Option
CoefficientPanel	Coefficients and CHOOSE= criterion by step	COEFFICIENTS
ChooseCriterionPlot	CHOOSE= criterion by step	COEFFICIENTS(UNPACK)
CoefficientPlot	Coefficients by step	COEFFICIENTS(UNPACK)
CriterionPanel	Fit criteria by step	CRITERIA
AICCPlot	Corrected Akaike's information criterion by step	CRITERIA(UNPACK)
AICPlot	Akaike's information criterion by step	CRITERIA(UNPACK)
SBCPlot	Schwarz Bayesian information criterion by step	CRITERIA(UNPACK)
TEST_ASEPlot	Average square error on testing data by step	CRITERIA(UNPACK)
TRAIN_ASEPlot	Average square error on training data by step	CRITERIA(UNPACK)
VAL_ASEPlot	Average square error on validation data by step	CRITERIA(UNPACK)
FitByRolePlot	Progression of average square error by role	FITBYROLE

Examples: GENSELECT Procedure

The examples in this chapter are available in the GitHub repository located at https://github.com/sascommunities/doc-supplement-casstat.

Example 14.1: Model Selection

(View the complete code for this example (genex1.sas) in the example repository.)

The following statements examine the same data set that is used in the section "Getting Started: GENSELECT Procedure" on page 708, but they request model selection via the forward selection technique. Model effects are added in the order of their significance until no more effects significantly improve the current model. The DETAILS=ALL option in the SELECTION statement requests that all tables that are related to model selection be produced.

The data set getStarted is shown in the section "Getting Started: GENSELECT Procedure" on page 708. It contains 100 observations on a count response variable (Y), a continuous variable (Total) to be used in Example 14.2, and five categorical variables (C1–C5), each of which has four numerical levels.

A log-linked Poisson regression model is specified by using classification effects for variables C1–C5. The following statements request model selection by the forward selection method:

```
ods graphics on;

proc genselect data=mylib.getStarted;
   class C1-C5;
   model Y = C1-C5 / Distribution=Poisson;
   selection method=forward details=all plots=all;
run;

ods graphics off;
```

The model selection tables are shown in Output 14.1.1 through Output 14.1.3. Selection graphics produced by the PLOTS= option are displayed in Output 14.1.6 and Output 14.1.7.

The "Selection Information" table in Output 14.1.1 summarizes the settings for the model selection. The effect that produces the smallest approximate SBC is added to the model. The forward selection stops three steps after the smallest SBC is obtained, or when all effects have been added to the model.

Output 14.1.1 Selection Information

The GENSELECT Procedure

Selection Information	
Selection Method	Forward
Select Criterion	SBC
Stop Criterion	SBC
Effect Hierarchy Enforced	None
Stop Horizon	3

The "Selection Summary" table in Output 14.1.2 shows the effects that were added to the model and the approximate SBC. Step 0 refers to the null model that contains only an intercept. In the next step, effect C2 resulted in the smallest approximate SBC among the candidate effects. In step 2, the smallest SBC when an effect is added to a model that contains the intercept and C2 was achieved by adding C5 to the model. Similarly, in steps 3, 4, and 5, effects were added in order of the minimum SBC among remaining candidates. Finally, the model in step 2 was chosen as the best because it had the smallest SBC among all the candidate models.

Output 14.1.2 Selection Summary Information

Selection Summary

Step	Effect Entered	Number Effects In	SBC
0	Intercept	1	354.7980
1	C2	2	342.8795
2	C5	3	333.8182*
3	C1	4	341.7993
4	C4	5	351.8375
5	C3	6	363.8674

* Optimal Value Of Criterion

Selection stopped at a local minimum of the STOP criterion.

The model at step 2 is selected.

Selected Effects: Intercept C2 C5

For each step of the selection process, the DETAILS=ALL option displays the candidate effects for entering the model along with their SELECT= criterion. Output 14.1.3 displays this table for the first step; the other steps are not shown here.

Output 14.1.3 Step1 Entry Candidates

Entry Candidates

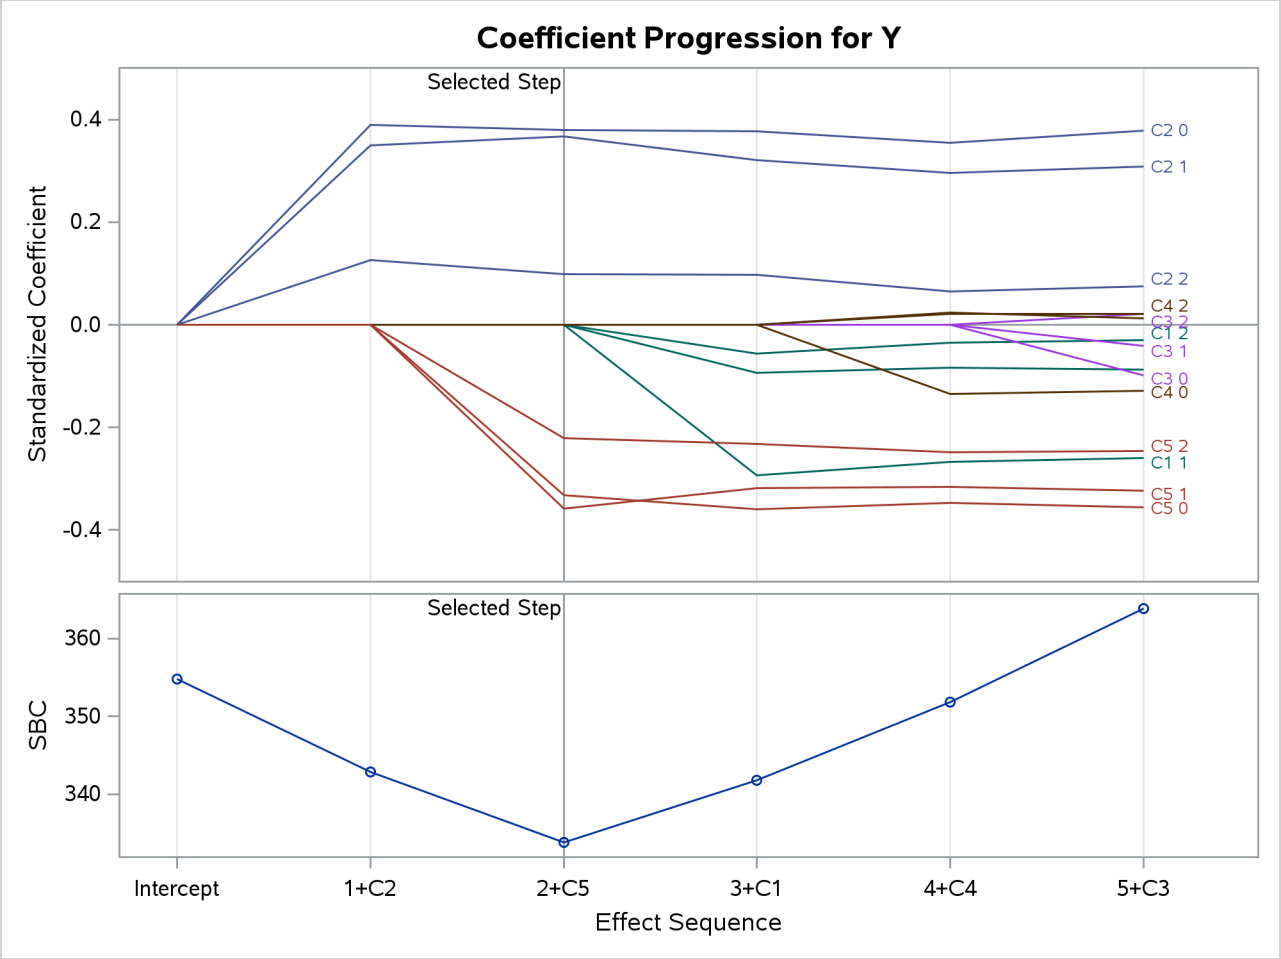
Rank	Effect	SBC
1	C2	342.8795
2	C5	347.5376
3	C1	355.7067
4	C4	361.7379
5	C3	365.7339

The DETAILS=ALL option also displays the dimensions, fit statistics, and parameter estimates at each step of the selection process; these details are not shown here.

Output 14.1.4 displays information about the selected model. Notice that the –2 log-likelihood value in the "Fit Statistics" table is larger than the value for the full model in Figure 14.6. This is expected because the selected model contains only a subset of the parameters. Because the selected model is more parsimonious than the full model, the information criteria AIC, AICC, and BIC are smaller than in the full model, indicating a better fit.

Output 14.1.4 Fit Statistics

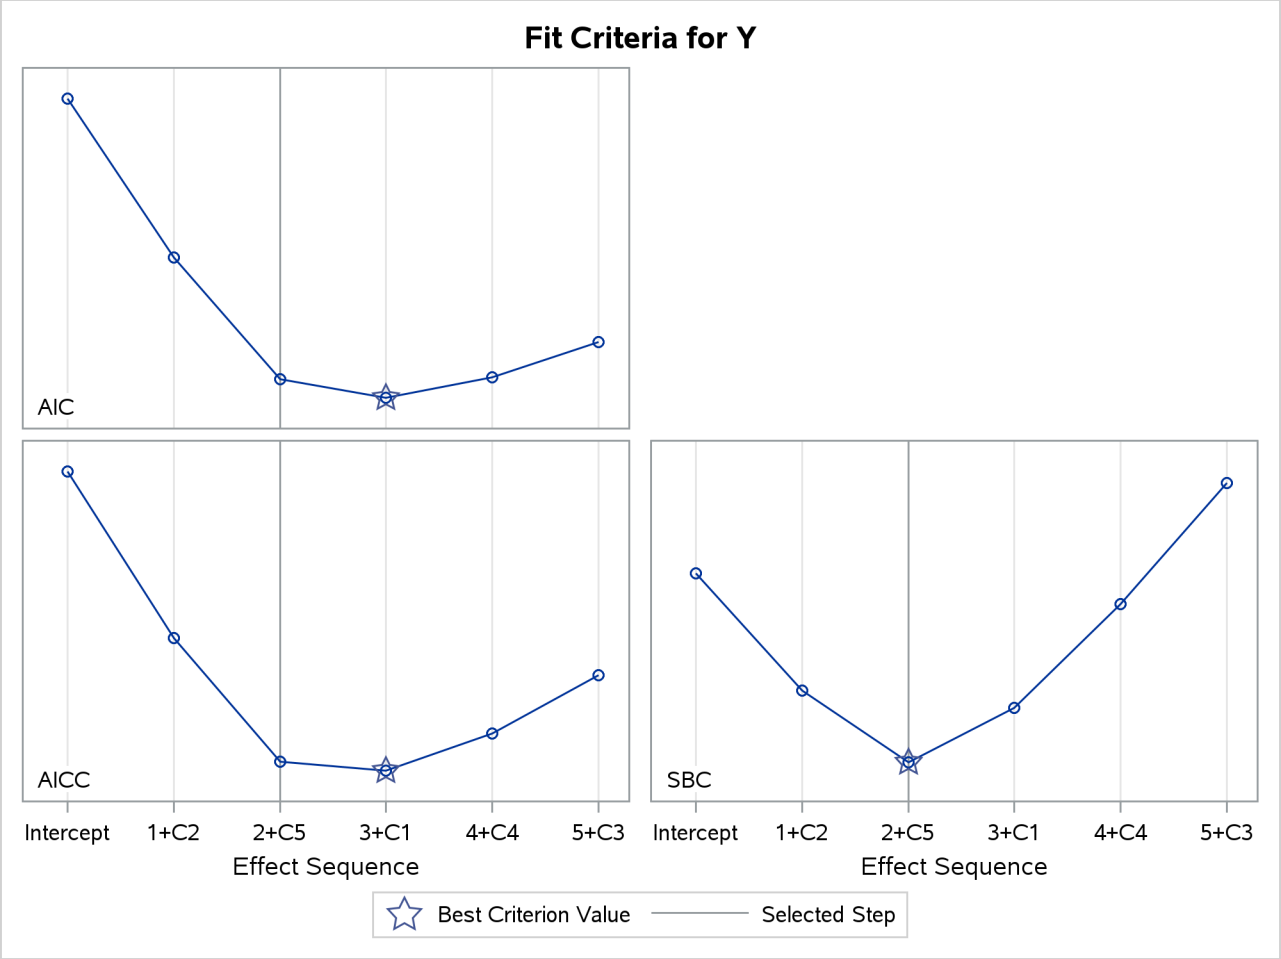
Fit Statistics	
-2 Log Likelihood	303.58036
AIC (smaller is better)	317.58036
AICC (smaller is better)	318.79775
SBC (smaller is better)	335.81655



The parameter estimates of the selected model are shown in Output 14.1.5. Notice that the effects are listed in the "Parameter Estimates" table in the order in which they were specified in the MODEL statement and not the order in which they were added to the model.

Output 14.1.5 Parameter Estimates

Parameter Estimates					
Parameter	**DF**	**Estimate**	**Standard Error**	**Chi-Square**	**Pr > ChiSq**
Intercept	1	0.528024	0.215231	6.0186	0.0142
C2 0	1	0.962636	0.236921	16.5088	<.0001
C2 1	1	0.845132	0.233634	13.0851	0.0003
C2 2	1	0.213247	0.248896	0.7341	0.3916
C2 3	0	0	.	.	.
C5 0	1	-0.763491	0.207082	13.5933	0.0002
C5 1	1	-0.785915	0.201271	15.2471	<.0001
C5 2	1	-0.541212	0.208661	6.7275	0.0095
C5 3	0	0	.	.	.



The coefficient panel in Figure 14.1.6 enables you to visualize the selection process. In this plot, standardized coefficients of all the effects that are selected at some step of the stepwise method are plotted as a function of the step number. This enables you to assess the relative importance of the effects that are selected at any step of the selection process and to know when effects entered the model. The lower plot in the panel shows how the criterion that is used to choose the selected model changes as effects enter or leave the model.

Output 14.1.6 Coefficient Progression

The criterion panel in Figure 14.1.7 provides a graphical view of the progression of the fit criteria as the selection process evolves.

Output 14.1.7 Criterion Panel

Example 14.2: Gamma Model

(View the complete code for this example (genex2.sas) in the example repository.)

The following statements examine the data set getStarted, which is used in the section "Getting Started: GENSELECT Procedure" on page 708, but they request that a log-linked gamma model be fit by using the continuous variable Total as the response instead of the count variable Y. The following statements fit a log-linked gamma model to these data by using classification effects for the variables C1–C5. The CLB MODEL statement option requests that 95% confidence limits be computed and displayed along with the parameter estimates. The CODE statement requests that a text file named "Scoring Parameters.txt" be created. This file contains a SAS program that has information from the model that allows scoring of a new data set based on the parameter estimates from the current model.

```
proc genselect data=mylib.getStarted;
   class C1-C5;
   model Total = C1-C5 / Distribution=Gamma Link=Log CLB;
   code File='ScoringParameters.txt';
run;
```

The "Parameter Estimates" table in Output 14.2.1 shows the resulting regression model parameter estimates and the estimated gamma dispersion parameter.

Output 14.2.1 Parameter Estimates

The GENSELECT Procedure

Parameter Estimates

Parameter	DF	Estimate	Standard Error	Chi-Square	Pr > ChiSq	95% Confidence Limits	
Intercept	1	4.028096	0.454883	78.4153	<.0001	3.13654	4.91965

C5 3	0	0	.	.	.	.	.
Dispersion	1	1.672305	0.238205			1.26494	2.21086

Now suppose you want to compute predicted values for some different data. If $\mathbf{x}$ is a vector of explanatory variables that might not be in the original data and $\hat{\boldsymbol{\beta}}$ is the vector of estimated regression parameters from the model, then $\mu = g^{-1}(\mathbf{x}'\hat{\boldsymbol{\beta}})$ is the predicted value of the mean, where g is the log link function in this case.

The following data contain new values of the regression variables C1–C5, from which you can compute predicted values based on information in the SAS program that is created by the CODE statement. This is called *scoring* the new data set.

```
data ScoringData;
   input C1-C5;
   datalines;
3 3 1 0 2
1 1 2 2 0
3 2 2 2 0
1 1 2 3 2
1 1 2 3 3
3 1 1 0 1
```

```
0 2 1 0 0
2 1 3 1 3
3 2 3 2 0
3 0 2 0 1
;
```

The following SAS DATA step creates the new data set Scores, which contains a variable P_Total that represents the predicted values of Total, along with the variables C1–C5. The resulting data are shown in Output 14.2.2.

```
data Scores;
   set ScoringData;
   %inc 'ScoringParameters.txt';
run;
proc print data=Scores;
run;
```

Output 14.2.2 Predicted Values for Scoring Data

Obs	C1	C2	C3	C4	C5	P_Total
1	3	3	1	0	2	27.449
2	1	1	2	2	0	10.349
3	3	2	2	2	0	12.590
4	1	1	2	3	2	25.020
5	1	1	2	3	3	32.222
6	3	1	1	0	1	46.020
7	0	2	1	0	0	7.282
8	2	1	3	1	3	138.244
9	3	2	3	2	0	13.523
10	3	0	2	0	1	82.063

Example 14.3: Binary Model with Repeated Measures

(View the complete code for this example (genex3.sas) in the example repository.)

This example uses data from the "Six Cities" study of the effects of air pollution on health (Ware et al. 1984). The analysis concerns the 16 selected cases in Lipsitz et al. (1994). The response is binary and indicates the wheezing status of 16 children. The children were assessed at ages 9, 10, 11, and 12 years. A value of 1 for wheezing status indicates the occurrence of wheezing at that age. The following statements create the data set:

```
data mylib.six;
     input case city$ @@;
   do i=1 to 4;
      input age smoke wheeze @@;
      output;
   end;
   datalines;
 1 portage   9 0 1  10 0 1  11 0 1  12 0 0
 2 kingston  9 1 1  10 2 1  11 2 0  12 2 0
 3 kingston  9 0 1  10 0 0  11 1 0  12 1 0
```

```
 4 portage   9 0 0  10 0 1  11 0 1  12 1 0
 5 kingston  9 0 0  10 1 0  11 1 0  12 1 0
 6 portage   9 0 0  10 1 0  11 1 0  12 1 0

16 portage   9 1 1  10 1 1  11 2 0  12 1 0
;
```

The mean response is modeled by using a logistic regression model. The explanatory variables are city of residence (city), age in years (age), and maternal smoking status at each age (smoke). The responses for each child are assumed to be equally correlated, indicating that an exchangeable correlation structure is appropriate. The following statements fit the model by using generalized estimating equations (GEEs) and the chosen correlation structure:

```
proc genselect data=mylib.six;
   class case city;
   model wheeze(event='1') = city age smoke / dist=binary;
   repeated subject=case / type=exch covb corrw printmle;
run;
```

The MODEL statement specifies the mean model for the wheeze response variable as a logistic regression that uses city, age, and smoke as explanatory variables. This is the same specification that you use for an ordinary logistic regression.

The REPEATED statement uses GEE for parameter estimation, specifies the working correlation structure, and controls the output that is displayed. The SUBJECT=CASE option specifies that the case variable identifies the individual subjects in the data set. The case variable must be listed in the CLASS statement. The TYPE=EXCH option specifies that the procedure use the exchangeable working correlation structure. The exchangeable correlation structure does not rely on an order in the repeated measurements, so you do not need to specify a within-subject effect in the WITHIN= option. The COVB option displays the parameter estimates covariance matrix, and the CORRW option displays the final working correlation matrix. The PRINTMLE option displays a table of the initial parameter estimates that are produced by maximum likelihood estimation.

The initial parameter estimates for the GEE fit are computed by an ordinary logistic regression, which assumes no dependence between the repeated measurements.

Figure 14.3.1 displays general information about the GEE model fit.

Output 14.3.1 GEE Model Information

The GENSELECT Procedure

GEE Model Information	
Correlation Structure	Exchangeable
Subject Effect	case (16 levels)
Number of Clusters	16
Correlation Matrix Dimension	4
Maximum Cluster Size	4
Minimum Cluster Size	4

Figure 14.3.2 displays the estimated parameter covariance matrices. The COVB option produces both the model-based and empirical covariance matrices.

Output 14.3.2 GEE Parameter Estimate Covariance Matrices

GEE Parameter Estimates
Model-Based Covariance Matrix

	Intercept	city kingston	age	smoke
Intercept	5.7495	-0.2226	-0.5347	0.01655
city kingston	-0.2226	0.4548	-0.00241	0.01876
age	-0.5347	-0.00241	0.05300	-0.01658
smoke	0.01655	0.01876	-0.01658	0.1910

GEE Parameter Estimates
Empirical Covariance Matrix

	Intercept	city kingston	age	smoke
Intercept	9.3399	-0.8510	-0.8325	-0.1653
city kingston	-0.8510	0.4737	0.05736	0.04023
age	-0.8325	0.05736	0.07778	-0.00236
smoke	-0.1653	0.04023	-0.00236	0.1305

The working correlation matrix that is specified by the CORRW option is displayed in Figure 14.3.3.

Output 14.3.3 GEE Working Correlation Matrix

Working Correlation Matrix				
	Col1	**Col2**	**Col3**	**Col4**
Row1	1.0000	0.1648	0.1648	0.1648
Row2	0.1648	1.0000	0.1648	0.1648
Row3	0.1648	0.1648	1.0000	0.1648
Row4	0.1648	0.1648	0.1648	1.0000

The exchangeable working correlation structure is characterized by a single parameter. Figure 14.3.4 shows the table that contains this information.

Output 14.3.4 GEE Exchangeable Correlation

GEE Exchangeable Correlation	
Correlation	0.164816

Figure 14.3.5 displays the parameter estimates table. This table shows the parameter estimates, standard errors, chi-square values, and *p*-values for the parameter estimates. The table uses the empirical standard error estimates. You can also produce a table that uses the model-based standard error estimates by specifying the MODELSE option in the REPEATED statement.

Output 14.3.5 GEE Parameter Estimates Table

Analysis of GEE Parameter Estimates Using Empirical Standard Error Estimates					
Parameter	**DF**	**Estimate**	**Standard Error**	**Chi-Square**	**Pr > ChiSq**
Intercept	1	1.2751	3.0561	0.1741	0.6765
city kingston	1	0.1223	0.6882	0.0316	0.8589
city portage	0	0	.	.	.
age	1	-0.2036	0.2789	0.5327	0.4655
smoke	1	-0.0935	0.3613	0.0670	0.7957

You can compare the GEE parameter estimates to the parameter estimates from the initial model. The parameter estimates from the initial model are displayed in Figure 14.3.6.

Output 14.3.6 Initial Parameter Estimates Table

Analysis of Initial Parameter Estimates					
Parameter	**DF**	**Estimate**	**Standard Error**	**Chi-Square**	**Pr > ChiSq**
Intercept	1	1.259707	2.610423	0.2329	0.6294
city kingston	1	0.139098	0.552686	0.0633	0.8013
city portage	0	0	.	.	.
age	1	-0.200315	0.250815	0.6379	0.4245
smoke	1	-0.128364	0.410239	0.0979	0.7544

The GEE parameter estimates are not substantially different from the parameter estimates in the initial model.

Overview: ICA Procedure

The ICA procedure performs independent component analysis in SAS Viya.

Independent component analysis attempts to extract from the observed multivariate data *independent components* (also called *factors* or *latent variables*) that are as statistically independent from each other as possible. The methods that PROC ICA implements, where statistical independence is defined as the maximization of non-Gaussianity, seek linear combinations of the observed random variables that maximize the non-Gaussianity of the estimated independent components.

Independent component analysis is one of the techniques for performing blind source separation or blind signal separation, where source means an original signal or independent component, and blind means that the mixing process of the source signals is unknown and few assumptions about the source signals are made. You can use independent component analysis to reveal the hidden structure of the data in many applications, including feature extraction and signal separation.

PROC ICA Features

The ICA procedure has the following main features:

- provides a VAR statement to specify the numeric variables for the analysis
- supports whitening and dimension reduction
- produces an output data table that contains independent components and whitened variables

PROC ICA implements the following methods in parallel, based on the FastICA algorithm of Hyvärinen and Oja (2000):

- symmetric decorrelation, which calculates all the independent components simultaneously
- deflationary decorrelation, which extracts the independent components successively

In addition, PROC ICA implements the following methods, based on the InfoMax algorithm of Bell and Sejnowski (1995):

- geodesic InfoMax, which uses geodesic-based gradient updates
- symmorth InfoMax, which uses a symmetric orthogonalized version of gradient updates
- unconstrained InfoMax, which uses Euclidean gradient updates

Because PROC ICA runs on SAS Cloud Analytic Services (CAS), it also does the following:

- enables you to run on a cluster of machines that distribute the data and the computations

- enables you to run in single-machine mode
- exploits all the available cores and concurrent threads. For information about how PROC ICA uses threads, see the section "Multithreading" on page 102 in Chapter 2, "Shared Concepts."

Using CAS Sessions and CAS Engine Librefs

SAS Cloud Analytic Services (CAS) is the analytic server and associated cloud services in SAS Viya. This section describes how to create a CAS session and set up a CAS engine libref that you can use to connect to the CAS session. It assumes that you have a CAS server already available; contact your system administrator if you need help starting and terminating a server. This CAS server is identified by specifying the host on which it runs and the port on which it listens for communications. To simplify your interactions with this CAS server, the host information and port information for the server are stored as SAS option values that are retrieved automatically whenever this CAS server needs to be accessed. You can examine the host and port values for the server at your site by using the following statements:

```
proc options option=(CASHOST CASPORT);
run;
```

In addition to starting a CAS server, your system administrator might also have created a CAS session and a CAS engine libref for your use. You can define your own sessions and CAS engine librefs that connect to the CAS server as shown in the following statements:

```
cas mysess;
libname mylib cas sessref=mysess;
```

The CAS statement creates the CAS session named mysess, and the LIBNAME statement creates the mylib CAS engine libref that you use to connect to this session. It is not necessary to explicitly name the CASHOST and CASPORT of the CAS server in the CAS statement, because these values are retrieved from the corresponding SAS option values.

If you have created the mysess session, you can terminate it by using the TERMINATE option in the CAS statement as follows:

```
cas mysess terminate;
```

For more information about the CAS and LIBNAME statements, see the section "Introduction to Shared Concepts" on page 6 in Chapter 2, "Shared Concepts."

Getting Started: ICA Procedure

(View the complete code for this example at https://github.com/sascommunities/doc-supplement-casstat/tree/main/Examples/icags.sas.)

NOTE: Input data must be in a CAS table that is accessible in your CAS session. You must refer to this table by using a two-level name. The first level must be a CAS engine libref, and the second level must be the table name. For more information, see the sections "Using CAS Sessions and CAS Engine Librefs" on page 7 and "Loading a SAS Data Set onto a CAS Server" on page 7 in Chapter 2, "Shared Concepts."

The following DATA step creates the mylib.sample data table, which provides simulated signal data, in your CAS session. The data for this example are the result of multiplying the source signal matrix $\mathbf{S}$ and the mixing matrix $\mathbf{A}$; that is, the data matrix $\mathbf{X} = \mathbf{SA}$. Figure 15.1 shows the original source signals. Figure 15.2 shows the observed mixtures of the source signals. The problem is to recover the original source signals (s1, s2, and s3) shown in Figure 15.1 only from the observed signal mixtures (x1, x2, and x3) shown in Figure 15.2.

```
data mylib.sample;
   keep t x:;
   array S[200,3];     /* S: source signals */
   array A[3,3];       /* A: mixing matrix */
   array x[3] x1-x3;   /* X: mixed signals */

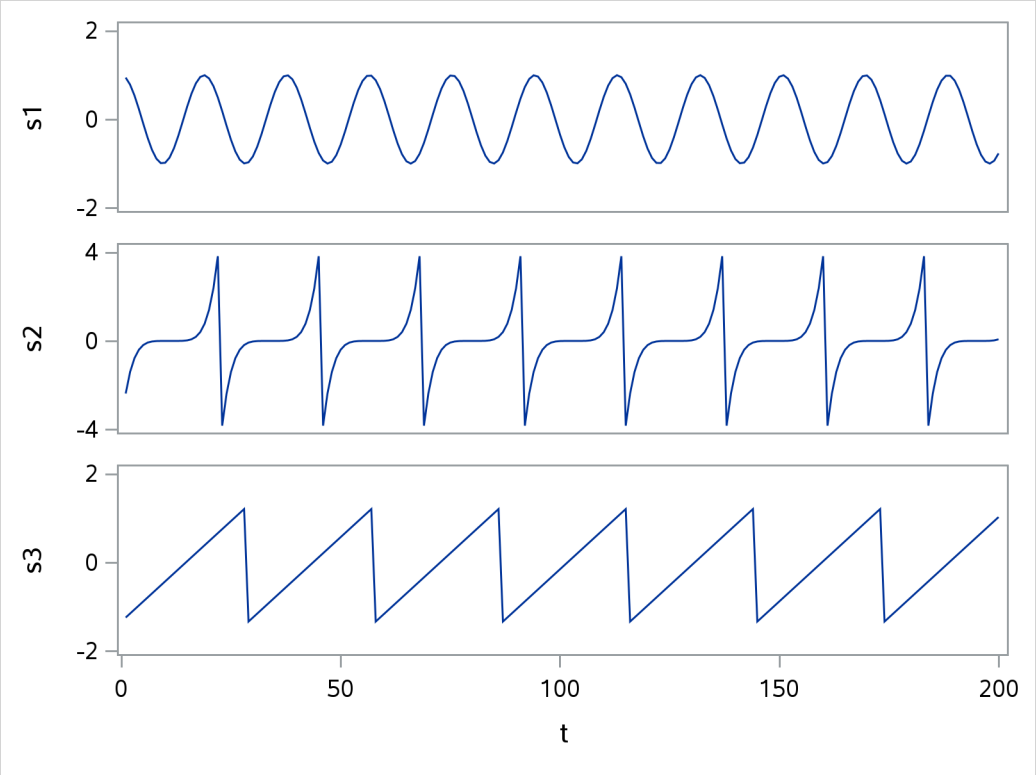
   N = 200;

   do i = 1 to 3;
      do j = 1 to 3;
         A[i,j] = 0.7*uniform(12345);
      end;
   end;

   do i = 1 to N;
      S[i,1] = cos(i/3);
      S[i,2] = 0.4*((mod(i,23)-11)/7)**5;
      S[i,3] = ((mod(i,29)-7)/11)-0.7;
   end;

   do i = 1 to N;
      t = i;
      do j = 1 to 3;
         x[j] = 0;
         do k = 1 to 3;
            x[j] = x[j] + S[i,k]*A[k,j];
         end;
      end;
      output;
   end;
run;
```

Figure 15.1 Original Source Signals



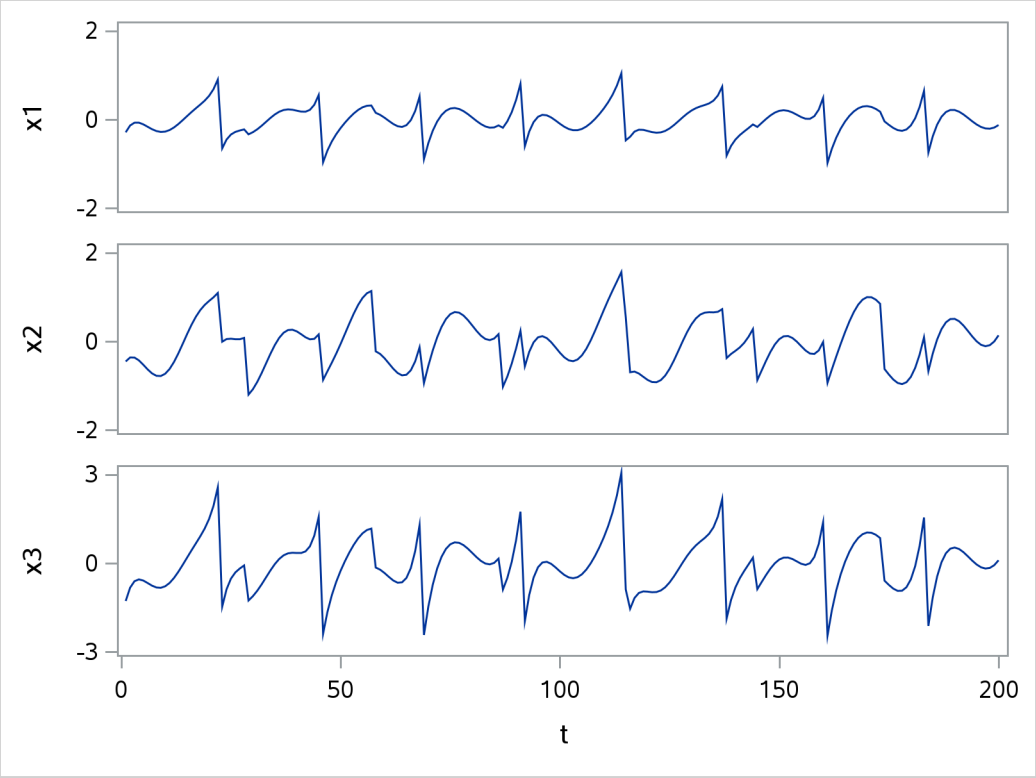


Figure 15.2 Observed Signal Mixtures

These statements assume that your CAS engine libref is named mylib, but you can substitute any appropriately defined CAS engine libref.

The following statements invoke the ICA procedure, which requests the independent component analysis of the data, outputs the computed independent components to an output data table, and produces the tables in Figure 15.3 through Figure 15.6:

```
proc ica data=mylib.sample seed=345;
   var x1-x3;
   output out=mylib.scores component=c copyvar=t;
run;
```

Figure 15.3 displays the "Model Information," "Dimensions," "Number of Observations," and "Centering and Scaling Information" tables.

The "Model Information" table identifies the data source and shows that the independent component extraction method is symmetric decorrelation, which is the default. The nonquadratic function $\log\cosh$ is used in the approximation of negentropy, and the eigenvalue proportion threshold is set to 0; these are the defaults. The random number seed is set to 345. Random number generation is used to initialize the demixing matrix. Changing the random number seed value changes the initial demixing matrix, which yields a different estimated demixing matrix.

The "Dimensions" table indicates that there are three variables to be analyzed and three independent components to be computed. If you omit the N= option in the PROC ICA statement, the default is the number of numeric variables to be analyzed. The table also shows that there are three whitened variables and that three independent components are actually extracted.

The "Number of Observations" table shows that all 200 of the sample observations in the input data are used in the analysis; all the samples are used because they all contain complete data.

The "Centering and Scaling Information" table displays the centering and scaling information of the analysis variables.

Figure 15.3 Model Information, Dimensions, Number of Observations, and Centering and Scaling Information

The ICA Procedure

Model Information	
Data Source	SAMPLE
Component Extraction Method	Symmetric Decorrelation
Negentropy Approximation Function	Log-cosh
Eigenvalue Proportion Threshold	0
Random Number Seed	345

Dimensions	
Number of Variables	3
Number of Whitened Variables	3
Number of Independent Components	3
Number of Independent Components Extracted	3

Number of Observations Read	200
Number of Observations Used	200

Figure 15.3 *continued*

Centering and Scaling Information		
Variable	Subtracted off	Divided by
x1	-0.01231	0.32312
x2	-0.04632	0.56436
x3	-0.05567	0.89319

Figure 15.4 displays the "Eigenvalues" table.

Figure 15.4 Eigenvalues Table

Eigenvalues				
	Eigenvalue	Difference	Proportion	Cumulative
1	2.663628	2.352835	0.8879	0.8879
2	0.310793	0.285215	0.1036	0.9915
3	0.025578		0.0085	1.0000

Figure 15.5 displays the "Whitening Transformation Matrix" and "Dewhitening Transformation Matrix" tables. In the whitening transformation matrix that is shown, the whitened variables are represented as a linear combination of the original variables that are centered and scaled. The dewhitening transformation matrix is the pseudoinverse of the whitening matrix.

Figure 15.5 Whitening and Dewhitening Transformation Matrices

Whitening Transformation Matrix			
Variable	White1	White2	White3
x1	-0.35446	-1.01630	3.66902
x2	-0.33541	1.44039	1.47348
x3	-0.37052	-0.33165	-4.84386

Dewhitening Transformation Matrix			
Whitened Variable	x1	x2	x3
White1	-0.94415	-0.89341	-0.98693
White2	-0.31586	0.44766	-0.10307
White3	0.09385	0.03769	-0.12390

Figure 15.6 displays the "Demixing Matrix" and "Mixing Matrix" tables. In the demixing matrix that is shown, the independent components are represented as a linear combination of the original variables that are standardized. The mixing matrix is the pseudoinverse of the demixing matrix.

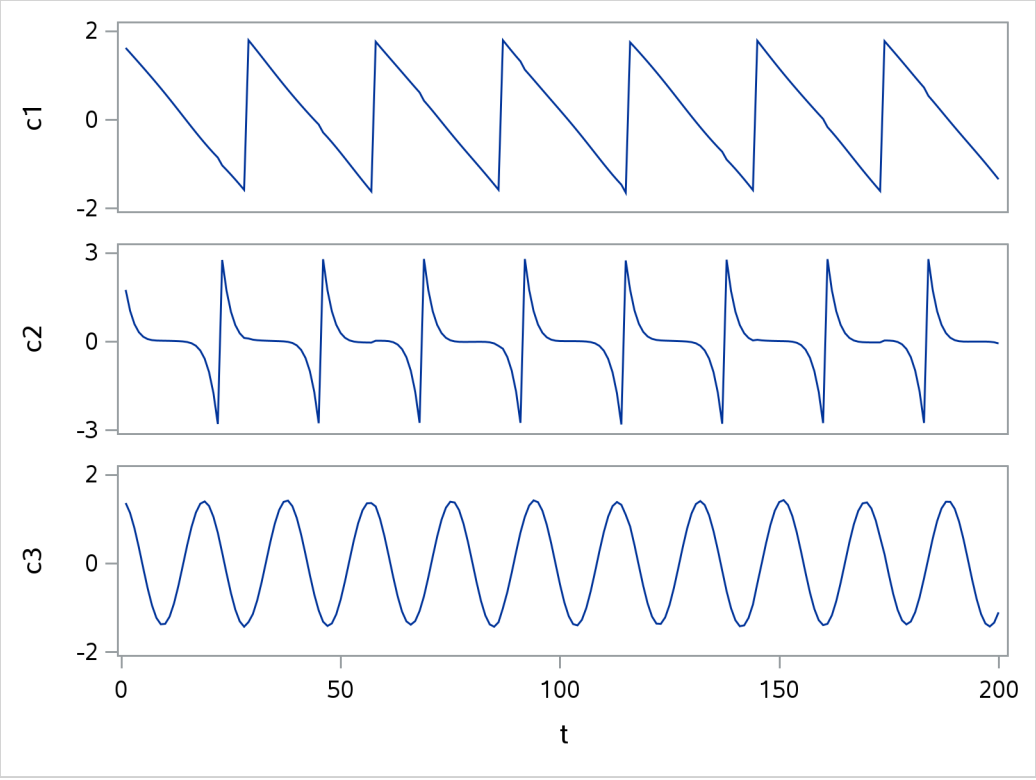

Figure 15.6 Demixing and Mixing Matrices

Demixing Matrix			
Variable	**Comp1**	**Comp2**	**Comp3**
x1	2.51490	0.32078	2.86227
x2	-0.43425	1.17723	1.66851
x3	-2.44766	-2.07527	-3.66231

Mixing Matrix			
Component	**x1**	**x2**	**x3**
Comp1	-0.12351	-0.69340	-0.41244
Comp2	-0.82569	-0.32078	-0.79147
Comp3	0.55043	0.64520	0.45108

Using the output data table mylib.scores and PROC SGPLOT or PROC SGRENDER (code not shown), you can plot the computed independent components. Figure 15.7 shows three independent components (c1, c2, and c3) that are the estimates of the three original source signals (s1, s2, and s3) in Figure 15.1. The original source signals are accurately estimated from the observed signal mixtures shown in Figure 15.2, up to multiplicative signed scalars. The order of the computed independent components cannot be determined in the independent component analysis model.

Figure 15.7 Estimated Source Signals

Syntax: ICA Procedure

The following statements are available in the ICA procedure:

```
PROC ICA < options > ;
    BY variables ;
    DISPLAY < table-list > < / options > ;
    DISPLAYOUT table-spec-list < / options > ;
    OUTPUT OUT=libref.data-table
            < COPYVARS=(variables) >
            < keyword < =prefix > >. . . < keyword < =prefix > > ;
    VAR variables ;
```

The PROC ICA statement is required. All other statements are optional. The following sections describe the PROC ICA statement and then describe the other statements in alphabetical order.

PROC ICA Statement

```
PROC ICA < options > ;
```

The PROC ICA statement invokes the ICA procedure. Table 15.1 summarizes the options available in the PROC ICA statement.

Table 15.1 PROC ICA Statement Options

Option	Description
Basic Options	
DATA=	Specifies the input data table
Analysis Options	
EIGTHRESH=	Specifies the threshold for the proportion of variance explained by eigenvalues
GFUNCTION=	Specifies the nonquadratic function to be used in the approximation of negentropy
METHOD=	Specifies the independent component extraction method to be used
N=	Specifies the number of independent components to be computed
NOCENTER	Suppresses centering of the numeric variables to be analyzed
NOSCALE	Suppresses scaling of the numeric variables to be analyzed
PREFIX=	Specifies a prefix for naming the independent components
SEED=	Specifies the seed value for pseudorandom number generation
WHITEPREFIX=	Specifies a prefix for naming the whitened variables

The following list provides details about these *options*.

DATA=*libref.data-table*

names the input data table for PROC ICA to use. The default is the most recently created data table. *libref.data-table* is a two-level name, where

libref refers to a collection of information that is defined in the LIBNAME statement and includes the library, which includes a path to the data, and a session identifier, which defaults to the active session but which can be explicitly defined in the LIBNAME statement. For more information about *libref*, see the section "Using CAS Sessions and CAS Engine Librefs" on page 797.

data-table specifies the name of the input data table.

EIGTHRESH=*p*

EIGENTHRESHOLD=*p*

specifies the threshold for the proportion of variance explained by eigenvalues, where $0 \leq p \leq 1$. If the proportion of variance that an eigenvalue explains is less than the threshold, the eigenvalue is discarded in the analysis. You can use this option to reduce the dimensionality of the input data. For more information, see the section "Whitening and Dimension Reduction" on page 812. By default, EIGTHRESH=0.

GFUNCTION=EXP | LOGCOSH

GFUNC=EXP | LOGCOSH

specifies the nonquadratic function $G(x)$ to be used in the approximation of negentropy. You can specify the following function types:

EXP

uses the exponential function, $G(u) = -e^{-u^2/2}$.

LOGCOSH

uses the $\log\cosh$ function, $G(u) = \log\cosh(u)$.

By default, GFUNCTION=LOGCOSH.

METHOD=*method***<(***options***)>**

specifies the independent component extraction method to be used. You can specify the following *methods*:

DEFLATION<(*options***)>**

requests the deflationary decorrelation method. You can specify the following *options*:

MAXITER=*n* specifies the maximum number of iterations to perform. By default, MAXITER=500.

TOL=*n* specifies the convergence criterion. By default, TOL=1E–4.

GEODESIC<(*options***)>**

requests the geodesic InfoMax method. You can specify the following *options*:

EXTENDED=0 | 1 | 2 specifies the extended option to use. All the sources are assumed to be super-Gaussians for option 0 and sub-Gaussians for option 2. For option 1, the types of sources are estimated. By default, EXTENDED=1.

LRATE=*n* specifies the learning rate to use. By default, LRATE=0.1.

MAXITER=*n* specifies the maximum number of iterations to perform. By default, MAXITER=500.

TOL=*n* specifies the convergence criterion. By default, TOL=1E–4.

SYMMETRIC< (*options***) >**
requests the symmetric decorrelation method. You can specify the following *options*:

MAXITER=*n* specifies the maximum number of iterations to perform. By default, MAXITER=500.

TOL=*n* specifies the convergence criterion. By default, TOL=1E–4.

SYMMORTH< (*options***) >**
requests the symmorth InfoMax method. You can specify the following *options*:

EXTENDED=0 | 1 | 2 specifies the extended option to use. All the sources are assumed to be super-Gaussians for option 0 and sub-Gaussians for option 2. For option 1, the types of sources are estimated. By default, EXTENDED=1.

LRATE=*n* specifies the learning rate to use. By default, LRATE=0.1.

MAXITER=*n* specifies the maximum number of iterations to perform. By default, MAXITER=500.

TOL=*n* specifies the convergence criterion. By default, TOL=1E–4.

UNCONSTRAINED< (*options***) >**
requests the unconstrained InfoMax method. You can specify the following *options*:

EXTENDED=0 | 1 | 2 specifies the extended option to use. All the sources are assumed to be super-Gaussians for option 0 and sub-Gaussians for option 2. For option 1, the types of sources are estimated. By default, EXTENDED=1.

LRATE=*n* specifies the learning rate to use. By default, LRATE=0.1.

MAXITER=*n* specifies the maximum number of iterations to perform. By default, MAXITER=500.

TOL=*n* specifies the convergence criterion. By default, TOL=1E–4.

By default, METHOD=SYMMETRIC.

N=*number*
specifies the number of independent components to be computed. The default is the number of numeric variables to be analyzed. The *number* must be an integer greater than or equal to 0. If N=0, the default is used.

NOCENTER
suppresses centering of the numeric variables to be analyzed. This option is useful if the analysis variables are already centered and scaled.

NOSCALE
suppresses scaling of the numeric variables to be analyzed. This option is useful if the analysis variables are already centered and scaled.

PREFIX=*name*
specifies a prefix for naming the independent components. By default, the *names* are Comp1, Comp2, . . . , Comp*n*. If you specify PREFIX=Abc, the components are named Abc1, Abc2, Abc3, and so on. The number of characters in the prefix plus the number of digits required to designate the variables should not exceed the current name length that is defined by the VALIDVARNAME= system option.

SEED=*number*
specifies an integer as the seed value for pseudorandom number generation. PROC ICA uses random values to initialize the demixing matrix. Changing the seed value changes the initial demixing matrix, resulting in a different estimated demixing matrix. If you do not specify this option or if *number* is less than or equal to 0, the seed is generated by reading the time of day from the computer's clock. By default, SEED=0.

WHITEPREFIX=*name*
WPREFIX=*name*
specifies a prefix for naming the whitened variables. By default, the *names* are White1, White2, . . . , White*n*. If you specify WHITEPREFIX=Abc, the components are named Abc1, Abc2, Abc3, and so on. The number of characters in the prefix plus the number of digits required to designate the variables should not exceed the current name length that is defined by the VALIDVARNAME= system option.

BY Statement

BY *variables* **;**

You can specify a BY statement in PROC ICA to obtain separate analyses of observations in groups that are defined by the values of the BY variables. If you specify more than one BY statement, only the last one specified is used. For more information, see the discussion of BY-group processing in the "Grouping Data" section of *SAS Programmers Guide: Essentials*.

DISPLAY Statement

DISPLAY < *table-list* > < / *options* > **;**

The DISPLAY statement enables you to specify a list of display tables to display or exclude. This statement is similar to the ODS SELECT, ODS EXCLUDE, and ODS TRACE statements. However, the DISPLAY statement can improve performance when a large number of tables could be generated (such as in BY-group processing). The procedure processes the DISPLAY statement on a CAS server and thus sends only a subset of ODS tables to the SAS client. Because ODS statements are processed on a SAS client, first all the generated display tables are sent to the client, and then the client creates a subset.

If you use both DISPLAY and ODS statements together, the DISPLAY statement takes precedence over the ODS statements. Note that the ODS EXCLUDE statement processes tables that are sent to the client after they have been filtered by the DISPLAY statement. In some cases, it might appear that the ODS EXCLUDE statement is taking precedence because it can further filter the tables. For more information about ODS, see *SAS Output Delivery System: Procedures Guide*.

You can specify the *table-list* as a list of table names, paths, partial pathnames, and regular expressions.

The table names that you can specify are listed in the section "ODS Table Names" on page 814. A path is a table name that is prefixed with dot-separated grouping information. For example, a SelectionSummary table that a procedure produces during a selection routine might have the path *Bygroup1.Summary.SelectionSummary*. A partial pathname does not include all groups; for example, *SelectionSummary* and *Summary.SelectionSummary* are partial pathnames for *Bygroup1.Summary.SelectionSummary*.

When you specify a table name or partial pathname, all display tables whose paths end in the specified name are selected for display or exclusion. For example, both *SelectionSummary* and *Summary.SelectionSummary* select *Bygroup1.Summary.SelectionSummary*.

A regular expression is enclosed in forward slashes (/). For example, specifying "/tions/" selects all pathnames that contain the substring "tions"; in particular, the *Bygroup1.Summary.SelectionSummary* table is selected. Specifying "!/tions/" selects all pathnames that do not contain the substring "tions"; in particular, the *Bygroup1.Summary.SelectionSummary* table is not selected.

You can specify the following *options* after a slash (/):

CASESENSITIVE
performs a case-sensitive comparison of table names in the *table-list* to display table names when tables are subsetted for display. To preserve case, you must enclose table names in the *table-list* in quotation marks.

EXCLUDE
displays all display tables except those that you specify in the *table-list*.

EXCLUDEALL
suppresses display of all tables. This option takes precedence over the other options.

TRACE
displays the display table names, labels, and paths.

DISPLAYOUT Statement

DISPLAYOUT *table-spec-list* < / *options* > **;**

The DISPLAYOUT statement enables you to create output tables from your displayed output. This statement is similar to the ODS OUTPUT statement. For more information about ODS, see *SAS Output Delivery System: Procedures Guide*.

The *table-spec-list* specifies a list of output tables to create. Each entry in the list has either a *key*=*value* format or a *key* format:

key=*value* specifies *key* as the ODS table name, path, or partial pathname, and specifies *value* as the output table name.

key specifies *key* as the ODS table name and also as the output table name.

The ODS table names that you can specify are listed in the section "ODS Table Names" on page 814. You cannot specify the ODS table named OutputCasTables in the *table-spec-list*.

Table names and partial pathnames are discussed under the DISPLAY statement. The DISPLAYOUT statement does not support regular expressions.

You can specify the following *options* after a slash (/):

INCLUDEALL
creates output tables for all display tables. The name of the created output table is the same as the name of the corresponding display table. If you specify this option, the *table-spec-list* specification is ignored.

NOREPLACE
does not replace any existing output table of the same name.

REPEATED
replicates all output tables on all nodes.

OUTPUT Statement

OUTPUT OUT=*libref.data-table*
< **COPYVARS=***(variables)* >
< *keyword* < **=***prefix* > > . . . < *keyword* < **=***prefix* > > **;**

The OUTPUT statement creates a data table that contains observationwise statistics, which are computed after PROC ICA fits the model. If you do not specify a *keyword*, then only the independent component values are included.

The variables in the input data table are *not* included in the output data table, in order to avoid data duplication for large data tables; however, variables that you specify in the COPYVARS= option are included.

You must specify the following option:

OUT=*libref.data-table*
names the output data table for PROC ICA to use. You must specify this option before any other options. *libref.data-table* is a two-level name, where

libref refers to a collection of information that is defined in the LIBNAME statement and includes the library, which includes a path to where the data table is to be stored, and a session identifier, which defaults to the active session but which can be explicitly defined in the LIBNAME statement. For more information about *libref*, see the section "Using CAS Sessions and CAS Engine Librefs" on page 797.

data-table specifies the name of the output data table.

You can also specify the following syntax elements:

COPYVAR=*variable*

COPYVARS=(*variables***)**
transfers one or more *variables* from the input data table to the output data table.

keyword **< =***prefix* **>**
specifies a statistic to include in the output data table and optionally a *prefix* for naming the output variables. If you do not provide a *prefix*, PROC ICA assigns a default prefix that is based on the type of statistic requested.

You can specify the following *keywords* to add statistics to the output data table:

COMP

COMPONENT
requests the source values for each independent component. The default prefix is the one that you specify in the PREFIX= option.

WHITE
requests the source values for each whitened variable. The default prefix is the one that you specify in the WHITEPREFIX= option.

The output variables that contain the requested statistic are named as follows, according to the *keyword* that you specify:

- The *keyword* COMP defines an output variable for each independent component, so the variables that correspond to each successive component are named by appending a number to the prefix. For example, if the model has three independent components, then COMP=C produces the variables C1, C2, and C3.
- The *keyword* WHITE defines an output variable for each whitened variable, so the variables that correspond to each successive whitened variable are named by appending a number to the prefix. For example, if the model has three whitened variables, then WHITE=W produces the variables W1, W2, and W3.

VAR Statement

VAR *variables* **;**

The VAR statement lists the numeric variables to be analyzed. If you omit the VAR statement, all numeric variables that are not specified in other statements are analyzed.

Details: ICA Procedure

Computing Independent Components

Independent component analysis defines a generative model for the observed data. In the model, the observed data variables are considered to be linear combinations of the latent variables that are non-Gaussian and maximally independent; that is, $\mathbf{X} = \mathbf{SA}$, where $\mathbf{X}$ is the data matrix, $\mathbf{S}$ are the latent variables or independent components, and $\mathbf{A}$ is the mixing matrix.

FastICA Algorithm

By applying the central limit theorem, you can estimate the independent components by maximizing the non-Gaussianity of $\mathbf{XW}$, where $\mathbf{W}$ is called the demixing matrix, the pseudoinverse of $\mathbf{A}$.

Let $\mathbf{X}$ be the centered and scaled data matrix that is whitened by using the eigenvalue decomposition, and let $\mathbf{w}_i$ be an orthonormal weight vector for the ith independent component. The FastICA algorithm of Hyvärinen and Oja (2000) that the ICA procedure implements is based on a fixed-point iteration scheme for finding a maximum of the non-Gaussianity of $\mathbf{Xw}_i$, which is measured by the approximation of negentropy,

$$J(u) \propto \Big(E[G(u)] - E[G(\nu)]\Big)^2$$

where the random variable u is assumed to be of zero mean and unit variance, ν is a Gaussian variable with zero mean and unit variance, and G is a nonquadratic function. PROC ICA provides the following choices of G as options: $G(u) = -e^{-u^2/2}$ and $G(u) = \log\cosh(u)$. The fixed-point iteration scheme in the FastICA algorithm is derived as an approximative Newton iteration,

$$\mathbf{w}_i \leftarrow E[\mathbf{X}^T g(\mathbf{X}\mathbf{w}_i)] - E[g'(\mathbf{X}\mathbf{w}_i)]\mathbf{w}_i$$

where g is the derivative of G.

To prevent the estimated weight vectors $\mathbf{w}_1, \ldots, \mathbf{w}_n$ from converging to the same maxima, the projections $\mathbf{X}\mathbf{w}_1, \ldots, \mathbf{X}\mathbf{w}_n$ must be decorrelated after every iteration. PROC ICA implements two methods to achieve this: the deflationary decorrelation method and the symmetric decorrelation method. The deflationary approach achieves decorrelation on the basis of the Gram-Schmidt orthogonalization method, which means that the independent components are computed sequentially:

$$\mathbf{w}_i \leftarrow \mathbf{w}_i - \sum_{j=1}^{i-1} (\mathbf{w}_j \mathbf{w}_j^T)\mathbf{w}_i$$

A problem with the deflationary decorrelation approach is the accumulation of numeric errors.

The symmetric approach estimates the independent components simultaneously by performing symmetric orthogonalization of the matrix $\mathbf{W} = (\mathbf{w}_1, \ldots, \mathbf{w}_n)$. This is accomplished by the classic method that involves matrix square roots:

$$\mathbf{W} \leftarrow \mathbf{W}\left(\mathbf{W}^T\mathbf{W}\right)^{-\frac{1}{2}}$$

The inverse square root is obtained from the eigenvalue decomposition of $\mathbf{W}^T\mathbf{W} = \mathbf{E}\mathbf{D}\mathbf{E}^T$ as $(\mathbf{W}^T\mathbf{W})^{-1/2} = \mathbf{E}\mathbf{D}^{-1/2}\mathbf{E}^T$, where $\mathbf{E}$ is an orthogonal matrix whose entries are the eigenvectors of $\mathbf{W}^T\mathbf{W}$ and $\mathbf{D}$ is a diagonal matrix whose entries are the eigenvalues of $\mathbf{W}^T\mathbf{W}$.

In the independent component analysis model, the variances and the order of the independent components cannot be determined. Each of the independent components is thus assumed to have unit variance in the computation because they are random variables. However, the sign is still indeterminable. By default, PROC ICA calculates the independent component scores by using the scaled input data and the estimated demixing matrix. You can use the NOSCALE option in the PROC ICA statement to suppress scaling; PROC ICA then calculates the independent component scores by using the original input data and the estimated demixing matrix.

Independent component analysis is closely related to projection pursuit, a technique that usually attempts to find the most non-Gaussian projections of multidimensional data. If the generative model holds for the data, optimizing the non-Gaussianity measures produces independent components; if the model is absent for the data, independent component analysis produces the projection pursuit directions.

InfoMax Algorithm

Given the data matrix X, you want to find the demixing matrix $\mathbf{W}$ so that the joint entropy of $\mathbf{Y} = \mathbf{XW}$ is maximized. It turns out that in this case, it also maximizes the mutual information between $\mathbf{X}$ and $\mathbf{Y}$. For this reason, this algorithm for extracting independent components is known as InfoMax (Bell and Sejnowski 1995). Essentially, the InfoMax algorithm is a parallel version of projection pursuit, but it uses the information maximization principle and maximum likelihood estimate instead of non-Gaussianity. The InfoMax algorithm uses gradient-based updates and learning rates, so it can be more adaptive in certain cases.

You can adapt the InfoMax algorithm to use the fact that the demixing matrix $\mathbf{W}$ must be orthogonal, such as by using geodesic-based gradient updates; see Nishimori (1999) for more information. To achieve this, PROC ICA implements three methods: geodesic InfoMax, symmorth InfoMax, and unconstrained InfoMax. The unconstrained InfoMax method uses the gradient updates of Bell and Sejnowski (1995), where the demixing matrix $\mathbf{W}$ can be any nonsingular matrix. The symmorth InfoMax method uses a symmetric orthogonalized version of the gradient updates, and the geodesic InfoMax method uses geodesic-based gradient updates on the orthogonal group.

Whitening and Dimension Reduction

Whitening can greatly simplify the complexity of the problem of independent component analysis by reducing the number of parameters to be estimated. A zero-mean random vector is said to be *white* if its elements are uncorrelated and have unit variances. A synonym for white is sphered.

By default, the input data variables are centered and scaled to have mean 0 and standard deviation 1. The centered and scaled data matrix $\mathbf{X}$ is then transformed linearly to become a new data matrix $\tilde{\mathbf{X}}$, which is *white*. In other words, the covariance matrix of $\tilde{\mathbf{X}}$ equals the identity matrix: $E[\tilde{\mathbf{X}}^T\tilde{\mathbf{X}}] = \mathbf{I}$. PROC ICA performs the whitening transformation by using the eigenvalue decomposition of the covariance matrix $E[\mathbf{X}^T\mathbf{X}] = \mathbf{EDE}^T$, where $\mathbf{E}$ is the orthogonal matrix of its eigenvectors and $\mathbf{D}$ is the diagonal matrix of its eigenvalues. Thus the whitening transformation matrix is given by $\mathbf{ED}^{-1/2}$, and whitening is done by $\tilde{\mathbf{X}} = \mathbf{XED}^{-1/2}$.

It can also be useful to reduce the dimensionality of the input data before extracting the independent components, which can usually reduce noise and prevent overlearning. PROC ICA performs dimension reduction and the whitening transformation at the same time by looking at the eigenvalues of $E[\mathbf{X}^T\mathbf{X}]$ and discarding those that are too small. You can use the EIGTHRESH= option in the PROC ICA statement to specify a threshold for the proportion of variance explained by the eigenvalues. An eigenvalue is discarded if the proportion of variance that it explains is less than the threshold.

When you use the EIGTHRESH= option for dimension reduction, you should suppress scaling by using the NOSCALE option in the PROC ICA statement. Scaling serves to place all dimensions of the space on an equal footing relative to their variation in the data. Performing dimension reduction with scaling poses the risk of dropping eigenvalues for the dimensions of the space that are spanned by the independent components but retaining those dimensions that are filled by noise.

Missing Values

Observations that have missing values for any variable in the VAR statement are omitted from the analysis and are given missing values for independent component values in the OUT= data table that is specified in the OUTPUT statement.

Displayed Output

The following sections describe the output that PROC ICA produces. The output is organized into various tables, which are discussed in their order of appearance.

Model Information

The "Model Information" table displays basic information about the model, including the input data table, the independent component extraction method, the nonquadratic function used in the negentropy approximation, and the eigenvalue proportion threshold.

Dimensions

The "Dimensions" table displays information about the number of VAR statement variables, the number of whitened variables after data whitening and dimension reduction, the number of independent components to extract, and the number of independent components that are actually extracted.

Number of Observations

The "Number of Observations" table displays the number of observations that are read from the input data table and the number of observations that are used in the analysis.

Centering and Scaling Information

The "Centering and Scaling Information" table displays the centering and scaling information for each analysis variable.

Eigenvalues

The "Eigenvalues" table displays eigenvalues of the covariance matrix that is calculated from the input data, along with the difference between successive eigenvalues, the proportion of variance explained by each eigenvalue, and the cumulative proportion of variance explained.

Whitening Transformation Matrix

The "Whitening Transformation Matrix" table displays the whitening transformation matrix, which is used to perform whitening and dimension reduction on the input data.

Dewhitening Transformation Matrix

The "Dewhitening Transformation Matrix" table displays the dewhitening transformation matrix, which is the pseudoinverse of the whitening matrix.

Demixing Matrix

The "Demixing Matrix" table displays the demixing matrix, which is used to extract the independent components from the input data.

Mixing Matrix

The "Mixing Matrix" table displays the mixing matrix, which is the pseudoinverse of the demixing matrix.

OutputCasTables Table

The OutputCasTables table is a special table that has information about each CAS table that is created during a CAS action execution. The information for each CAS table consists of the CAS table name, the caslib in which the table resides, and the number of columns and rows in the CAS table. Because this table is not a typical ODS table that contains analytical results, you cannot include it in the *table-spec-list* in the DISPLAYOUT statement.

ODS Table Names

Each table that the ICA procedure creates has a name associated with it. You must use this name to refer to the table when you use the DISPLAY statement, the DISPLAYOUT statement, or the Output Delivery System (ODS) statements. These names are listed in Table 15.2.

Table 15.2 ODS Tables Produced by PROC ICA

Table Name	Description	Required Statement / Option
CenScaleInfo	Centering and scaling information	Default output
Demixing	Demixing matrix	Default output
Dewhitening	Dewhitening transformation matrix	Default output
Dimensions	Model dimensions	Default output
Eigenvalues	Eigenvalues	Default output
Mixing	Mixing matrix	Default output
ModelInfo	Model information	Default output
NObs	Number of observations read and used	Default output
OutputCasTables	See the section "OutputCasTables Table" on page 814	DISPLAYOUT statement or OUTPUT statement
Whitening	Whitening transformation matrix	Default output
Timing	Absolute and relative times of tasks that are performed by the procedure	Default output

Examples: ICA Procedure

The examples in this chapter are available in the GitHub repository located at https://github.com/sascommunities/doc-supplement-casstat.

NOTE: Input data must be in a CAS table that is accessible in your CAS session. You must refer to this table by using a two-level name. The first level must be a CAS engine libref, and the second level must be the table name. For more information, see the sections "Using CAS Sessions and CAS Engine Librefs" on page 7 and "Loading a SAS Data Set onto a CAS Server" on page 7 in Chapter 2, "Shared Concepts."

Example 15.1: Extracting Independent Components with Dimension Reduction

(View the complete code for this example (icaex1.sas) in the example repository.)

This example demonstrates that applying dimension reduction in PROC ICA provides a better estimate of the independent components by using simulated data, compared to extracting the independent components without reducing the dimension of the data. The data that this example uses are from the Getting Started section, and an extra noise signal (x4) is added to the observed signal mixtures. The following DATA step generates the data:

```
data mylib.ex1data;
   keep t x:;
   array S[200,3];      /* S: source signals */
   array A[3,3];        /* A: mixing matrix */
   array x[4] x1-x4;    /* X: observed signals */

   N = 200;

   do i = 1 to 3;
      do j = 1 to 3;
         A[i,j] = 0.7*uniform(12345);
      end;
   end;

   do i = 1 to N;
      S[i,1] = cos(i/3);
      S[i,2] = 0.4*((mod(i,23)-11)/7)**5;
      S[i,3] = ((mod(i,29)-7)/11)-0.7;
   end;

   do i = 1 to N;
      t = i;
      do j = 1 to 3;
         x[j] = 0;
         do k = 1 to 3;
            x[j] = x[j] + S[i,k]*A[k,j];
         end;
      end;
```

```
      x[4] = 0.1*uniform(67890);
      output;
   end;
run;
```

These statements assume that your CAS engine libref is named mylib, but you can substitute any appropriately defined CAS engine libref.

The following statements extract the independent components by using dimension reduction and output the computed independent components to an output data table:

```
proc ica data=mylib.ex1data eigthresh=0.004 noscale seed=345;
   var x1-x4;
   output out=mylib.scores1 component=c copyvar=t;
run;
```

Output 15.1.1 displays the PROC ICA output. The "Model Information" table shows that the eigenvalue proportion threshold is set to 0.004. The "Dimensions" table indicates that there are four variables to be analyzed and four independent components to be computed. It also shows that three whitened variables are generated by using whitening and three independent components are actually extracted, thanks to the use of dimension reduction.

Output 15.1.1 Results of Independent Component Analysis with Dimension Reduction

The ICA Procedure

Model Information	
Data Source	EX1DATA
Component Extraction Method	Symmetric Decorrelation
Negentropy Approximation Function	Log-cosh
Eigenvalue Proportion Threshold	0.004
Random Number Seed	345

Dimensions	
Number of Variables	4
Number of Whitened Variables	3
Number of Independent Components	4
Number of Independent Components Extracted	3

Number of Observations Read	200
Number of Observations Used	200

Centering and Scaling Information

Variable	Subtracted off	Divided by
x1	-0.01231	1.00000
x2	-0.04632	1.00000
x3	-0.05567	1.00000
x4	0.05224	1.00000

Output 15.1.1 *continued*

Eigenvalues

	Eigenvalue	Difference	Proportion	Cumulative
1	1.129934	1.045020	0.9251	0.9251
2	0.084915	0.079040	0.0695	0.9946
3	0.005874	0.005123	0.0048	0.9994
4	0.000752		0.0006	1.0000

Whitening Transformation Matrix

Variable	White1	White2	White3
x1	-0.26624	1.12655	11.73306
x2	-0.44684	-2.96560	2.16685
x3	-0.78387	1.30782	-5.22151
x4	-0.00124	0.04711	0.78387

Dewhitening Transformation Matrix

Whitened Variable	x1	x2	x3	x4

White2	0.09566	-0.25182	0.11105	0.00400
White3	0.06892	0.01273	-0.03067	0.00460

Demixing Matrix

Variable	Comp1	Comp2	Comp3
x1	0.96285	7.75333	8.82969
x2	2.08133	-0.76730	2.96125
x3	-2.31137	-2.73321	-4.09587
x4	0.09540	0.50802	0.59118

Mixing Matrix

Component	x1	x2	x3	x4
Comp1	-0.26709	-0.18133	-0.70731	-0.00299
Comp2	-0.04024	-0.39162	-0.36922	0.00468
Comp3	0.17732	0.36367	0.40146	0.00289

You can produce a plot of the computed independent components by using the output data table mylib.scores1 and the SGRENDER procedure, as shown in the following statements:

```
proc template;
   define statgraph ScoresPanel;
      beginGraph;
         layout lattice / rows=3
                          columns=1
                          rowgutter=10
                          columndatarange=unionall
                          order=packed;

         columnaxes;
            columnaxis / label="t";
         endcolumnaxes;
```

```
            layout overlay / yaxisopts=
               (linearopts=(viewmin=-3 viewmax=3 tickvaluelist=(-3 0 3)));
               seriesplot x=t y=c1;
            endlayout;

            layout overlay / yaxisopts=
               (linearopts=(viewmin=-2 viewmax=2 tickvaluelist=(-2 0 2)));
               seriesplot x=t y=c2;
            endlayout;

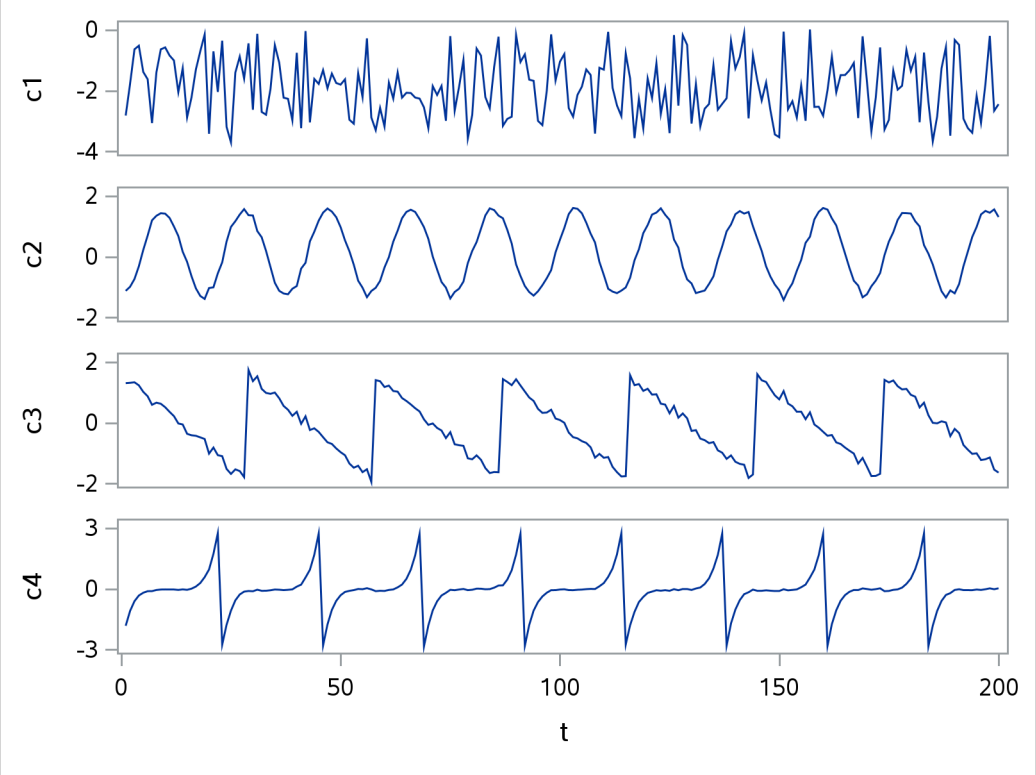
            layout overlay / yaxisopts=
               (linearopts=(viewmin=-2 viewmax=2 tickvaluelist=(-2 0 2)));
               seriesplot x=t y=c3;
            endlayout;

            endlayout;
         endGraph;
      end;
   run;

   proc sgrender data=mylib.scores1 template=ScoresPanel;
   run;
```

Output 15.1.2 displays the computed independent components. The original source signals (s1, s2, and s3) in Figure 15.1 are accurately estimated by the computed independent components (c1, c2, and c3) up to multiplicative signed scalars.

Output 15.1.2 Independent Components Computed with Dimension Reduction



The following statements extract the independent components by using all dimensions of the input data (x1–x4) and output the computed independent components to an output data table:

```
proc ica data=mylib.ex1data noscale seed=345;
   var x1-x4;
   output out=mylib.scores2 component=c copyvar=t;
run;
```

Output 15.1.3 displays the computed independent components by using the output data table mylib.scores2 and PROC SGRENDER (code not shown). The original source signals (s1, s2, and s3) in Figure 15.1 are closely estimated by the three computed independent components (c2, c3, and c4) up to multiplicative signed scalars. However, you can clearly see that the estimates are affected by the addition of the noise signal (x4) compared to the independent components that are computed using dimension reduction in Output 15.1.2. Because there are fewer independent components than analysis variables in the input data, the computed component c1 is the projection pursuit direction.

Output 15.1.3 Independent Components Computed with Full Dimensions

Overview: KCLUS Procedure

The KCLUS procedure performs clustering (a common step in data exploration) in SAS Viya.

You can use the KCLUS procedure to read and write data in distributed form, and to perform clustering and scoring in parallel by making full use of multicore computers or distributed computing environments.

The KCLUS procedure performs a cluster analysis on the basis of distances that are computed from quantitative or qualitative variables (or both). The observations are divided into clusters such that every observation belongs to one and only one cluster.

The KCLUS procedure uses the *k*-means algorithm for clustering interval input variables, uses the *k*-modes algorithm for clustering nominal input variables, and uses *k*-prototypes algorithm for clustering mixed input that contains both interval and nominal variables.

The KCLUS procedure accomplishes the clustering by updating the cluster centroids and the cluster membership of the data iteratively until the convergence criterion (for example, the least squares criterion for the Euclidean distance in *k*-means clustering) is satisfied or until the maximum iteration number is reached.

PROC KCLUS produces brief summaries of the cluster analysis in two output data tables:

- The OUT= data table is produced by the SCORE statement. This data table contains the cluster membership and distance variables for each observation in the input data table. It can be used for more detailed examination of the clusters.
- The OUTSTAT= data table is produced by the PROC KCLUS statement. This data table can be used for more detailed examination of between-cluster statistics.

PROC KCLUS Features

PROC KCLUS enables you to use parallel execution for clustering in a distributed computing environment. The following list summarizes the basic features of PROC KCLUS:

- uses the *k*-means method to cluster interval input variables
- uses the *k*-modes method to cluster nominal input variables
- uses the *k*-prototypes method to cluster mixed input variables
- provides a new technique called the aligned box criterion (ABC) for estimating the number of clusters in the data table
- enables you to run on a cluster of machines that distribute the data and the computations
- enables you to run in single-machine mode
- exploits all the available cores and concurrent threads

Using CAS Sessions and CAS Engine Librefs

SAS Cloud Analytic Services (CAS) is the analytic server and associated cloud services in SAS Viya. This section describes how to create a CAS session and set up a CAS engine libref that you can use to connect to the CAS session. It assumes that you have a CAS server already available; contact your system administrator if you need help starting and terminating a server. This CAS server is identified by specifying the host on which it runs and the port on which it listens for communications. To simplify your interactions with this CAS server, the host information and port information for the server are stored as SAS option values that are retrieved automatically whenever this CAS server needs to be accessed. You can examine the host and port values for the server at your site by using the following statements:

```
proc options option=(CASHOST CASPORT);
run;
```

In addition to starting a CAS server, your system administrator might also have created a CAS session and a CAS engine libref for your use. You can define your own sessions and CAS engine librefs that connect to the CAS server as shown in the following statements:

```
cas mysess;
libname mylib cas sessref=mysess;
```

The CAS statement creates the CAS session named mysess, and the LIBNAME statement creates the mylib CAS engine libref that you use to connect to this session. It is not necessary to explicitly name the CASHOST and CASPORT of the CAS server in the CAS statement, because these values are retrieved from the corresponding SAS option values.

If you have created the mysess session, you can terminate it by using the TERMINATE option in the CAS statement as follows:

```
cas mysess terminate;
```

For more information about the CAS and LIBNAME statements, see the section "Introduction to Shared Concepts" on page 6 in Chapter 2, "Shared Concepts."

Getting Started: KCLUS Procedure

(View the complete code for this example at https://github.com/sascommunities/doc-supplement-casstat/tree/main/Examples/kclus_gs.sas.)

NOTE: Input data must be in a CAS table that is accessible in your CAS session. You must refer to this table by using a two-level name. The first level must be a CAS engine libref, and the second level must be the table name. For more information, see the sections "Using CAS Sessions and CAS Engine Librefs" on page 7 and "Loading a SAS Data Set onto a CAS Server" on page 7 in Chapter 2, "Shared Concepts."

This example shows how to use the KCLUS procedure to compute clusters of observations in an input data table.

Suppose you want to group the observations in the input CAS table mylib.inpData, in which the variables are raw measures on interval scales.

The following DATA step creates the input data table, mylib.inpData, in your CAS session. This data table contains four variables: the first two variables are the input variables among which x has missing values, the third variable is the frequency variable, and the last variable is an index variable.

```
data mylib.inpData;
   title 'Using PROC KCLUS to Analyze Data';
   drop n;
   id=1;
   do n=1 to 1000;
      x=2*rannor(12345)+20;
      y=4*rannor(12345)+20;
      freq = 1;
      id = id + 1;
      output;
   end;
   do n=1 to 1000;
      x=3*rannor(12345)+10;
      y=5*rannor(12345)+10;
      freq=2;
      id = id + 1;
      output;
   end;
   do n=1 to 700;
      x=10*rannor(12345);
      y=10*rannor(12345);
      freq=1;
      id = id + 1;
      output;
   end;
   do n=1 to 200;
```

```
      x=.;
      y=10*rannor(12345);
      freq=1;
      id = id + 1;
      output;
   end;
run;
```

These statements assume that your libref is named mylib, but you can substitute any appropriately defined libref.

The following statements run PROC KCLUS and output the results to ODS tables:

```
proc kclus data=mylib.inpData maxclusters=3;
   input x y;
   freq freq;
run;
```

Figure 16.1 shows that the "Number of Observations Used" is less than the "Number of Observations Read". By default, the KCLUS procedure ignores observations that have missing values, and it does not use them in the analysis. The two additional rows, "Sum of Frequencies Read" and "Sum of Frequencies Used" are displayed when the FREQ statement is specified. They provide information about the frequency values that are read and used.

Figure 16.1 Number of Observations

Using PROC KCLUS to Analyze Data

The KCLUS Procedure

Number of Observations Read	2900
Number of Observations Used	2700
Sum of Frequencies Read	3900
Sum of Frequencies Used	3700

Figure 16.2 shows the values of the parameters that are used in clustering. Because the number of clusters is not estimated by default and MAXCLUSTERS=3, three clusters are generated. Figure 16.2 shows the number of clusters and the default values for other options.

Figure 16.2 Model Information

Model Information	
Clustering Algorithm	K-means
Maximum Iterations	10
Stop Criterion	Cluster Change
Stop Criterion Value	0
Clusters	3
Initialization	Forgy
Seed	578406742
Distance for Interval Variables	Euclidean
Standardization	None
Interval Imputation	None

For each cluster, Figure 16.3 shows the number of observations; the maximum, minimum, and average distances from that cluster's centroid to the observations in that cluster; the sum of squares error; and the standard deviation. Figure 16.3 also displays information about the nearest cluster to that cluster and the distance between their centroids.

Figure 16.3 Cluster Summary

Cluster Summary for Interval Variables

		Distance from Cluster Centroid to Observation						
Cluster	Frequency	Minimum	Maximum	Average	SSE	Standard Deviation	Nearest Cluster	Distance to Nearest Cluster Centroid
1	2038	0.2289	31.7970	5.2019	78608.4	6.2106	2	13.8882
2	1175	0.0202	29.2304	4.4741	31968.1	5.2160	1	13.8882
3	487	0.5652	30.4447	10.7298	73156.7	12.2564	1	18.3687

Figure 16.4 shows the sum of squared errors (SSE) for each iteration. If the variables are interval, then the "Iteration History" table displays SSE Change and Stop Criterion columns. The SSE Change column displays the change in within-cluster distances. The Stop Criterion column displays the stopping criterion for each iteration. If the input variables are nominal, then the "Iteration History" table displays Within Distance Change and Stop Criterion columns. If the input variables are both interval and nominal, then the "Iteration History" table also displays Within Distance Change and Stop Criterion columns, but with the distance in the sense of mixed distance with both the interval and nominal parts as detailed in Clustering Both Interval and Nominal Variables.

Figure 16.4 Iteration History

Iteration History

Iteration Number	SSE	SSE Change	Stop Criterion
0	325431		
1	204706	-120725	8.851852
2	188187	-16519	3.407407
3	185097	-3089.291959	1.629630
4	184358	-739.528456	0.962963
5	184083	-275.000574	0.777778
6	183876	-206.393291	0.740741
7	183770	-106.591597	0.333333
8	183739	-30.920207	0.074074
9	183733	-5.722173	0
10	183733	0	0

Figure 16.5 and Figure 16.6 show statistics for each variable in the INPUT statement. Figure 16.5 shows the variable statistics for all the observations in the input data table, and Figure 16.6 shows the variable statistics for the observations that belong to a specific cluster.

Figure 16.5 Descriptive Statistics

Descriptive Statistics

Variable	Mean	Standard Deviation
x	11.020648	8.189686
y	10.246546	9.472050

Figure 16.6 Within-Cluster Statistics

Within Cluster Statistics

Variable	Cluster	Mean	Standard Deviation
x	1	9.5626	10.5049
	2	18.9930	6.0294
	3	-2.1130	9.0921
y	1	9.3852	11.0225
	2	19.5808	7.9047
	3	-4.7954	8.3923

Syntax: KCLUS Procedure

The following statements are available in the KCLUS procedure:

PROC KCLUS < *options* > **;**
CODE < *options* > **;**
DISPLAY < *table-list* > < */options* > **;**
DISPLAYOUT *table-spec-list* < */options* > **;**
FREQ *variable* **;**
INPUT *variables* < **LEVEL= NOMINAL** | **INTERVAL** > **;**
SCORE OUT=*libref.data-table* < *options* > **;**
SAVESTATE RSTORE=*libref.data-table* < *option* > **;**
WEIGHT *variable* **;**

The PROC KCLUS statement and an INPUT statement are required. You can specify multiple INPUT statements.

The following sections describe the PROC KCLUS statement and then describe the other statements in alphabetical order.

PROC KCLUS Statement

PROC KCLUS < *options* > **;**

The PROC KCLUS statement invokes the procedure. Table 16.1 summarizes the *options* available in this statement.

Table 16.1 PROC KCLUS Statement Options

Option	Description
Input and Output Data Set Options	
APPLYROWORDER	Specifies that the procedure use a prespecified data distribution
DATA=	Specifies the input data table
OUTSTAT(OUTITER)=	Specifies the output data table to contain cluster centroids
PRINTALLDISTANCES	Outputs the interval distance, nominal distance, and total distance (this option can be used only for mixed input variables)
Clustering Options	
DISTANCE=	Specifies the distance measure for similarity measurement (used for interval input variables)
DISTANCENOM=	Specifies the distance measure for similarity measurement (used for nominal input variables)
INIT=	Specifies the method for obtaining the initial estimate of cluster centers
MAXCLUSTERS=	Specifies the number of clusters
MAXITER=	Specifies the maximum number of iterations
SEED=	Specifies the seed that is used for pseudorandom number generation
STOPCRITERION=	Specifies the stop criterion method to use for convergence
KPROTOTYPEPARAMS=	Specifies the *k*-prototypes parameters for clustering interval and nominal variables at the same time (this option can be used only for mixed input variables)
Data Processing Options	
IMPUTE=	Specifies the imputation method for interval input variables
IMPUTENOM=	Specifies the imputation method for nominal input variables
STANDARDIZE=	Specifies the method for standardizing interval input variables
Number of Clusters Estimation Options	
NOC=	Specifies the method for estimating the number of clusters
Performance Options	
NTHREADS=	Specifies the number of threads for the computation

You can specify the following *options*:

APPLYROWORDER
uses a data distribution and row order as determined by a previous **partition** action call. For more information, see the section "The APPLYROWORDER Option" on page 107 in Chapter 2, "Shared Concepts."

DATA=*libref.data-table*
names the input data table for PROC KCLUS to use. The default is the most recently created data table. *libref.data-table* is a two-level name, where

libref refers to a collection of information that is defined in the LIBNAME statement and includes the library, which includes a path to the data, and a session identifier, which defaults to the active session but which can be explicitly defined in the LIBNAME statement. For more information about *libref*, see the section "Using CAS Sessions and CAS Engine Librefs" on page 823.

data-table specifies the name of the input data table.

DISTANCE=EUCLIDEAN | MANHATTAN
specifies the distance measure for similarity that is used for interval input variables.

You can choose from the following measures:

EUCLIDEAN calculates the Euclidean distance.

MANHATTAN calculates the Manhattan distance.

By default, DISTANCE=EUCLIDEAN.

DISTANCENOM=BINARY | GLOBALFREQ | RELATIVEFREQ
specifies the distance measure for similarity that is used for nominal input variables.

You can choose from the following measures:

BINARY calculates a simple matching distance.

GLOBALFREQ calculates the distance based on the frequency of levels of nominal input variables in the input data table.

RELATIVEFREQ calculates the distance based on the frequency of levels of nominal input variables in each cluster.

By default, DISTANCENOM=BINARY. For more information about these distance functions, see the section "Clustering Nominal Variables" on page 840.

INIT=FORGY | RAND
specifies the method for obtaining the initial estimate of cluster centers.

You can choose from the following methods:

FORGY selects the initial cluster centers randomly from observations.

RAND assigns all observations randomly to one of the clusters.

By default, INIT=FORGY.

IMPUTE=MEAN | NONE
specifies the imputation method to be used when the INPUT statement specifies interval variables.

You can choose from the following methods:

MEAN imputes missing values of variables in observations by using the mean value for that variable.

NONE does not do any imputation and excludes observations that have missing values.

If IMPUTE=NONE and the number of observations that have nonmissing values is less than the value of the MAXCLUSTERS= option, then the number of clusters is set to the number of observations that have nonmissing values.

By default, IMPUTE=NONE.

IMPUTENOM=MODE | NONE
specifies the imputation method to be used when the INPUT statement specifies nominal variables.

You can choose from the following methods:

MODE imputes missing values of variables in observations by using the mode value for that variable.

NONE does not do any imputation and excludes observations that have any missing values.

If IMPUTENOM=NONE and the number of observations that have nonmissing values is less than the value of the MAXCLUSTERS= option, then the number of clusters is set to the number of observations that have nonmissing values.

By default, IMPUTENOM=NONE.

MAXCLUSTERS=*number*
specifies either the number of clusters to be used (if the NOC= option is not specified or NOC=NONE) or the maximum number of clusters to be searched (if NOC=ABC).

By default, MAXCLUSTERS=6.

MAXITER=*number*
specifies the maximum number of iterations for the algorithm to perform. In each iteration of the *k*-means or *k*-modes clustering method, each observation is assigned to the nearest cluster centroid, and the centroids are recomputed.

By default, MAXITER=10.

NOC= NONE | ABC < *suboptions* **>**
specifies the method for estimating the number of clusters.

You can specify the following values:

ABC < *suboptions* **>** estimates the number of clusters by using the aligned box criterion (ABC) method. For more information about this method, see the section "Finding the Number of Clusters" on page 839.

You can specify one or more of the following *suboptions*:

ALIGN=*keyword* specifies the method for aligning the reference data based on the input data.

You can specify the following *keywords*:

NONE generates the reference data from a uniform distribution over the range of values for each subset of the input data table.

PCA generates the reference data from a uniform distribution over a box that is aligned with the principal components of each subset of the input data table.

By default, ALIGN=NONE.

B=*number* specifies the number of reference data to be created for each cluster candidate. By default, B=1.

CRITERION=*keyword* specifies the criterion to be used to estimate the number of clusters that use the statistics obtained by the ABC method.

You can specify the following *keywords*:

ALL uses all the following options and selects the number of clusters based on which number of clusters is chosen the most often. If each option selects a different number of clusters, then the number selected by GLOBALPEAK is used.

FIRSTMAXWITHSTD uses the smallest k such that the gap value for that k is greater than the one-standard-error adjusted gap value for k+1.

FIRSTPEAK uses the first peak value among the peak values in gap statistics.

GLOBALPEAK uses the maximum peak value among all the peak values in gap statistics.

By default, CRITERION=GLOBALPEAK.

MINCLUSTERS=*number* specifies the minimum number of clusters for searching for the best number of clusters. By default, MINCLUSTERS=2.

NONE does not estimate the number of clusters and uses the value specified in MAXCLUSTERS= option.

By default, NOC=NONE.

NTHREADS=*number-of-threads*
specifies the number of threads that are used in the computation. The default value is the number of CPUs available in the machine.

OUTSTAT <(OUTITER)>=*libref.data-table*
creates the output data table that contains the cluster centroids for each cluster. *libref.data-table* is a two-level name, where *libref* refers to the library, and *data-table* specifies the name of the output data table. For more information about this two-level name, see the DATA= option and the section "Using CAS Sessions and CAS Engine Librefs" on page 823.

This data table includes the iteration number as _ITERATION_, the cluster ID as _CLUSTER_ID_ and the cluster centroids, which consist of the variables that are specified in the INPUT statement. If you specify STANDARDIZE=RANGE or STANDARDIZE=STD, the data table also contains the standardized values of the cluster centroids, which are displayed by adding the S_ prefix to the variables in the INPUT statement.

You can also specify the following suboption:

OUTITER also outputs the cluster centroids to the OUTSTAT= data table for each iteration.

SEED=*number*
specifies an integer to be used to start the pseudorandom number generator. If you do not specify a seed or if you specify a value less than or equal to 0, the seed is generated from reading the time of day from the computer's clock.

STANDARDIZE=NONE | RANGE | STD
specifies the method for standardizing the interval input variables. PROC KCLUS uses the location and scale measures specific to the method. You can specify the following values:

NONE does not standardize and uses the actual values for the input variables.

RANGE standardizes the input variables by using the range method. PROC KCLUS uses the minimum as the location and the range as the scale.

STD standardizes the input variables by using the traditional standardization method. PROC KCLUS uses the mean as the location and the standard deviation as the scale.

By default, STANDARDIZE=NONE.

STOPCRITERION=*convergence_method***<(VALUE=***number***)>**
specifies the method to use for convergence. If you do not specify this option, the algorithm stops after it reaches the maximum number of iterations (which is specified in MAXITER= option).

You can specify the following *convergence_methods*:

CLUSTER_CHANGE <(VALUE=*number***)>**
uses the percentile of observations that do not change their cluster membership for that iteration. The optional VALUE= suboption enables you to specify the percentile of observations.

By default or if VALUE=0, PROC KCLUS runs until the cluster centroids no longer change.

WCSD_CHANGE < (VALUE=*number*) >
uses the within-cluster distance change as a convergence criterion. The optional VALUE= suboption enables you to specify the change in SSE for the k-means algorithm or specify the sum of within-cluster distances for the k-modes algorithm and the k-prototypes algorithm. For the k-prototypes algorithm, the distance is a mixed distance that includes both the interval and nominal parts.

KPROTOTYPEPARAMS=*gamma_method*
specifies the method for obtaining the γ parameter in the k-prototypes clustering algorithm (Huang 1997) for clustering mixed input data that contain both interval and nominal variables.

You can specify either of the following *gamma_methods*:

USERGAMMA(VALUE=*number*)
specifies the γ parameter value (in the VALUE= suboption) for the k-prototypes clustering algorithm. The value of γ should be an appropriate positive number that balances the difference between the scales of the nominal and interval input variables.

AUTOGAMMA
estimates the γ parameter value for the k-prototypes clustering algorithm. You can use this option when you do not have a clear idea of how large the γ value would be. When you specify the AUTOGAMMA option, the value of γ is inferred to be the average of the standard deviations of the interval input variables.

By default, KPROTOTYPEPARAMS=USERGAMMA(VALUE=0.5).

PRINTALLDISTANCES
prints the distance that is contributed by the interval variables (as _DISTANCEINT_) and the distance that is contributed by the nominal variables (as _DISTANCENOM_) in the mixed distance that is used by the k-prototypes algorithm to the output table that is specified in the SCORE statement. For more information, see the section "Score Output for Clustering Both Interval and Nominal Variables" on page 842.

CODE Statement

CODE < *options* > **;**

The CODE statement generates the SAS DATA step code that mimics the computations that are done by the SCORE statement.

You can specify the following *options*:

FILE=*filename*
specifies the filename of the file to write the SAS score code to.

LABELID=*number*
specifies a number used to construct array names and statement labels in the generated code. You can specify a value in the range 0 to 1024; by default, LABELID=0.

DISPLAY Statement

DISPLAY < *table-list* > < / *options* > **;**

The DISPLAY statement enables you to specify a list of display tables to display or exclude. This statement is similar to the ODS SELECT, ODS EXCLUDE, and ODS TRACE statements. However, the DISPLAY statement can improve performance when a large number of tables could be generated (such as in BY-group processing). The procedure processes the DISPLAY statement on a CAS server and thus sends only a subset of ODS tables to the SAS client. Because ODS statements are processed on a SAS client, first all the generated display tables are sent to the client, and then the client creates a subset.

If you use both DISPLAY and ODS statements together, the DISPLAY statement takes precedence over the ODS statements. Note that the ODS EXCLUDE statement processes tables that are sent to the client after they have been filtered by the DISPLAY statement. In some cases, it might appear that the ODS EXCLUDE statement is taking precedence because it can further filter the tables. For more information about ODS, see *SAS Output Delivery System: Procedures Guide*.

You can specify the *table-list* as a list of table names, paths, partial pathnames, and regular expressions.

The table names that you can specify are listed in the section "ODS Table Names" on page 847. A path is a table name that is prefixed with dot-separated grouping information. For example, a SelectionSummary table that a procedure produces during a selection routine might have the path *Bygroup1.Summary.SelectionSummary*. A partial pathname does not include all groups; for example, *SelectionSummary* and *Summary.SelectionSummary* are partial pathnames for *Bygroup1.Summary.SelectionSummary*.

When you specify a table name or partial pathname, all display tables whose paths end in the specified name are selected for display or exclusion. For example, both *SelectionSummary* and *Summary.SelectionSummary* select *Bygroup1.Summary.SelectionSummary*.

A regular expression is enclosed in forward slashes (/). For example, specifying "/tions/" selects all pathnames that contain the substring "tions"; in particular, the *Bygroup1.Summary.SelectionSummary* table is selected. Specifying "!/tions/" selects all pathnames that do not contain the substring "tions"; in particular, the *Bygroup1.Summary.SelectionSummary* table is not selected.

You can specify the following *options* after a slash (/):

CASESENSITIVE
performs a case-sensitive comparison of table names in the *table-list* to display table names when tables are subsetted for display. To preserve case, you must enclose table names in the *table-list* in quotation marks.

EXCLUDE
displays all display tables except those that you specify in the *table-list*.

EXCLUDEALL
suppresses display of all tables. This option takes precedence over the other options.

TRACE
displays the display table names, labels, and paths.

DISPLAYOUT Statement

DISPLAYOUT *table-spec-list* < / *options* > **;**

The DISPLAYOUT statement enables you to create output tables from your displayed output. This statement is similar to the ODS OUTPUT statement. For more information about ODS, see *SAS Output Delivery System: Procedures Guide*.

The *table-spec-list* specifies a list of output tables to create. Each entry in the list has either a *key*=*value* format or a *key* format:

key=*value*	specifies *key* as the ODS table name, path, or partial pathname, and specifies *value* as the output table name.
key	specifies *key* as the ODS table name and also as the output table name.

The ODS table names that you can specify are listed in the section "ODS Table Names" on page 847. You cannot specify the ODS table named OutputCasTables in the *table-spec-list*.

Table names and partial pathnames are discussed under the DISPLAY statement. The DISPLAYOUT statement does not support regular expressions.

You can specify the following *options* after a slash (/):

INCLUDEALL
creates output tables for all display tables. The name of the created output table is the same as the name of the corresponding display table. If you specify this option, the *table-spec-list* specification is ignored.

NOREPLACE
does not replace any existing output table of the same name.

REPEATED
replicates all output tables on all nodes.

FREQ Statement

FREQ *variable* **;**

The *variable* in the FREQ statement identifies a numeric variable in the input data table that contains the frequency of occurrence of each observation. PROC KCLUS treats each observation as if it appears f times, where f is the value of the FREQ *variable* for the observation. If f is not an integer, it is truncated to an integer. If f is less than 1 or missing, the observation is not used in the analysis. When you omit the FREQ statement, each observation is assigned a frequency of 1.

INPUT Statement

INPUT *variables* < **LEVEL= NOMINAL | INTERVAL** > **;**

The INPUT statement specifies the names of the *variables* to be used in clustering. It names one or more input variables that use common options. If you want to use different options for different variables, you can specify multiple INPUT statements.

To trigger the *k*-prototypes clustering algorithm for clustering mixed input data that contain both interval and nominal input variables, either you can use two INPUT statements with one INPUT statement that includes the LEVEL=INTERVAL option for interval input variables and another INPUT statement that includes the LEVEL=NOMINAL option for nominal input variables, or you can use a single INPUT statement without the LEVEL= option specified. In the latter case, PROC KCLUS detects the types of the input variables and uses the *k*-prototypes clustering algorithm if the input variables include both interval and nominal types.

You can include the following option in each INPUT statement:

LEVEL= NOMINAL | INTERVAL

specifies the level of measurement of the variables. For clustering, only interval, binary, and nominal variables are accepted.

By default, LEVEL=INTERVAL for numeric variables, and LEVEL=NOMINAL for categorical character variables.

SAVESTATE Statement

SAVESTATE RSTORE=*libref.data-table* **;**

The SAVESTATE statement creates an analytic store for the model and saves it as a binary object in a data table. You can then use the analytic store in the ASTORE procedure to score new data. The analytic store inherits the same parameters that the procedure uses.

RSTORE=*libref.data-table*

specifies a data table in which to save the analytic store for the model. *libref.data-table* is a two-level name, where *libref* refers to the library, and *data-table* specifies the name of the output data table. For more information about this two-level name, see the DATA= option and the section "Using CAS Sessions and CAS Engine Librefs" on page 823.

SCORE Statement

SCORE OUT=*libref.data-table* < *option* > **;**

OUTPUT OUT=*libref.data-table* < *option* > **;**

The SCORE statement writes the cluster membership information of each observation to the output data table that is specified in the OUT= option. This information includes the variables that are specified in the COPYVARS= option and additional variables, as described in the section "Score Output for Clustering Both Interval and Nominal Variables" on page 842.

You must specify the following option:

OUT=*libref.data-table*

names the output data table for PROC KCLUS to use. You must specify this option before any other options. *libref.data-table* is a two-level name, where

libref refers to a collection of information that is defined in the LIBNAME statement and includes the library, which includes a path to where the data table is to be stored, and a session identifier, which defaults to the active session but which can be explicitly defined in the LIBNAME statement. For more information about *libref*, see the section "Using CAS Sessions and CAS Engine Librefs" on page 823.

data-table specifies the name of the output data table.

The output data table contains the scored data. When you specify this option, all variables that are specified in the COPYVARS= option, followed by the _CLUSTER_ID_ variable and the _DISTANCE_ variable, are added to the output data table that is specified in this option.

You can also specify the following *option*:

COPYVAR=*variable*

COPYVARS=(*variables***)**

lists one or more variables from the input data table that are transferred to the scored output data table, provided that the output data table produces one or more records per input observation. By default, the KCLUS procedure does not transfer any variables from the input data table to the output data table. The COPYVARS= option accepts numeric and character variables. You can also use COPYVARS=(_ALL_) option to include all the input variables.

WEIGHT Statement

WEIGHT *variable* **;**

The *variable* in the WEIGHT statement is used as a weight to perform a weighted analysis of the data. Observations that have nonpositive or missing weights are not included in the analysis. When you omit the WEIGHT statement, all observations that are used in the analysis are assigned a weight of 1.

Details: KCLUS Procedure

Obtaining the Statistics for Clustering

The KCLUS procedure calculates the following cluster-based statistics (in addition to the variable-based statistics) about the data in the input data table.

- summary statistics for each cluster (for example, the number of observations)
- summary statistics for the variables in each cluster (for example, the mean value of an interval input variable in a cluster)

You can use these statistics in addition to the output data tables to further analyze the clustering results.

Missing Values

Observations that have missing values affect the clustering results because the distance measures that are computed for these observations do not reflect the actual values. To solve this problem, you can use the IMPUTE= option for interval input variables and the IMPUTENOM= option for nominal input variables in the PROC KCLUS statement. If IMPUTE=NONE, observations that have missing values for interval input variables are not considered in cluster analysis. If IMPUTE=MEAN, observations that have missing values for interval input variables are considered by replacing the missing values with the average value for that missing variable, and the mean is calculated based on all nonmissing values of this variable. Similarly, if IMPUTENOM=NONE, observations that have missing values for nominal input variables are not considered in cluster analysis. If IMPUTENOM=MODE, observations that have missing values for nominal input variables are considered by replacing the missing values with the mode value for that missing variable. However, observations that have all missing values are not considered in cluster analysis.

Initial Seed Selection

When INIT=FORGY in the PROC KCLUS statement (the default), random observations from the input data table are selected as initial cluster centroids by default. The initial aim of PROC KCLUS is to select the observations that have no missing values.

You can change the observations that are selected from the input data table by using the SEED= option. You can use this option to set the seed value for the random number generator, which is used for generating random observation indices.

Because the random number generator creates indices for the observations, the initial cluster centroids will be different depending on where and how you run the procedure and where the input data reside. When the data are distributed or the computation is done in parallel, the indices of the observations will change depending on the number of nodes and number of threads that are used. Thus, you might get different initial cluster centroids.

Standardization

Because variables that have large variances tend to affect the distance measure more than variables that have small variances, it is recommended that you standardize the variables before clustering the observations. The STANDARDIZE= option in the PROC KCLUS statement provides a convenient way to standardize the INPUT variables. This option standardizes all the variables by using the method that is specified in that option and adds the standardized values to the output data tables.

Finding the Number of Clusters

To estimate the number of clusters (NOC), you can specify NOC=ABC in the PROC KCLUS statement. This option uses the aligned box criterion (ABC) method to estimate an interim number of clusters and then runs the *k*-means clustering method to produce the final clusters. If the NOC= option is not specified, PROC KCLUS uses the MAXCLUSTERS= option in the PROC KCLUS statement to set the number of the clusters, and then runs the *k*-means clustering method to produce the final clusters.

The ABC method estimates the number of clusters for well-separated clusters. Similar to the gap statistics method that is presented in Tibshirani, Walther, and Hastie (2001), the ABC method uses within-cluster dispersion from the results of clustering as an error measure, making the ABC method independent of the method that is used for clustering. In order to estimate the number of clusters, the ABC method compares the change in the error measure with the change that is expected under an appropriate reference null distribution.

The cubic clustering criterion (CCC), proposed in Sarle (1983), is based on the assumption that a uniform distribution on a hyperrectangle is divided into clusters that are shaped approximately like hypercubes. In recent and widely accepted work, Tibshirani, Walther, and Hastie (2001) propose a gap statistics method that uses Monte Carlo simulation (instead of a heuristic) to generate a hypercube reference distribution. The ABC method improves on the CCC and gap statistics methods by generating more restricted and aligned reference distributions that consider different features in the input data table.

Although the ABC method calculates the reference distribution differently than the other methods do, the computation of the error measure is similar to the method presented in Tibshirani, Walther, and Hastie (2001).

The error measure—also called the gap and represented as *Gap(k)*—is obtained by subtracting the logarithm of the within-cluster sum of squares error from the logarithm of its expectation for clustering solutions over a range of possible k values. The simulation-adjusted standard deviation of the reference distribution—represented as *s(k)*—is obtained by using the standard deviation of the logarithm of the within-cluster sum of squares errors for reference data. The one-standard-error adjusted gap is obtained by subtracting *s(k)* from the gap. For more information, see Tibshirani, Walther, and Hastie (2001).

A notable feature of the ABC algorithm is that it also applies to clustering both interval and nominal inputs. In the k-prototypes clustering algorithm, the ABC algorithm is performed with a mixed distance to which both the interval and nominal inputs contribute.

The number of clusters is estimated by considering the *Gap(k)* and *s(k)* values for each cluster candidate k. You can choose one of four methods for estimating the number of clusters by specifying the CRITERION= suboption in the NOC=ABC option in the PROC KCLUS statement:

- The FIRSTPEAK option selects the first peak value among all the values in *Gap(k)*.
- The GLOBALPEAK option selects the peak value that has the maximum value among the peak values in *Gap(k)*.
- The FIRSTMAXWITHSTD option considers the standard deviation in each cluster in addition to the values in *Gap(k)*. It considers the values in the one-standard-error adjusted gap to estimate the number of clusters. It selects the smallest k such that the gap value for that k is greater than the one-standard-error adjusted gap value for k+1.
- The ALL option uses all the preceding options and selects the number of clusters based on which number of clusters is chosen the most often. If each option selects a different number, then the number selected by the GLOBALPEAK option is used.

Clustering Nominal Variables

The k-means algorithm works only with interval inputs. One way to apply the k-means algorithm to nominal data is to use data transformation methods to transform the nominal data into a new feature space. However, this approach can be very inefficient, and it does not produce good results. For clustering nominal inputs, the KCLUS procedure implements the k-modes clustering algorithm, which extends the k-means algorithm by using different dissimilarity measures and a different method for computing cluster centers (Huang 1997).

Dissimilarity Measures

In the k-modes clustering algorithm, distance measures depend on the level of nominal variables. Let X and Y be two observations, which are described by F nominal variables. Each nominal variable j in F has a different number of distinct values, which are called levels (or sometimes called categories).

The dissimilarity measure between observations X and Y is

$$d(X,Y) = \sum_{j=1}^{F} \delta(x_j, y_j)$$

where $\delta(x_j, y_j)$ is the dissimilarity measure between X and Y on the jth nominal variable.

PROC KCLUS supports the following dissimilarity measures:

- The simple matching dissimilarity measure calculates the total number of mismatches of the corresponding variables of two observations. If the number of mismatches is small, then the observations are similar to each other. The dissimilarity measure between X and Y on the jth nominal variable is

$$\delta(x_j, y_j) = \begin{cases} 0 & \text{if } x_j = y_j \\ 1 & \text{if } x_j \neq y_j \end{cases}$$

  This algorithm is very efficient. However, it might lead to clusters that have weak intrasimilarity, depending on the number of levels and the number of observations that have these levels. For more information, see Huang (1997). Specify DISTANCENOM=BINARY in the PROC KCLUS statement to use this distance measure.

- The frequency-based dissimilarity measure takes into account the frequencies of levels of each variable in the input data table. The dissimilarity measure between X and Y on the jth nominal variable is

$$\delta(x_j, y_j) = \begin{cases} 0 & \text{if } x_j = y_j \\ \frac{(n_{x_j} + n_{y_j})}{n_{x_j} * n_{y_j}} & \text{if } x_j \neq y_j \end{cases}$$

  where n_{x_j} is the number of observations that have level x_j of variable j in the input data table and n_{y_j} is the number of observations that have level y_j of variable j in the input data table. You can use this measure to find underrepresented clusters because it assigns more importance to rare categories than to frequent ones. For more information, see Huang (1997). Specify DISTANCENOM=GLOBALFREQ in the PROC KCLUS statement to use this distance measure.

- The cluster frequency-based dissimilarity measure takes into account the relative frequencies of levels of each variable in each cluster. The dissimilarity measure between X and Y on the jth nominal variable is

$$\delta(x_j, y_j) = \begin{cases} 1 - \frac{n_{x_j^c}}{n_c} & \text{if } x_j = y_j \\ 1 & \text{if } x_j \neq y_j \end{cases}$$

  where n_c is the number of observations in cluster c and $n_{x_j^c}$ is the number of objects that have level x_j of variable j in cluster c.

  This distance measure enables the algorithm to assign less similar observations to the clusters that have weak intrasimilarity. Thus, the generated clusters have strong intrasimilarities. For more information, see Ng et al. (2007). Specify DISTANCENOM=RELATIVEFREQ in the PROC KCLUS statement to use this distance measure.

Computing Cluster Centers

The k-modes algorithm uses modes instead of means as cluster centers. The KCLUS procedure uses a frequency-based method to update the modes after each iteration in order to minimize the clustering cost function. Cluster centers are updated using the same approach for all the distance measures.

Clustering Both Interval and Nominal Variables

For clustering inputs that include only interval or only nominal variables, the KCLUS procedure implements the *k*-means or *k*-modes clustering algorithm, respectively. For clustering inputs that include both interval and nominal variables, the KCLUS procedure implements the *k*-prototypes clustering algorithm (Huang 1997). The *k*-prototypes clustering algorithm uses a mixed distance that combines the distance contributed by the interval inputs and the distance contributed by the nominal inputs. This mixed distance is characterized with a weight parameter, γ, to balance the scales of the interval and nominal distances.

Mixed Distance Measure

The mixed distance measure d_{mixed} is defined as

$$d_{mixed} = d_{int}^2 + \gamma \times d_{nom}$$

where d_{int} is the distance of the interval input variables and d_{nom} is the distance of the nominal input variables. The interval distance measure, d_{int}, is specified in the DISTANCE= option, and the nominal distance measure, d_{nom}, is specified in the DISTANCENOM= option.

Weight of Nominal Distance

A weight parameter, γ, is used to balance any possible difference between the scales of the nominal variables and the interval variables. You can specify this value in the KPROTOTYPEPARAMS= option. By default, the weight is 0.5.

Score Output for Clustering Both Interval and Nominal Variables

The KCLUS procedure writes the cluster membership information to the output table that is specified in the OUT= option in the SCORE statement. This information always includes the variables that are specified in the COPYVARS= option and the following variables:

- _CLUSTER_ID_ (the ID of the closest cluster)
- _DISTANCE_ (the distance between the observation and the centroid of that cluster)

In addition, cluster membership information can include one or more of the following variables:

- _STANDARDIZED_DISTANCE_ (the distance between the standardized values of the observation and the standardized values of cluster centroid). This variable is included if you specify STANDARDIZE=RANGE or STANDARDIZE=STD in the PROC KCLUS statement.
- _DISTANCEINT_ (the interval part of the distance between the observation and the centroid of that cluster). This variable is included if the *k*-prototypes clustering algorithm is used and you specify the PRINTALLDISTANCES option in the PROC KCLUS statement.
- _DISTANCENOM_ (the nominal part of the distance between the observation and the centroid of that cluster). This variable is included if the *k*-prototypes clustering algorithm is used and you specify the PRINTALLDISTANCES option in the PROC KCLUS statement.

- _DISTANCE_, which is equal to _DISTANCEINT_^{2} + $\gamma \times$ _DISTANCENOM_.
- _STANDARDIZED_DISTANCEINT_ (the interval part of the distance between the standardized values of the observation and the standardized values of cluster centroid). This variable is included if the *k*-prototypes clustering algorithm is used and you specify the both the PRINTALLDISTANCES and the STANDARDIZE= options in the PROC KCLUS statement.
- _STANDARDIZED_DISTANCE_, which is equal to _STANDARDIZED_DISTANCEINT_^{2} + $\gamma \times$ _DISTANCENOM_.

Displayed Output

The KCLUS procedure displays various tables for cluster analysis.

The following sections describe the output in the order of their appearance when the related options are specified.

Number of Observations

The "Number of Observations" table displays the number of observations that are read from the input data table and the number of observations that are used in the clustering. The Number of Observations Read column displays the count of raw data that are read from the input data table, and the Number of Observations Used column displays the count of data that are actually used in the clustering. The latter count is affected by the missing values in the raw data and the setting of the IMPUTE= and IMPUTENOM= options in the PROC KCLUS statement. When the FREQ statement is specified, then the Sum of Frequencies Read and Sum of Frequencies Used are also displayed.

Model Information

The "Model Information" table provides basic information about the parameters that are used in the cluster analysis. This information includes the clustering algorithm, maximum number of iterations, stop criterion method and the value for that criterion, number of clusters, initialization technique, seed value, distance method, standardization method, imputation method, and the value of γ when the *k*-prototypes clustering algorithm is used.

Cluster Summary

The "Cluster Summary" table displays the following for each cluster when the variables in INPUT statement are interval:

- cluster number
- frequency (the number of observations in the cluster)
- maximum, minimum, and average distances from the cluster centroid to the observations in the cluster
- SSE (sum of squared errors between the observations and the closest cluster centroids to them)

- standard deviation (the root mean square distances between the observations and the cluster centroids that are closest to them)
- nearest cluster (the ID of the cluster whose centroid is closest to the current cluster's)
- distance between the cluster centroid of the current cluster and the nearest cluster

If the number of observations in a cluster is zero, then this cluster is not displayed in the "Cluster Summary" table.

Iteration History

The "Iteration History" table displays the following when the variables that are specified in the INPUT statement are interval:

- iteration number
- SSE (sum of squared distances between the observations and the closest cluster centroids)
- SSE change
- stop criterion

The "Iteration History" table displays the following when the variables that are specified in the INPUT statement are nominal:

- iteration number
- WithinDist (sum of distances between the observations and the closest cluster centroids)
- within distance change
- stop criterion

Descriptive Statistics

The "Descriptive Statistics" table displays the mean and standard deviation for each interval variable that is specified in the INPUT statement. The calculation of the mean and standard deviation for an interval variable uses all the data in its own column and discards the missing values. So the calculation of mean and standard deviation for one interval variable is independent of the calculation for other interval variables.

Within-Cluster Statistics

The "Within Cluster Statistics" table displays the following for each interval variable that is specified in the INPUT statement in each cluster:

- mean of the values for each variable in that cluster
- standard deviations of the values for each variable in that cluster

Cluster Summary for Nominal Variables

The "Cluster Summary for Nominal Variables" table displays the following for each cluster when the variables that are specified in the INPUT statement are nominal:

- cluster number
- frequency (the number of observations in the cluster)
- maximum, minimum, and average distances from the cluster centroid to the observations in the cluster
- within-cluster distance
- nearest cluster (the ID of the cluster whose centroid is closest to the current cluster's centroid)
- distance between the cluster centroid of the current cluster and the nearest cluster

If the number of observations in a cluster is zero, then this cluster is not displayed in the "Cluster Summary for Nominal Variables" table.

Frequencies for Nominal Variables

The "Frequencies for Nominal Variables" table displays the following for each nominal variable in the INPUT statement in each cluster:

- levels of each variable in the input data table, including any missing levels (if present)
- frequencies of the levels for each variable in the input data table, including frequencies of missing levels (if present)
- frequencies of the levels for each variable within the specific cluster, excluding frequencies of missing levels when the value of the IMPUTENOM= option is NONE

Cluster Summary for Mixed Variables

The "Cluster Summary for Mixed Variables" table displays the following for each cluster when the *k*-prototypes clustering algorithm is performed:

- cluster number
- frequency (the number of observations in the cluster)
- maximum, minimum, and average distances from the cluster centroid to the observations in the cluster
- within-cluster distance
- nearest cluster (the ID of the cluster whose centroid is closest to the current cluster's centroid)
- distance between the cluster centroid of the current cluster and the nearest cluster

If the number of observations in a cluster is 0, then that cluster is not displayed in the "Cluster Summary for Mixed Variables" table.

Standardization

The "Standardization" table displays the following:

- variable name
- location value that is used for standardization
- scale value that is used for standardization

Aligned Box Criterion Parameters

The "ABC Parameters" table displays the following:

- minimum number of clusters that are searched
- maximum number of clusters that are searched
- reference distribution count
- alignment method used for determining the region for generating the reference data

Aligned Box Criterion Statistics

The "ABC Statistics" table displays the following:

- number of clusters (k)
- logarithm of within-cluster sum of squares (W_k^*) for the input data for k number of clusters
- logarithm of within-cluster sum of squares (W_k) for the reference data for k number of clusters
- gap between the error measure from the reference data and the input data
- simulation-adjusted standard deviation (s) that is obtained from the reference data
- one-standard-error adjusted gap

Estimated Number of Clusters

The "Estimated Number of Clusters" table displays the following:

- criterion used for estimating the number of clusters from the measures that are calculated in the specified method
- estimated number of clusters for the input data table

OutputCasTables Table

The OutputCasTables table is a special table that has information about each CAS table that is created during a CAS action execution. The information for each CAS table consists of the CAS table name, the caslib in which the table resides, and the number of columns and rows in the CAS table. Because this table is not a typical ODS table that contains analytical results, you cannot include it in the *table-spec-list* in the DISPLAYOUT statement.

ODS Table Names

Each table created by the KCLUS procedure has a name associated with it. You must use this name to refer to the table when you use ODS statements. These names are listed in Table 16.2.

Table 16.2 ODS Tables Produced by PROC KCLUS

Table Name	Description	Statement	Option
ABCParameters	Parameters that are specified in the NOC= option	PROC KCLUS	NOC=ABC
ABCResults	Estimated number of clusters and the criteria that are used to calculate them	PROC KCLUS	NOC=ABC
ABCStats	Statistics that are computed for estimating the number of clusters	PROC KCLUS	NOC=ABC
ClusterSum	Cluster summary for interval input variables	INPUT	LEVEL=INTERVAL
ClusterSumIntNom	Cluster summary for mixed input variables	INPUT	LEVEL=INTERVAL and LEVEL=NOMINAL
ClusterSumNom	Cluster summary for nominal input variables	INPUT	LEVEL=NOMINAL
DescStats	Descriptive statistics for interval input variables	INPUT	LEVEL=INTERVAL
FreqNom	Frequencies for nominal variables in the input table and within each cluster	INPUT	LEVEL=NOMINAL
IterStats	Iteration history	PROC KCLUS	Default output
ModelInfo	Model information	PROC KCLUS	Default output
NObs	Number of observations	PROC KCLUS	Default output
OutputCasTables	See the section "OutputCasTables Table" on page 847	PROC KCLUS	Default output

Table 16.2 *continued*

Table Name	Description	Statement	Option
Standardization	Information about the standardization method and its parameters	PROC KCLUS	STANDARDIZE=RANGE or STANDARDIZE=STD
WithinClusStats	Statistics for interval input variables within clusters	INPUT	LEVEL=INTERVAL

Examples: KCLUS Procedure

The examples in this chapter are available in the GitHub repository located at `https://github.com/sascommunities/doc-supplement-casstat`.

NOTE: Input data must be in a CAS table that is accessible in your CAS session. You must refer to this table by using a two-level name. The first level must be a CAS engine libref, and the second level must be the table name. For more information, see the sections "Using CAS Sessions and CAS Engine Librefs" on page 7 and "Loading a SAS Data Set onto a CAS Server" on page 7 in Chapter 2, "Shared Concepts."

Example 16.1: Cluster Analysis

(View the complete code for this example (kclus_ex1.sas) in the example repository.)

This example uses the Iris data set in the Sashelp library to demonstrate how to use PROC KCLUS to perform cluster analysis. The iris data published by Fisher (1936) have been widely used for examples in discriminant and cluster analyses. The sepal length, sepal width, petal length, and petal width are measured in millimeters on 50 iris specimens from each of three species: *Iris setosa, I. versicolor, and I. virginica*. Mezzich and Solomon (1980) discuss a variety of cluster analyses that use the Iris data.

You can load the Sashelp.Iris data set into your CAS session by naming your libref in the first statement of the following DATA step:

```
data mylib.iris;
   set sashelp.iris;
run;
```

These statements assume that your libref is named mylib, but you can substitute any appropriately defined libref.

The following statements perform clustering:

```
proc kclus
   data=mylib.iris
   seed=12345
   maxclusters=3
   outstat(outiter)=mylib.kclusOutstat1;
```

```
    input SepalLength SepalWidth PetalLength PetalWidth;
    score out=mylib.kclusOut1
    copyvars=(SepalLength SepalWidth PetalLength PetalWidth Species);
run;
```

In this example, PROC KCLUS generates the data table mylib.kclusOut1, which contains the cluster membership information for each observation in the input data table. For each observation, the mylib.kclusOut1 data table includes the variables that are specified in the COPYVARS= option in the SCORE statement and two new variables: _CLUSTER_ID_, which is the ID of the closest cluster, and _DISTANCE_, which is the distance between the observation and the centroid of the closest cluster. This example uses the variables in both the INPUT statement and the COPYVARS= option in order to transfer these variables to the output data table to do further analysis.

PROC KCLUS generates several ODS tables, some of which are shown in Output 16.1.1 through Output 16.1.6.

Output 16.1.1 Number of Observations

The KCLUS Procedure

Number of Observations Read	150
Number of Observations Used	150

Output 16.1.2 Model Information

Model Information	
Clustering Algorithm	K-means
Maximum Iterations	10
Stop Criterion	Cluster Change
Stop Criterion Value	0
Clusters	3
Initialization	Forgy
Seed	12345
Distance for Interval Variables	Euclidean
Standardization	None
Interval Imputation	None

Output 16.1.3 Cluster Summary

Cluster Summary for Interval Variables

		Distance from Cluster Centroid to Observation						
Cluster	**Frequency**	**Minimum**	**Maximum**	**Average**	**SSE**	**Standard Deviation**	**Nearest Cluster**	**Distance to Nearest Cluster Centroid**
1	62	2.1994	16.6064	7.3815	3982.1	8.0142	2	17.9718
2	38	2.5958	15.2971	7.1984	2387.9	7.9272	1	17.9718
3	50	0.6618	12.4803	4.8171	1515.1	5.5047	1	33.5693

Output 16.1.4 Iteration History

Iteration History			
Iteration Number	SSE	SSE Change	Stop Criterion
0	75216		
1	19644	-55572	25.333333
2	9352.340043	-10292	8.000000
3	8148.103759	-1204.236284	4.000000
4	7919.714264	-228.389495	2.000000
5	7885.144143	-34.570121	0

Output 16.1.5 Descriptive Statistics

Descriptive Statistics		
Variable	Mean	Standard Deviation
SepalLength	58.433333	8.280661
SepalWidth	30.573333	4.358663
PetalLength	37.580000	17.652982
PetalWidth	11.993333	7.622377

Output 16.1.6 Within-Cluster Statistics

Within Cluster Statistics			
Variable	Cluster	Mean	Standard Deviation
SepalLength	1	59.0161	4.6641
	2	68.5000	4.9416
	3	50.0600	3.5249
SepalWidth	1	27.4839	2.9628
	2	30.7368	2.9009
	3	34.2800	3.7906
PetalLength	1	43.9355	5.0889
	2	57.4211	4.8859
	3	14.6200	1.7366
PetalWidth	1	14.3387	2.9750
	2	20.7105	2.7987
	3	2.4600	1.0539

The following statements extract the first 10 observations from the output data table; they are shown in Output 16.1.7.

```
proc print noobs data=mylib.kclusOut1(obs=10);
run;
```

Output 16.1.7 First 10 Observations in the Output Data Table

SepalLength	SepalWidth	PetalLength	PetalWidth	Species	_CLUSTER_ID_	_DISTANCE_
50	33	14	2	Setosa	3	1.4959946524
46	34	14	3	Setosa	3	4.1518670499
46	36	10	2	Setosa	3	6.4029680618

49	36	14	1	Setosa	3	2.5686572368
44	32	13	2	Setosa	3	6.6901420015
50	35	16	6	Setosa	3	3.8675573687

PROC KCLUS creates the output statistics data table, which contains the cluster centroids. This data table includes the iteration number as _ITERATION_, the cluster ID as _CLUSTER_ID_, and the cluster centroids, which consist of the variables that are specified in the INPUT statement. Because the OUTITER= suboption is included in the OUTSTAT= option in the PROC KCLUS statement, cluster centroids for each iteration are added to the kclusOutstat1 data table.

The following statements extract the centroids before the first iteration and after the last iteration:

```
proc print noobs data=mylib.kclusOutstat1(firstobs=1 obs=3);
run;

proc print noobs data=mylib.kclusOutstat1(firstobs=16 obs=18);
run;
```

Output 16.1.8 and Output 16.1.9 show the results.

Output 16.1.8 Cluster Centroids before the First Iteration

ITERATION	_CLUSTER_ID_	SepalLength	SepalWidth	PetalLength	PetalWidth
0	1	63	25	49	15
0	2	63	33	60	25
0	3	61	28	47	12

Output 16.1.9 Cluster Centroids after the Last Iteration

ITERATION	_CLUSTER_ID_	SepalLength	SepalWidth	PetalLength	PetalWidth
5	1	59.0161	27.4839	43.9355	14.3387
5	2	68.5000	30.7368	57.4211	20.7105
5	3	50.0600	34.2800	14.6200	2.4600

Example 16.2: Finding the Number of Clusters

(View the complete code for this example (kclus_ex2.sas) in the example repository.)

This example uses the same data table that is loaded into your CAS session in Example 16.1.

You can find the number of clusters in the data table by specifying NOC=ABC in the PROC KCLUS statement as follows:

```
data mylib.iris;
   set sashelp.iris;
run;

proc kclus data=mylib.iris maxclusters=9 seed=1234
           NOC=ABC(B=10 minclusters=2 align=PCA criterion=FIRSTPEAK);
   input SepalLength SepalWidth PetalLength PetalWidth;
   ods output ABCStats=ABCStats1;
run;
```

PROC KCLUS generates several ODS tables, some of which are shown in Output 16.2.1 through Output 16.2.4.

Output 16.2.1 shows the parameters that are used in the aligned box criterion (ABC) method.

Output 16.2.1 Aligned Box Criterion Parameters

The KCLUS Procedure

ABC Parameters

Minimum Cluster	Maximum Cluster	Reference Distribution Count	Alignment Method
2	9	10	PCA

Output 16.2.2 shows the statistics that are obtained for each candidate number of clusters.

Output 16.2.2 Aligned Box Criterion Statistics

ABC Statistics

	Logarithm of Within-Cluster SSE				
Number of Clusters	Input	Reference	Gap	Simulation Adjusted Standard Deviation	One Standard Error Adjusted Gap
2	9.6313	10.1237	0.4923	0.0531	0.4392
3	8.9727	9.4894	0.5167	0.3678	0.1489
4	8.6811	8.9211	0.2400	0.0408	0.1992
5	8.5528	8.8012	0.2485	0.0536	0.1948
6	8.2784	8.4730	0.1945	0.0587	0.1359
7	8.2133	8.3702	0.1569	0.0517	0.1053
8	8.0750	8.5884	0.5134	0.0419	0.4715
9	8.0444	8.1240	0.0796	0.0639	0.0158

Output 16.2.3 Estimated Number of Clusters

Estimated Number of Clusters	
Criterion	Number of Clusters
FirstPeak	3

Output 16.2.4 Cluster Summary Table for Each Cluster

Cluster Summary for Interval Variables								
		Distance from Cluster Centroid to Observation						
Cluster	Frequency	Minimum	Maximum	Average	SSE	Standard Deviation	Nearest Cluster	Distance to Nearest Cluster Centroid
1	62	2.1994	16.6064	7.3815	3982.1	8.0142	2	17.9718
2	38	2.5958	15.2971	7.1984	2387.9	7.9272	1	17.9718
3	50	0.6618	12.4803	4.8171	1515.1	5.5047	1	33.5693

When you use the NOC= option, the KCLUS procedure first estimates the number of clusters, *k*, and then it displays the cluster analysis results for each of the *k* clusters as shown in Output 16.2.4.

Example 16.3: Clustering Nominal Variables

(View the complete code for this example (kclus_ex3.sas) in the example repository.)

In this example, PROC KCLUS clusters nominal variables in the Baseball data set. The Baseball data set includes 322 observations, and each observation has 24 variables. Among these 24 variables, the 5 nominal ones are selected as the input data to show an example of running *k*-modes clustering on a nominal data set. You can load the Sashelp.Baseball data set into your CAS session by naming your libref in the first statement of the following DATA step.

```
data mylib.baseball;
  Set sashelp.baseball;
  Keep Team League Division Position Div;
Run;
```

These statements assume that your libref is named mylib, but you can substitute any appropriately defined libref.

The following statements run the *k*-modes clustering algorithm with a frequency-based distance measure (DISTANCENOM=RELATIVEFREQ) and verify whether the clusters that the procedure obtains match the labels of the observations in the data table:

```
proc kclus data=mylib.baseball maxiter=10 maxc=5 DISTANCENOM=RELATIVEFREQ
   outstat(outiter)=mylib.kclusOutstat2;
input Team League Division Position Div / level=nominal;
```

```
score out=mylib.kclusOut2 copyvars=(Team League Division Position Div);
ods output FreqNom=FreqNom1;
run;
```

Output 16.3.1 shows the cluster summary table that is produced for five clusters.

Output 16.3.1 Cluster Summary Table for Five Clusters

The KCLUS Procedure

Cluster Summary for Nominal Variables

Cluster	Frequency	Distance from Cluster Centroid to Observation			Within Cluster Distance	Nearest Cluster	Distance to Nearest Cluster Centroid
		Minimum	Maximum	Average			
1	90	1.7111	2.0000	1.9580	176.2	3	3.8824
2	85	1.7059	2.0000	1.9550	166.2	1	3.8667
3	72	1.6806	2.0000	1.9466	140.2	3	3.8824
4	75	1.6800	2.0000	1.9474	146.1	1	4.0000

Output 16.3.2 shows the frequencies of levels for the nominal input variable Team and information about how the levels of variables are distributed in each cluster; this information is important for revealing intracluster similarity. The following statement prints the observations from the frequency table, as shown in Output 16.3.2:

```
proc print noobs data=FreqNom1(obs=12);
run;
```

Output 16.3.2 Frequencies for Nominal Variables

Variable	Level	FrequencyRead	_1	_2	_3	_4
Team	Atlanta	11	0	0	0	11
Team	Baltimore	15	0	15	0	0
Team	Boston	10	0	10	0	0
Team	California	13	13	0	0	0
Team	Chicago	24	13	0	11	0
Team	Cincinnati	12	0	0	0	12
Team	Cleveland	12	0	12	0	0
Team	Detroit	12	0	12	0	0
Team	Houston	11	0	0	0	11
Team	Kansas City	14	14	0	0	0
Team	Los Angeles	14	0	0	0	14
Team	Milwaukee	14	0	14	0	0

Example 16.4: Clustering Mixed Variables

(View the complete code for this example (kclus_ex4.sas) in the example repository.)

In this example, PROC KCLUS uses the *k*-prototypes clustering algorithm to cluster mixed input data that contain both interval and nominal variables in the Baseball data set, which is the same data set that is used in Example 16.3. You can execute the following SAS code to load the input data table, mylib.baseball.

```
data mylib.baseball;
  Set sashelp.baseball;
  Keep CrAtBat CrHits CrRuns CrRbi CrBB Team League Division Position Div;
Run;
```

These statements assume that your libref is named mylib, but you can substitute any appropriately defined libref.

The following statements run the *k*-prototypes clustering algorithm on mixed input data. The first INPUT statement uses the LEVEL=INTERVAL option to specify the input variables CrAtBat, CrHits, CrRuns, CrRbi, and CrBB as the interval input variables; the second INPUT statement uses the LEVEL=NOMINAL option to specify the input variables Team, League, Division, Position, and Div as the nominal input variables.

The KPROTOTYPEPARAMS=USERGAMMA(VALUE=10) option specifies $\gamma = 10$ for the *k*-prototypes clustering algorithm. The NOC=ABC option uses the ABC algorithm to search for the best number of clusters in a range of 2 to 10. The PRINTALLDISTANCES option prints two additional variables, _DISTANCEINT_ and _DISTANCENOM_, in the output table kclusout4.

```
proc kclus data=mylib.baseball maxiter=10 maxc=10 distancenom=relativefreq
   outstat(outiter)=mylib.kclusOutstat4 printalldistances
   noc=abc(B=10 minclusters=2 align=none criterion=all)
   kprototypeparams=usergamma(value=10);
   input CrAtBat CrHits CrRuns CrRbi CrBB / level=interval;
   input Team League Division Position Div / level=nominal;
   score out=mylib.kclusOut4 copyvars=
   (CrAtBat CrHits CrRuns CrRbi CrBB Team League Division Position Div);
   ods output FreqNom=FreqNom4;
run;
```

Output 16.4.1 shows the "Model Information" table. The clustering algorithm in use is the *k*-prototypes, and the γ value is 10. Since PROC KCLUS is implementing the *k*-prototypes algorithm on mixed input data, the distance measures for both the interval and nominal variables are displayed in the table, as Euclidean and RelativeFreq, respectively.

Output 16.4.1 Model Information for k-Prototypes Clustering Algorithm

The KCLUS Procedure

Model Information	
Clustering Algorithm	K-prototypes
Gamma Value	10
Maximum Iterations	10
Stop Criterion	Cluster Change
Stop Criterion Value	0
Clusters	2
Initialization	Forgy
Seed	1065607171
Distance for Interval Variables	Euclidean
Distance for Nominal Variables	RelativeFreq
Number of Clusters Estimation	ABC
Standardization	None
Interval Imputation	None
Nominal Imputation	None

Output 16.4.2 shows the cluster summary table that is produced for the k-prototypes algorithm.

Output 16.4.2 Cluster Summary Table for k-Prototypes Clustering Algorithm

Overview: LMIXED Procedure

The LMIXED procedure fits a variety of linear mixed models to data and enables you to use these fitted models to make statistical inferences about the data. A *linear mixed model* is a generalization of the standard linear model that is used in the GLM procedure in SAS/STAT software; the generalization is that the data are permitted to exhibit correlation and nonconstant variability. Therefore, the linear mixed model provides you with the flexibility of modeling not only the means of your data (as in the standard linear model) but also their variances and covariances.

The primary assumptions underlying the analyses that the LMIXED procedure performs are as follows:

- The data are normally distributed (Gaussian).
- The means (expected values) of the data are linear in terms of a certain set of parameters.
- The variances and covariances of the data are conditioned on a different set of parameters, with a structure that the LMIXED procedure supports.

Because Gaussian data can be modeled entirely in terms of their means, variances and covariances, the two sets of parameters in a linear mixed model specify the complete probability distribution of the data. The parameters of the mean model are called *fixed-effects parameters*, and the parameters of the variance-covariance model are called *covariance parameters*.

The fixed-effects parameters are associated with known explanatory variables, as in the standard linear model. These variables can be either qualitative (as in the traditional analysis of variance) or quantitative (as in standard linear regression).

The covariance parameters are what distinguishes the linear mixed model from the standard linear model. The need for covariance parameters arises quite frequently in applications. A typical application follows a scenario in which the experimental units that the data are measured on can be grouped into clusters and the data from a common cluster are correlated. This scenario can be generalized to include one set of clusters nested within another. For example, if students are the experimental unit, they can be clustered into classes, which in turn can be clustered into schools. Each level of this hierarchy can introduce an additional source of variability and correlation.

The LMIXED procedure provides a variety of covariance structures. The most common covariance structures arise from the use of *random effects*, which are additional unknown random variables that are assumed to affect the variability of the data. The variances of the random effects, commonly known as *variance components*, become the covariance parameters for this particular structure. Traditional linear mixed models contain both fixed and random effects; in fact, it is the combination of these two types of effects that led to the name *mixed model*. The LMIXED procedure fits not only these traditional variance component models but also numerous other covariance structures.

The LMIXED procedure fits the structure you select by using the method of *restricted maximum likelihood (REML)*, also known as *residual maximum likelihood*. It is here that the Gaussian assumption for the data is exploited. Other estimation methods are also available, including *maximum likelihood (ML)* and *minimum variance quadratic unbiased estimation (MIVQUE0)*. The details of these estimation methods are discussed in subsequent sections.

PROC LMIXED Features

The LMIXED procedure provides easy accessibility to numerous linear mixed models that are useful in many common statistical analyses.

Here are the main features of the LMIXED procedure:

- The RANDOM statement supports many covariance structures, including variance components, compound symmetry, unstructured, AR(1), Toeplitz, factor analytic, and so on.
- Both the MODEL statement and the RANDOM statement are supported for model specification, as in the MIXED procedure.
- The REPEATED statement supports many residual covariance structures, including variance components, compound symmetry, unstructured, AR(1), and so on.
- Inference features include standard errors and *t* tests for fixed and random effects.
- A subject effect for blocking is supported.

- Both REML and ML estimation methods are supported; they are implemented with a variety of optimization algorithms.
- It handles unbalanced data.
- Specialized dense and sparse matrix algorithms are provided.
- The CONTRAST statement provides a mechanism for obtaining custom linear hypothesis tests that involve the fixed and/or random effects.
- The ESTIMATE statement provides a mechanism for obtaining custom linear estimates of the fixed and/or random effects.
- The FREQ statement enables you to input the frequency of occurrence for each observation as if it appears multiple times in the data set.
- The LSMEANS statement computes least squares means for classification fixed effects.
- The LSMESTIMATE statement computes least squares means estimates for classification fixed effects.
- The MARGINS statement computes predictive margins of fixed effects.
- The OUTPUT statement produces output data tables that contain predicted values, residuals, studentized residuals, confidence limits, and influence statistics.
- The PARMS statement enables you to fit a linear mixed model that has known covariance values or to set boundary values for the parameters.
- The SLICE statement performs a partitioned analysis of the LS-means for an interaction.
- The TEST statement performs Type III tests of the fixed effects in the model.

Because the LMIXED procedure runs on SAS Cloud Analytic Services (CAS; see the section "Using CAS Sessions and CAS Engine Librefs" on page 864), it also does the following:

- enables you to run on a cluster of machines that distribute the data and the computations
- enables you to run in single-machine mode on CAS
- exploits all the available cores and concurrent threads. For information about how the LMIXED procedure uses threads, see the section "Multithreading" on page 102 in Chapter 2, "Shared Concepts."

Notation for the Mixed Model

This section introduces the mathematical notation that is used throughout this chapter to describe the linear mixed model. It assumes familiarity with basic matrix algebra (for an overview, see Searle 1982). A more detailed description of the mixed model is contained in the section "Linear Mixed Models Theory" on page 935.

A statistical model is a mathematical description of how data are generated. The standard linear model, as used by the GLM procedure, is one of the most common statistical models:

$$\mathbf{y} = \mathbf{X}\boldsymbol{\beta} + \boldsymbol{\epsilon}$$

In this expression, $\mathbf{y}$ represents a vector of observed data, $\boldsymbol{\beta}$ is an unknown vector of fixed-effects parameters with a known design matrix $\mathbf{X}$, and $\boldsymbol{\epsilon}$ is an unknown random error vector that models the statistical noise around $\mathbf{X}\boldsymbol{\beta}$. The focus of the standard linear model is to model the mean of $\mathbf{y}$ by using the fixed-effects parameters $\boldsymbol{\beta}$. The residual errors $\boldsymbol{\epsilon}$ are assumed to be independent and identically distributed Gaussian random variables with mean 0 and variance σ^2.

The mixed model generalizes the standard linear model as follows:

$$\mathbf{y} = \mathbf{X}\boldsymbol{\beta} + \mathbf{Z}\boldsymbol{\gamma} + \boldsymbol{\epsilon}$$

Here, $\boldsymbol{\gamma}$ is an unknown vector of random-effects parameters with a known design matrix $\mathbf{Z}$, and $\boldsymbol{\epsilon}$ is an unknown random-error vector whose elements are no longer required to be independent and homogeneous.

The number of fixed-effects parameters is called the number of levels for fixed effects throughout this chapter. The number of random-effects parameters is called the number of levels for random effects throughout this chapter.

To further develop this notion of variance modeling, assume that $\boldsymbol{\gamma}$ and $\boldsymbol{\epsilon}$ are Gaussian random variables that are uncorrelated, have expectations $\mathbf{0}$, and have variances $\mathbf{G}$ and $\mathbf{R}$, respectively. The variance of $\mathbf{y}$ is thus

$$\mathbf{V} = \mathbf{Z}\mathbf{G}\mathbf{Z}' + \mathbf{R}$$

Note that when $\mathbf{Z} = \mathbf{0}$, the mixed model reduces to the standard linear model.

You can model the variance of the data $\mathbf{y}$ by specifying the structures of $\mathbf{Z}$, $\mathbf{G}$, and $\mathbf{R}$. The model matrix $\mathbf{Z}$ is set up in the same fashion as $\mathbf{X}$, the model matrix for the fixed-effects parameters. For $\mathbf{G}$ and $\mathbf{R}$, you must select some covariance structures. Possible covariance structures include the following:

- variance components
- compound symmetry (common covariance plus diagonal)
- unstructured (general covariance)
- autoregressive

By appropriately defining the model matrices $\mathbf{X}$ and $\mathbf{Z}$ in addition to the covariance structure matrices $\mathbf{G}$ and $\mathbf{R}$, you can perform numerous mixed model analyses.

PROC LMIXED Compared to Other SAS Procedures

The LMIXED procedure provides linear mixed modeling functionality that is most comparable to that of the MIXED, HPMIXED, and HPLMIXED procedures in SAS/STAT software. The GLIMMIX procedure and the NLMIXED procedure can also be used to fit linear mixed models, but these procedures are primarily designed to fit generalized linear mixed models (GLMMs) and nonlinear mixed models, respectively.

The LMIXED procedure, like PROC HPMIXED, can fit linear mixed models by using sparse matrix storage and sparse matrix computations. These sparse matrix techniques are particularly suitable for problems in which the $[\mathbf{XZ}]'[\mathbf{XZ}]$ crossproducts matrix is large and sparse.

The LMIXED procedure, like PROC HPLMIXED, can fit linear mixed models by using specialized efficient algorithms. This is particularly suitable for models that have thousands of levels in a common subject effect.

The LMIXED procedure is designed to fit the following large linear mixed models:

- models that have thousands of levels in the common subject effect. For information about the common subject effect, see "Common Subject Effect" on page 943.
- models that have a large and sparse design matrix.

Using CAS Sessions and CAS Engine Librefs

SAS Cloud Analytic Services (CAS) is the analytic server and associated cloud services in SAS Viya. This section describes how to create a CAS session and set up a CAS engine libref that you can use to connect to the CAS session. It assumes that you have a CAS server already available; contact your system administrator if you need help starting and terminating a server. This CAS server is identified by specifying the host on which it runs and the port on which it listens for communications. To simplify your interactions with this CAS server, the host information and port information for the server are stored as SAS option values that are retrieved automatically whenever this CAS server needs to be accessed. You can examine the host and port values for the server at your site by using the following statements:

```
proc options option=(CASHOST CASPORT);
run;
```

In addition to starting a CAS server, your system administrator might also have created a CAS session and a CAS engine libref for your use. You can define your own sessions and CAS engine librefs that connect to the CAS server as shown in the following statements:

```
cas mysess;
libname mylib cas sessref=mysess;
```

The CAS statement creates the CAS session named mysess, and the LIBNAME statement creates the mylib CAS engine libref that you use to connect to this session. It is not necessary to explicitly name the CASHOST and CASPORT of the CAS server in the CAS statement, because these values are retrieved from the corresponding SAS option values.

If you have created the mysess session, you can terminate it by using the TERMINATE option in the CAS statement as follows:

```
cas mysess terminate;
```

For more information about the CAS and LIBNAME statements, see the section "Introduction to Shared Concepts" on page 6 in Chapter 2, "Shared Concepts."

Getting Started: LMIXED Procedure

(View the complete code for this example at https://github.com/sascommunities/doc-supplement-casstat/tree/main/Examples/lmixedgs.sas.)

This example demonstrates how you can perform a mixed model analysis of covariance when you have many groups. Suppose you are an educational researcher who studies how student scores on math tests change over time. Students are tested four times, and you want to estimate the overall rise or fall, accounting for correlation between test response behaviors of students in the same neighborhood and school. One way to model this correlation is by using a random-effects analysis of covariance, where in addition to having a student-specific quadratic mean response function, the scores for students from the same neighborhood and school are all assumed to share the same quadratic mean test response function, whose parameters are random. The following statements simulate data that have this structure; these statements assume that your libref is named mylib, but you can substitute any appropriately defined libref.

NOTE: Input data must be in a CAS table that is accessible in your CAS session. You must refer to this table by using a two-level name. The first level must be a CAS engine libref, and the second level must be the table name. For more information, see the sections "Using CAS Sessions and CAS Engine Librefs" on page 7 and "Loading a SAS Data Set onto a CAS Server" on page 7 in Chapter 2, "Shared Concepts."

```
data mylib.SchoolSample;
   do SchoolID = 1 to 1000;
      do nID = 1 to 50;
         Neighborhood = (SchoolID-1)*15 + nId;
         bInt   = 15*ranuni(1);
         bTime  = 15*ranuni(1);
         bTime2 =   ranuni(1);
         do sID = 1 to 2;
            do Time = 1 to 4;
               Math = bInt + bTime*Time + bTime2*Time*Time + rannor(2);
               output;
               end;
            end;
         end;
      end;
run;
```

These data comes from 1,000 schools and about 15,035 neighborhoods; neighborhoods are associated with more than one school and vice versa. There are 400,000 observations and 50,000 levels of the subject effect.

The following statements use the LMIXED procedure to fit a linear mixed model to these data and produce Figure 17.1 through Figure 17.4:

```
proc lmixed data=mylib.SchoolSample;
   class Neighborhood SchoolID;
   model Math = Time Time*Time / solution;
   random   int Time Time*Time / sub=Neighborhood(SchoolID) type=un;
run;
```

This model fits a quadratic mean response model that has an unstructured covariance matrix to model the covariance between the random parameters of the response model. With 15,035 neighborhood/school combinations, this model can be computationally daunting to fit, but the LMIXED procedure finishes quickly by multithreaded computing.

Figure 17.1 displays the "Model Information," "Optimization Information," "Class Level Information," "Number of Observations Information," and "Dimensions" tables.

UN(3,3)	Neighborhood(SchoolID)	0.08394
Residual		0.9998

Figure 17.3 displays the "Fit Statistics" table.

Figure 17.3 Mixed Model Analysis of Covariance

Fit Statistics	
-2 Res Log Likelihood	1681870
AIC (smaller is better)	1681884
AICC (smaller is better)	1681884
BIC (smaller is better)	1681945
CAIC (smaller is better)	1681952
HQIC (smaller is better)	1681903

Figure 17.4 displays the "Solution for Fixed Effects" table.

Figure 17.4 Mixed Model Analysis of Covariance

Solution for Fixed Effects

Effect	Estimate	Standard Error	DF	t Value	Pr > |t|
Intercept	7.4961	0.02129	4E5	352.04	<.0001
Time	7.4939	0.02108	4E5	355.55	<.0001
Time*Time	0.5009	0.002044	4E5	245.03	<.0001

These estimates are very close to the quadratic coefficients that are used in the DATA step multiplied by 1/2, which is the expected value of a uniform random variable on [0,1].

Syntax: LMIXED Procedure

The following statements are available in the LMIXED procedure:

PROC LMIXED < *options* > ;
BLUP OUT= *libref.data-table* < *options* > ;
BY *variables* ;
CLASS *variable* < **(** *options* **)** >. . . < *variable* < **(** *options* **)** > > < / *global-options* > ;
CONTRAST *'label' contrast-specification* < **,** *contrast-specification* > < **,** . . . > < / *options* > ;
DISPLAY < *table-list* > < / *options* > ;
DISPLAYOUT *table-spec-list* < / *options* > ;
EFFECT *name* **=** *effect-type* **(** *variables* < / *options* > **)** ;
ESTIMATE *'label' contrast-specification* < **(** *divisor* **=** *n* **)** >
< **,** *'label' contrast-specification* < **(** *divisor* **=** *n* **)** > > < **,** . . . > < / *options* > ;
FREQ *variable* ;
LSMEANS *fixed-effects* < / *options* > ;
LSMESTIMATE *fixed-effect* < *'label'* > *values* < *divisor* **=** *n* > < **,** < *'label'* > *values* < *divisor* **=** *n* > > < **,**
. . . > < / *options* > ;
MARGINS *fixed-effects* < / *options* > ;
MODEL *dependent* **=** < *fixed-effects* > < / *options* > ;
OPTIMIZATION < *options* > ;
OUTPUT OUT= *libref.data-table*
< **COPYVARS=** *(variables)* >
< *keyword* < *=name* > >. . . < *keyword* < *=name* > > ;
PARMS < **(** *value-list* **)** . . . > < / *options* > ;
RANDOM *random-effects* < */options* > ;
REPEATED *repeated-effect* < */options* > ;
SLICE *model-effect* < */options* > ;
STORE < **OUT=** > *libref.data-table* ;
TEST *fixed-effects* < */options* > ;
WEIGHT *variable* ;

Items within angle brackets (< >) are optional.

The PROC LMIXED and MODEL statements are required, and the MODEL statement must appear after the CLASS statement if a CLASS statement is included. The RANDOM statement must follow the MODEL statement. The CLASS, CONTRAST, EFFECT, ESTIMATE, LSMEANS, LSMESTIMATE, MARGINS, RANDOM, SLICE, and TEST statements can appear multiple times. Other statements can appear only once.

The BLUP, BY, CONTRAST, ESTIMATE, LSMEANS, LSMESTIMATE, MARGINS, MODEL, OPTIMIZATION, OUTPUT, PARMS, RANDOM, REPEATED, SLICE, TEST, and WEIGHT statements are described in full in alphabetical order after the PROC LMIXED statement. The CLASS and EFFECT statements are described by summarizing their functionality and syntax; for more information about these statements, see Chapter 2, "Shared Concepts."

Table 17.1 summarizes the basic functions and important options and statements that are supported by the LMIXED procedure.

Table 17.1 Summary of PROC LMIXED Statements

Statement	Description	Important Options
PROC LMIXED	Invokes the procedure	The DATA= option specifies the input data table; the METHOD= option specifies the estimation method.
BLUP	Creates a data table that contains the estimation of fixed and random effects	The OUT= option specifies the output data table; the SOLVER= option specifies the mixed model equations solver.
CLASS	Declares qualitative variables that create indicator variables in **X** and **Z** matrices	None
CONTRAST	Constructs custom linear hypothesis tests	The E option displays the **L** matrix coefficients.
ESTIMATE	Constructs custom linear estimates	The CL option produces confidence limits.
LSMEANS	Computes least squares means for classification fixed effects	The DIFF option computes differences of the least squares means; the CL option produces confidence limits; the SLICE= option tests simple effects.
LSMESTIMATE	Computes least squares means estimates for classification fixed effects	The ADJUST= option determines the method of multiple comparison adjustment; the FTEST option produces an *F* test.
MARGINS	Computes predictive margins of fixed effects	The DIFF= option computes differences of predictive margins; the SLICEBY= option computes predictive margins by slices.
MODEL	Specifies the dependent variable and the fixed effects, setting up **X**	The S option requests a solution for fixed-effects parameters.
OPTIMIZATION	Controls aspects of the nonlinear optimizations	The TECHNIQUE= option specifies the optimization technique.
OUTPUT	Creates a data table that contains observationwise statistics	The ALLSTATS option requests that all statistics be computed.
PARMS	Specifies a grid of initial values for the covariance parameters	The HOLD= and NOITER options hold the covariance parameters or their ratios constant; the PARMSDATA= option reads the initial values from a data table.
RANDOM	Specifies random effects, setting up **Z** and **G**	The SUBJECT= option creates block-diagonality; the TYPE= option specifies the covariance structure; the S option requests a solution for the random effects.
REPEATED	Specifies **R**	The SUBJECT= option creates block-diagonality; the TYPE= option specifies covariance structure; the R= option displays estimated blocks of **R**; the GROUP= option enables between-subject heterogeneity.
SLICE	Performs a partitioned analysis of the LS-means for an interaction	The SLICEBY option provides a simple effect to partition the LS-means.

Table 17.1 *continued*

Statement	Description	Important Options
STORE	Saves the model and results of the statistical analysis	The OUT= option specifies the name of the table where the model and results are stored.
TEST	Performs hypothesis tests on the fixed effects	The CHISQ option performs χ^2 tests in addition to any F tests.

PROC LMIXED Statement

PROC LMIXED < *options* > **;**

The PROC LMIXED statement invokes the procedure. Table 17.2 summarizes important options in the PROC LMIXED statement by function. These and other options in the PROC LMIXED statement are then described fully in alphabetical order.

Table 17.2 PROC LMIXED Statement Options

Option	Description
Basic Options	
BYOP=	Specifies the BY-group processing approach
DATA=	Specifies the input data table
METHOD=	Specifies the estimation method
NOBOUND	Removes boundary constraints on covariance parameters
NTHREADS=	Specifies the maximum number of concurrently scheduled threads to use
TIMING	Displays the "Timing" table
Options Related to Output	
ITDETAILS	Displays estimates and gradients added to the "Iteration History" table
MAXCLPRINT=	Specifies the maximum number of levels of CLASS variables to print
MMEQ	Displays the mixed model equations
NOCLPRINT	Suppresses the "Class Level Information" table completely or in part
RANKS	Displays the rank of the design matrix **X**
SEED=	Specifies the seed for pseudorandom number generation
SIMPLE	Displays the "Descriptive Statistics" table
Singularity Tolerances	
SINGCHOL=	Specifies the singularity criterion for Cholesky decomposition
SINGRES=	Specifies the singularity criterion for the residual variance
SINGULAR=	Specifies the general singularity criterion

Table 17.2 *continued*

Option	Description
Design Matrix Method	
DMMETHOD=	Specifies the computing method (sparse or dense)

You can specify the following *options*:

BYOP=PARALLEL | SEQUENTIAL
specifies the computational approach to take in BY-group processing. You can specify the following approaches:

PARALLEL performs the analysis for the BY groups in parallel on each thread. This approach can significantly improve performance when you have a lot of BY groups. But it requires a large amount of memory for a large number of BY groups.

SEQUENTIAL performs the analysis for the BY groups sequentially, one group at a time.

By default, BYOP=SEQUENTIAL.

DATA=*libref.data-table*
names the input data table for PROC LMIXED to use. The default is the most recently created data table. *libref.data-table* is a two-level name, where

libref refers to a collection of information that is defined in the LIBNAME statement and includes the library, which includes a path to the data, and a session identifier, which defaults to the active session but which can be explicitly defined in the LIBNAME statement. For more information about *libref*, see the section "Using CAS Sessions and CAS Engine Librefs" on page 864.

data-table specifies the name of the input data table.

DMMETHOD=DENSE | SPARSE<(*sparse-options***)>**
DMM=DENSE | SPARSE<(*sparse-options***)>**
specifies the method for computing the likelihood, gradient, and Hessian. For more information, see the section "Common Subject Effect" on page 943. Also see Table 17.13 for information about the covariance types that these two computing methods support.

You can specify the following methods:

DENSE is more suitable for models that have a large number of levels for a common subject effect and a relatively small number of levels for fixed effects.

SPARSE is more memory-efficient and faster for models that have a large and sparse design matrix. However, this method works only when you specify METHOD=REML. In general, the solutions for fixed-effects parameters are not the same as the solutions when you specify DMM=DENSE. But you can specify the DENSESOL option in the MODEL statement to request the solutions for fixed-effects parameters to match the solutions when DMM=DENSE.

For more information about these two methods, see the section "Computing Methodologies for REML in the Mixed Model" on page 940.

If you omit this option, the default is set according to the following rules:

- In fixed-effects models without CLASS variables, DMMETHOD=DENSE by default.
- In fixed-effects models with CLASS variables, DMMETHOD=SPARSE by default.
- In random-effects models without a common subject effect, DMMETHOD=SPARSE by default.
- In random-effects models with a common subject effect, DMMETHOD=DENSE by default.
- In models with a REPEATED statement, DMMETHOD=SPARSE by default.
- In all other situations, DMMETHOD=SPARSE.

You can specify the following *sparse-options* for the DMMETHOD=SPARSE option in parentheses:

METHOD=BASIC | NDORDERING
specifies the algorithm on which sparse matrix computing is based. You can specify the following algorithms:

BASIC is the algorithm with minimum memory consumption.

NDORDERING is the algorithm for permutation and inverse permutation. This algorithm achieves significant speed, but at the cost of memory.

By default, METHOD=BASIC unless the number of rows of the mixed model equations (MMEq) exceeds 2,000, in which case the default is METHOD=NDORDERING.

ITDETAILS
displays the parameter values at each iteration and enables the writing of notes to the SAS log that pertain to infinite likelihood and singularities during optimization iterations.

MAXCLPRINT=*number*
specifies the maximum number of levels of CLASS variables to print in the ODS table ClassLevels. MAXCLPRINT=0 enables you to print all levels of each CLASS variable. However, the NOCLPRINT option takes precedence over the MAXCLPRINT= option. By default, MAXCLPRINT=20.

METHOD=MIVQUE0 | ML | REML
specifies the estimation method for the covariance parameters.

MIVQUE0 performs minimum variance quadratic unbiased estimation of the covariance parameters (Rao 1972; Giesbrecht 1989).

ML performs maximum likelihood estimation.

REML performs residual (restricted) maximum likelihood estimation.

By default, METHOD=REML.

MMEQ
displays the coefficients of the mixed model equations, which are

$$\begin{bmatrix} \mathbf{X}'\widehat{\mathbf{R}}^{-1}\mathbf{X} & \mathbf{X}'\widehat{\mathbf{R}}^{-1}\mathbf{Z} \\ \mathbf{Z}'\widehat{\mathbf{R}}^{-1}\mathbf{X} & \mathbf{Z}'\widehat{\mathbf{R}}^{-1}\mathbf{Z}+\widehat{\mathbf{G}}^{-1} \end{bmatrix} \begin{bmatrix} \mathbf{X}'\widehat{\mathbf{R}}^{-1}\mathbf{y} \\ \mathbf{Z}'\widehat{\mathbf{R}}^{-1}\mathbf{y} \end{bmatrix}$$

where $\widehat{\mathbf{G}}$ and $\widehat{\mathbf{R}}$ are estimates of $\mathbf{G}$ and $\mathbf{R}$.

For more information about these equations, see the section "Linear Mixed Models Theory" on page 935.

NOBOUND
removes boundary constraints on covariance parameters. This option is supported only when METHOD=MIVQUE0.

For example, variance components have a default lower boundary constraint of 0, and the NOBOUND option allows their estimates to be negative.

NOBLUPVAR
suppresses computing the covariances of random-effects estimates, which are used in the computation required by the OUTPUT statement and by the SOLUTION option in the RANDOM statement. Computing the covariances of random-effects estimates usually consumes a large amount of memory resources. You can use this option to reduce the consumption of memory resources when you are not interested in the covariances of random-effects estimates.

This option is supported only when DMMETHOD=DENSE.

NOCLPRINT<=*number*>
suppresses the display of the "Class Level Information" table if you do not specify *number*. If you specify *number*, the values of the classification variables are displayed only for variables whose number of levels is less than *number*. Specifying a *number* helps reduce the size of the "Class Level Information" table if some classification variables have a large number of levels.

NOINFO
suppresses the display of the "Model Information," "Number of Observations," and "Dimensions" tables.

NOITPRINT
suppresses the display of the "Iteration History" table.

NOPRINT
suppresses the normal display of results. This option is useful when you want only to create one or more output data tables by using the OUTPUT statement.

NOPROFILE
includes the residual variance as one of the covariance parameters in the optimization iterations. (By default, this parameter is profiled out of the optimization iterations, except when you have specified the HOLD= option in the PARMS statement.)

The NOPROFILE option is supported only when DMMETHOD=SPARSE.

NTHREADS=*number*

specifies the maximum number of concurrently scheduled threads for analytic computations and overrides the SAS system option THREADS or NOTHREADS. If you do not specify the NTHREADS= option, the number of threads is determined by the number of CPUs on the host on which the analytic computations run. PROC LMIXED creates one thread per CPU for the analytic computations.

By default, PROC LMIXED runs in multiple concurrent threads unless multithreading has been turned off by the NOTHREADS system option or by specifying NTHREADS=1. The largest *number* that you can specify is 1,024; however, the actual number of threads available depends on your system.

For more information about how PROC LMIXED uses threads, see the section "Multithreading" on page 102 in Chapter 2, "Shared Concepts."

NOTE: The SAS system option THREADS or NOTHREADS applies to the client machine on which the procedures that are based on CAS run. It does not apply to the compute nodes in a distributed environment.

RANKS

displays the rank of the design matrix **X**.

This option is supported only when DMMETHOD=SPARSE.

SEED=*number*

specifies an integer to be used to start the pseudorandom number generator. If you do not specify a seed, or if you specify a *number* less than or equal to 0, the seed is generated by reading the time of day from the computer's clock.

SIMPLE

displays the mean, standard deviation, coefficient of variation, minimum, and maximum for each variable that is not a classification variable in the input DATA= table.

SINGCHOL=*number*

tunes the singularity criterion in Cholesky decompositions. The default is 1E4 times the machine epsilon, which is approximately 1E–12 on most computers.

SINGRES=*number*

sets the tolerance for which the residual variance is considered to be zero. The default is 1E4 times the machine epsilon, which is approximately 1E–12 on most computers.

SINGULAR=*number*

tunes the general singularity criterion that the LMIXED procedure applies in sweeps and inversions. The default is 1E4 times the machine epsilon, which is approximately 1E–12 on most computers.

TIMING

displays the amount of time (in seconds) that PROC LMIXED took to perform each different task in the analysis and its percentage of the total time.

BLUP Statement

BLUP OUT=*libref.data-table* < *options* > **;**

The BLUP statement creates a data table that contains the best linear unbiased estimation (BLUE) of fixed effects and the best linear unbiased prediction (BLUP) of random effects. To use the BLUP statement, you must also use the PARMS statement to specify fixed values for all covariance parameters. When you use the BLUP statement, the ODS IterHistory table displays solver iterations that are used for BLUP solutions rather than displaying optimization iterations.

You must specify the following option:

OUT=*libref.data-table*
names the output data table for PROC LMIXED to use. You must specify this option before any other options. *libref.data-table* is a two-level name, where

libref refers to a collection of information that is defined in the LIBNAME statement and includes the library, which includes a path to where the data table is to be stored, and a session identifier, which defaults to the active session but which can be explicitly defined in the LIBNAME statement. For more information about *libref*, see the section "Using CAS Sessions and CAS Engine Librefs" on page 864.

data-table specifies the name of the output data table.

You can also specify the following *options*:

ITPRINT=*number*
displays that the iteration history after every *number* of iterations. By default, ITPRINT=10, which means the procedure displays the iteration history for every 10 iterations.

MAXITER=*number*
specifies the maximum number of iterations. The default value is the number of parameters in the OUT= data table plus 2.

SOLVER=DIRECT | IOC | IOD
specifies the solver to use for BLUP solutions.

DIRECT requires storing mixed model equations (MMEQ) in memory and computing the Cholesky decomposition of MMEQ. This solver is the most accurate, but it is the most inefficient in terms of speed and memory.

IOC requires storing mixed model equations in memory and iterates on MMEQ to solve for the solutions.This solver is the most efficient in terms of speed.

IOD does not build mixed model equations; instead it iterates on data to solve for the solutions. This solver is most efficient in terms of memory.

By default, SOLVER=IOC.

TOL=*number*
specifies the tolerance value. The default value is the square root of machine precision.

BY Statement

BY *variables* **;**

You can specify a BY statement in PROC LMIXED to obtain separate analyses of observations in groups that are defined by the values of the BY variables. If you specify more than one BY statement, only the last one specified is used. For more information, see the discussion of BY-group processing in the "Grouping Data" section of *SAS Programmers Guide: Essentials*.

CLASS Statement

CLASS *variable* < **(***options***)** >. . . < *variable* < **(***options***)** > > < / *global-options* > **;**

The CLASS statement names the classification variables to be used as explanatory variables in the analysis. Table 17.3 summarizes the values that you can use as either an *option* or a *global-option*. The options are fully documented in the section "CLASS Statement" on page 9 in Chapter 2, "Shared Concepts."

Table 17.3 CLASS Statement Options

Option	Description
DESCENDING	Reverses the sort order
MISSING	Treats missing values as valid levels
ORDER=	Specifies the sort order for the levels
PARAM=	Specifies the parameterization of the variable
REF=	Specifies the reference level of the variable and puts this level at the end of the list of levels. This interpretation of the specified REF= level does not apply when DMMETHOD=SPARSE, because in this case PROC LMIXED does not necessarily solve mixed model equations in the original order.

Note that the term 'INTERCEPT' is reserved as a keyword in several statements in PROC LMIXED. Therefore, you cannot use it it as a classification variable name in the CLASS statement.

CONTRAST Statement

CONTRAST *'label' contrast-specification* < **,** *contrast-specification* > < **,** . . . > < / *options* > **;**

The CONTRAST statement provides a mechanism for obtaining custom hypothesis tests. It is patterned after the CONTRAST statement in PROC MIXED and enables you to select an appropriate inference space (McLean, Sanders, and Stroup 1991).

You can test the hypothesis $\mathbf{L}'\boldsymbol{\phi} = \mathbf{0}$, where $\mathbf{L}' = [\mathbf{K}' \; \mathbf{M}']$ and $\boldsymbol{\phi}' = [\boldsymbol{\beta}' \; \boldsymbol{\gamma}']$, in several inference spaces. The inference space corresponds to the choice of $\mathbf{M}$. When $\mathbf{M} = \mathbf{0}$, your inferences apply to the entire population from which the random effects are sampled; this is known as the *broad* inference space. When all elements of $\mathbf{M}$ are nonzero, your inferences apply only to the observed levels of the random effects. This is known as the *narrow* inference space, and you can also choose it by specifying all the random effects as fixed. The GLM procedure uses the narrow inference space. Finally, by zeroing portions of $\mathbf{M}$ that correspond to selected main effects and interactions, you can choose *intermediate* inference spaces. The broad inference space is usually the most appropriate, and it is used when you do not specify any random effects in the CONTRAST statement.

You can specify the following:

label identifies the contrast in the table. A label is required for every contrast that you specify. Labels can be up to 20 characters long and must be enclosed in single quotes.

contrast-specification identifies the fixed and random effects and their coefficients from which the $\mathbf{L}'$ matrix is formed. Each *contrast-specification* is referred to as a row in the $\mathbf{L}'$ matrix. Specifically, *contrast-specification* takes the form

< *fixed-effect values* . . . > < | *random-effect values* . . . >

fixed-effect identifies an effect that appears in the MODEL statement. The keyword INTERCEPT can be used as an effect when an intercept is fitted in the model. You do not need to include all effects that appear in the MODEL statement.

random-effect identifies an effect that appears in the RANDOM statement. The first random effect must follow a vertical bar (|); however, random effects are not required.

values are constants that are elements of the $\mathbf{L}$ matrix associated with the fixed and random effects.

The *contrast-specification* is specified by a series of nonpositional units. Each unit starts with an effect name, followed by a list of elements in square brackets. In each set of square brackets, you enter the coefficient and level indicators for each variable in an effect. A nonpositional unit has the following form:

```
effect-name [coefficient, level indicators]
            [coefficient, level indicators]
            ...
            [coefficient, level indicators]
```

For example, in the following CONTRAST statement, the *contrast-specification* has two nonpositional units. The first unit is “b [1, 1] [-1, 2]”, and the second unit is “a*b [1, 2 1] [-1, 2 2]”.

```
class a b;
model y = a b a*b;
contrast 'B at A2'
          b   [1, 1]   [-1, 2]
          a*b [1, 2 1] [-1, 2 2];
```

The first nonpositional unit starts with effect 'b', followed by two sets of square brackets. In bracket [1,1], the first element is the coefficient, and the second element is the level indicator 1, which corresponds to the first level of the CLASS variable 'b'.

The second nonpositional unit starts with effect 'a*b', followed by two sets of square brackets, [1, 2 1] and [-1, 2 2]. In bracket [1,2 1], the coefficient is 1, and the level indicators are the second level of variable 'a' and the first level of variable 'b'. In bracket [-1,2 2], the coefficient is -1, and the level indicators are the second level of variable 'a' and the second level of variable 'b'.

The comma that separates the coefficient and level indicators in a bracket is optional.

The rows of the $\mathbf{K}'$ component of $\mathbf{L}'$ are specified on the left side of the vertical bars (|). These rows test the fixed effects and are therefore checked for estimability. The rows of the $\mathbf{M}'$ component of $\mathbf{L}'$ are specified on the right side of the vertical bars. They test the random effects, and no estimability checking is necessary.

If PROC LMIXED finds the fixed-effects portion in at least one specified *contrast-specification* to be nonestimable (see the SINGULAR= option on page 880), then it determines that the whole contrast is nonestimable and displays missing values for the test statistics and a note in the log.

Assume that there are two fixed effects, 'a' and 'a*b'. If you specify the coefficient for effect 'a' but not for effect 'a*b', then the coefficients for effect 'a' are automatically "filled in" over the levels of the higher-order effect 'a*b'. This feature is designed to preserve estimability in cases where there are complex higher-order effects. The coefficients for the higher-order effect are determined by equitably distributing the coefficients of the lower-level effect. In addition, if the intercept is specified, it is distributed over all classification effects that are not contained by any other specified effect. If an effect is not specified for coefficients and does not contain any coefficient-specified effects, then all of its coefficients in $\mathbf{L}$ are set to 0. You can override this default by specifying coefficients for the higher-order effect.

If you specify a SUBJECT effect in the RANDOM statement, then the coefficients that you specify for the effects in the RANDOM statement are equitably distributed across the levels of the SUBJECT effect. You can use the E option to see exactly what $\mathbf{L}$ matrix is used.

The SUBJECT and GROUP options in the CONTRAST statement are useful for the case where a SUBJECT= or GROUP= variable appears in the RANDOM statement, and you want to contrast different subjects or groups. By default, CONTRAST statement coefficients about random effects are distributed equally across subjects and groups.

PROC LMIXED handles missing level combinations of CLASS variables similarly to the way PROC GLM does. Both procedures delete fixed-effects parameters that correspond to missing levels in order to preserve estimability. However, PROC LMIXED does not delete missing level combinations for random-effects parameters because linear combinations of the random-effects parameters are always estimable. These conventions can affect the way that you specify the CONTRAST statement coefficients.

The CONTRAST statement computes the statistic

$$F = \frac{\begin{bmatrix} \widehat{\boldsymbol{\beta}} \\ \widehat{\boldsymbol{\gamma}} \end{bmatrix}' \mathbf{L}(\mathbf{L}'\widehat{\mathbf{C}}\mathbf{L})^{-1}\mathbf{L}' \begin{bmatrix} \widehat{\boldsymbol{\beta}} \\ \widehat{\boldsymbol{\gamma}} \end{bmatrix}}{r}$$

where $r = \mathrm{rank}(\mathbf{L}'\widehat{\mathbf{C}}\mathbf{L})$ and approximates its distribution with an F distribution. In this expression, $\widehat{\mathbf{C}}$ is an estimate of the generalized inverse of the coefficient matrix in the mixed model equations.

The numerator degrees of freedom in the F approximation is $r = \mathrm{rank}(\mathbf{L}'\widehat{\mathbf{C}}\mathbf{L})$, and the denominator degrees of freedom is the residual degrees of freedom that you define by specifying the DDFM=RESIDUAL option. You can change the denominator degrees of freedom by using the DF= option.

Results from all CONTRAST statements are displayed together in the Contrasts ODS table.

You can specify the following *options* in the CONTRAST statement after a slash (/):

CHISQ
performs χ^2 tests in addition to any F tests. A χ^2 statistic equals its corresponding F statistic times the associate numerator degrees of freedom, and the same degrees of freedom is used to compute the p-value for the χ^2 test. This p-value will always be less than that for the F test, because it effectively corresponds to an F test with infinite denominator degrees of freedom.

DF=*number*
specifies the denominator degrees of freedom for the F test. The default is the residual degrees of freedom that you define by specifying the DDFM=RESIDUAL option.

E
displays the **L** matrix coefficients for the contrast. In the ODS output, the name of this "L Matrix Coefficients" table is Coef.

GROUP *coeffs*
sets up random-effect contrasts between different groups when a GROUP= variable appears in the RANDOM statement. By default, CONTRAST statement coefficients about random effects are distributed equally across groups. You can enter a multiple-row contrast, but you can enter only one row for the GROUP coefficients. For example, the following CONTRAST statement has a GROUP option with two sets of brackets; these two sets of brackets apply to each row of contrast.

```
contrast 'Trt @ x=0.4 and 0.5' trt [1 1] [-1 2] | x [0.4 1],
                               trt [1 1] [-1 3] | x [0.4 1],
                               trt [1 1] [-1 2] | x [0.5 1],
                               trt [1 1] [-1 3] | x [0.5 1] /
                               group [1 1] [-1 2];
```

If the GROUP effect has two levels and random effect 'x' has one level, then the specified coefficient 0.4 in the first contrast row is expanded across two levels of the GROUP effect weighted by GROUP coefficients. The resulting coefficients are

```
0.4 -0.4
```

SINGULAR=*number*

tunes the estimability checking. If $\mathbf{U}$ is a matrix, define ABS($\mathbf{U}'$) to be a vector $\mathbf{v}$ whose element v_i is the largest absolute value of the elements of row i of $\mathbf{U}'$. If one of the elements in (ABS($\mathbf{K}' - \mathbf{K}'\mathbf{T}$) - ABS($\mathbf{K}'$)**number*) is greater than zero, then the corresponding row of $\mathbf{K}'$ is declared nonestimable. If any row is nonestimable, then $\mathbf{K}$ is declared nonestimable. Here $\mathbf{T}$ is the Hermite form matrix $(\mathbf{X}'\mathbf{X})^{-}\mathbf{X}'\mathbf{X}$. The value of *number* must be between 0 and 1, inclusive. By default, SINGULAR=1E–4.

SUBJECT *coeffs*

sets up random-effects contrasts between different subjects when a SUBJECT= variable appears in the RANDOM statement. By default, CONTRAST statement coefficients about random effects are distributed equally across subjects. The rules for listing subject coefficients for multiple-row CONTRAST statements are the same as the rules for listing GROUP coefficients.

DISPLAY Statement

DISPLAY < *table-list* > < / *options* > **;**

The DISPLAY statement enables you to specify a list of display tables to display or exclude. This statement is similar to the ODS SELECT, ODS EXCLUDE, and ODS TRACE statements. However, the DISPLAY statement can improve performance when a large number of tables could be generated (such as in BY-group processing). The procedure processes the DISPLAY statement on a CAS server and thus sends only a subset of ODS tables to the SAS client. Because ODS statements are processed on a SAS client, first all the generated display tables are sent to the client, and then the client creates a subset.

If you use both DISPLAY and ODS statements together, the DISPLAY statement takes precedence over the ODS statements. Note that the ODS EXCLUDE statement processes tables that are sent to the client after they have been filtered by the DISPLAY statement. In some cases, it might appear that the ODS EXCLUDE statement is taking precedence because it can further filter the tables. For more information about ODS, see *SAS Output Delivery System: Procedures Guide*.

You can specify the *table-list* as a list of table names, paths, partial pathnames, and regular expressions.

The table names that you can specify are listed in the section "ODS Table Names" on page 947. A path is a table name that is prefixed with dot-separated grouping information. For example, a SelectionSummary table that a procedure produces during a selection routine might have the path *Bygroup1.Summary.SelectionSummary*. A partial pathname does not include all groups; for example, *SelectionSummary* and *Summary.SelectionSummary* are partial pathnames for *Bygroup1.Summary.SelectionSummary*.

When you specify a table name or partial pathname, all display tables whose paths end in the specified name are selected for display or exclusion. For example, both *SelectionSummary* and *Summary.SelectionSummary* select *Bygroup1.Summary.SelectionSummary*.

A regular expression is enclosed in forward slashes (/). For example, specifying "/tions/" selects all pathnames that contain the substring "tions"; in particular, the *Bygroup1.Summary.SelectionSummary* table is selected. Specifying "!/tions/" selects all pathnames that do not contain the substring "tions"; in particular, the *Bygroup1.Summary.SelectionSummary* table is not selected.

You can specify the following *options* after a slash (/):

CASESENSITIVE
performs a case-sensitive comparison of table names in the *table-list* to display table names when tables are subsetted for display. To preserve case, you must enclose table names in the *table-list* in quotation marks.

EXCLUDE
displays all display tables except those that you specify in the *table-list*.

EXCLUDEALL
suppresses display of all tables. This option takes precedence over the other options.

TRACE
displays the display table names, labels, and paths.

DISPLAYOUT Statement

DISPLAYOUT *table-spec-list* < / *options* > **;**

The DISPLAYOUT statement enables you to create output tables from your displayed output. This statement is similar to the ODS OUTPUT statement. For more information about ODS, see *SAS Output Delivery System: Procedures Guide*.

The *table-spec-list* specifies a list of output tables to create. Each entry in the list has either a *key*=*value* format or a *key* format:

key=*value*	specifies *key* as the ODS table name, path, or partial pathname, and specifies *value* as the output table name.
key	specifies *key* as the ODS table name and also as the output table name.

The ODS table names that you can specify are listed in the section "ODS Table Names" on page 947. You cannot specify the ODS table named OutputCasTables in the *table-spec-list*.

Table names and partial pathnames are discussed under the DISPLAY statement. The DISPLAYOUT statement does not support regular expressions.

You can specify the following *options* after a slash (/):

INCLUDEALL
creates output tables for all display tables. The name of the created output table is the same as the name of the corresponding display table. If you specify this option, the *table-spec-list* specification is ignored.

NOREPLACE
does not replace any existing output table of the same name.

REPEATED
replicates all output tables on all nodes.

EFFECT Statement

EFFECT *name*=*effect-type* **(***variables* < / *options* >**) ;**

The EFFECT statement enables you to construct special collections of columns for design matrices. These collections are called *constructed effects* in order to distinguish them from the usual model effects that are formed from continuous or classification variables, as discussed in the section "GLM Parameterization of Classification Variables and Effects" on page 67 in Chapter 2, "Shared Concepts."

You can specify the following *effect-types*:

COLLECTION specifies a collection effect that defines one or more variables as a single effect that has multiple degrees of freedom. The variables in a collection are considered as a unit for purposes of estimation and inference.

MULTIMEMBER | MM specifies a multimember classification effect whose levels are determined by one or more variables that appear in a CLASS statement.

POLYNOMIAL | POLY specifies a multivariate polynomial effect in the specified numeric variables.

SPLINE specifies a regression spline effect whose columns are univariate spline expansions of one or more variables. A spline expansion replaces the original variable with an expanded or larger set of new variables.

For more information about the syntax of these *effect-types* and how columns of constructed effects are computed, see the section "EFFECT Statement" on page 18 in Chapter 2, "Shared Concepts."

Table 17.4 summarizes the *options* available in the EFFECT statement.

Table 17.4 EFFECT Statement Options

Option	Description
Collection Effects Options	
DETAILS	Displays the constituents of the collection effect
Multimember Effects Options	
DETAILS	Displays the levels of the multimember effect
NOEFFECT	Requests that observations whose levels are all missing for the multimember variables have 0 values in the corresponding design matrix columns
STDIZE	Standardizes the design matrix entries so that each observation has a sum of 1
